The synchronizing circuit which was described by Milnes is ingeniously simple. It employs two saturating reactors and eight diodes for each pair of inverters to be phase locked. Thus, for a 3-phase system, two reactors and eight diodes are required to lock phase 2 on phase 1, and two reactors and eight diodes are required to lock phase 3 on phase 2. To lock phase 2 on phase 1, circuits which measure the sum and difference voltages of these two phases are used. If the sum and difference voltages are other than some prescribed value which is determined by the phase angle desired, corrective action takes place. Consider the 2-phase circuit shown in Fig. 7. Phase 2 is locked 90 degrees behind phase 1 [Fig. 8(A)]. To accomplish this, L_1 and L_2, the two saturating reactors, must saturate in $T/4$ seconds, where T is the period of the fundamental phase frequency. The sum and difference voltages, (V_1+V_2) N'/N and (V_1-V_2) N'/N respectively, are positive for one-quarter cycle, zero for the next quarter cycle and then repeat negatively. As long as the circuit maintains this 90-degree phase relationship, reactors L_1 and L_2 will completely absorb the sum and difference voltages. Now, suppose for some reason phase 2 is caused to lag phase 1 by some angle less then 90 degrees, say 90 degrees$-\theta$ [Fig. 8(B)]. The sum voltage will be positive for $(T/4+\theta/\omega)$ seconds, where ω is the fundamental angular velocity of the phase voltages. The reactor L_1 saturates in $T/4$ seconds as the magnitude of the voltage applied to it remains unchanged. The voltage (V_1+V_2) N'/N is then applied across resistor R in the base circuit of transistor $1A$ in such a direction as to make the base of the transistor positive with respect to its emitter. Since the transistors are p-n-p types, $1A$ will cut off and $1B$ will conduct. At this instant phase 2 lags phase 1 by 90-degrees again. Corrective action is not complete, however, as the transformer core of phase 1 has undergone only a partial flux swing. Corrective action will continue to take place until the 90-degree relationship with phase 2 lagging is maintained; about six cycles of time are required.

It is obvious from Fig. 8(A) that the sum circuit does the correcting for phase angles between -90 degrees and $+90$ degrees; and the difference circuit does the correcting for angles greater than $+90$ degrees and less than -90 degrees. Phase angles are considered positive when phase 2 lags phase 1.

For phase 2 to lock 120 degrees behind phase 1 requires that L_1 saturate in $T/6$ seconds and L_2 saturate in $T/3$ seconds where T is once again the period of fundamental frequency of the phase voltages. If a third phase is added and locked 120 degrees behind phase 2 a 3-phase system is obtained. The third phase is locked on the second phase in exactly the same manner that the second phase is locked on the first.

POWER AMPLIFIER STAGE

Because the gyroscope motors require more than six times their running power on start, and because, for reasons of reliability and flexibility, the inverter must be able to work into reasonably unbalanced loads, some method of making the locking circuitry insensitive to load variations and unbalance had to be devised. A push-pull power stage for each phase driven by the basic inverters was decided upon. Two of these push-pull power stages, one for phase 1 and one for phase 2, are shown in Fig. 9. The base-emitter impedance of the transistors used in these stages is approximately equal to $R/10$ where R is the resistance shown in the figure. Therefore, a change in base-emitter impedance of 10% constitutes a change of 1% in the impedance presented to the basic inverters. And since the base-emitter impedance is fairly independent of collector current, the three single-phase inverters work into an essentially constant impedance. The importance of this is discussed in the following section.

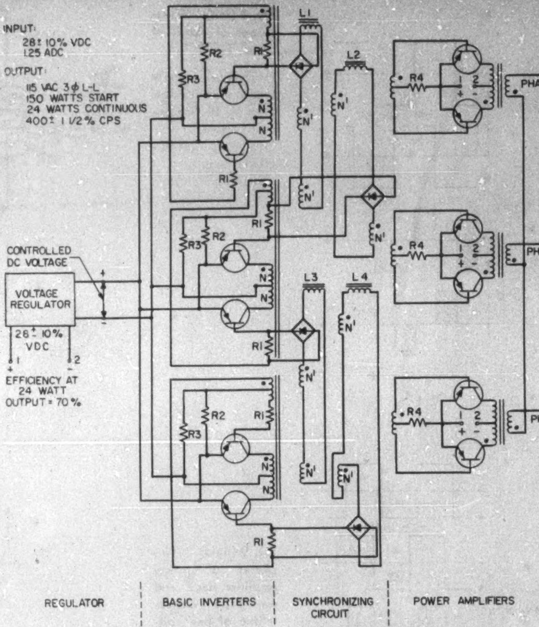

Fig. 10. Complete schematic of 3-phase inverter including regulator

Reasons for Adding Additional Circuitry to Milnes' Inverter

Shown in Fig. 10 is a complete schematic of the 3-phase inverter. The voltage regulator shown as a block diagram is a series-transistor type and is used to control the system frequency to $1^{1}/_{2}\%$ of its nominal 400 cps (cycles per second). This is accomplished by controlling the input voltage to the basic inverter stages for battery voltage changes of $\pm 10\%$ over a temperature range of -40 C (degrees centigrade) to $+65$ C. At constant temperature, the regulator is a constant voltage device within this tolerance of $\pm 1^{1}/_{2}\%$. For varying temperatures the output voltage of the regulator varies in such a manner as to maintain the system frequency to within $\pm 1^{1}/_{2}\%$ of its nominal value. As the basic inverter stages experience an essentially constant impedance, their frequency is a function of input voltage and temperature only.

If the performance of an inverter without the power-amplifier stage is considered, note the following:

1. A simple voltage regulator will no longer regulate the frequency. The frequency will vary when the induced voltages in the basic inverter windings vary and this will happen as the load is varied even if the input voltage is held constant.
2. A discriminator-type regulator must be used to regulate the frequency. It will also be noted that full power must now come through the regulator. This feature is highly undesirable from an efficiency and a size and weight point of view. It does, however, provide a considerable amount of load-voltage regulation which would be desirable for certain types of loads such as filaments. The gyroscope motors performed well for load voltage variations of $\pm 10\%$ so no consideration was given to voltage regulation.
3. For unbalanced loads the locking angle is affected because the induced voltages in the three phases differ. If the unbalance is too great the phases will not lock.
4. The currents which flow in the primary windings of the three inverters will look like I_{na} of Fig. 2 for resistive loads, and I_{na} of Fig. 3 for inductive loads. These currents of odd waveshape affect the voltages applied to the saturating reactors, especially when the motors are started; under this condition these currents are more than six times the value they attain when the motors are running at rated speed.

Our experience in the laboratory has been: for extreme conditions of load variation and load unbalance, a frequency-regulated, more stable, 3-phase transistor-core power inverter could be made by adding a stage of power amplifiers and regulating the voltage into the three single phase inverters. Since the inverter circuit is used in one of our military missile systems, reliability is the first concern. The circuit of Fig. 10 is highly stable and very insensitive to variation of circuit parameters. Even without the regulator, no change in frequency could be detected for a load swing from 24 watts to 150 watts at constant temperature and input voltage.

If two of the phases are loaded for 50 watts each and the third phase unloaded, the only measurable effect on the system is an unbalance of the line-to-line output voltages. This unbalance is of course due to the IR drops in the windings of the loaded phases.

Conclusions

A 3-phase transistor-core power inverter that is almost completely insensitive to the degree of load variation and unbalance has been developed as a power source for 3-phase gyroscope motors in one of our missile systems. Laboratory tests have shown that 3-phase gyroscope motors perform as well when powered by this square-wave inverter as they do when powered from a sine-wave system.

1959

There seems to be no reason why this inverter, which was designed for a power output of 24 watts continuously and peak loads of 150 watts, could not, with slight adjustment of the transistor-base circuitry and transformer-copper area, be made to supply almost 1,000 watts continuously.

Appendix. Component Data, Fig. 10

Reactors L_1 and L_3

Cores: 2 mils 50% Ni (nickel), 50% Fe (iron) tape, 0.5-inch ID (inside diameter), 0.75-inch OD (outside diameter), 0.125-inch height.

Winding: 103 turns no. *30* Awg HF wire, 0.9 ohm.

Reactors L_2 and L_4

Cores: 2 mils 50% Ni, 50% Fe tape, 0.5-inch ID, 0.75-inch OD, 0.125-inch height.

Winding: 206 turns no. *30* Awg HF wire, 1.8 ohms.

Single-Phase Inverter Transformers

Cores: 2 mils 50% Ni, 50% Fe tape, 1.0-inch ID, 1.5-inch OD, 0.25-inch height.

Windings:
1. Primary; 258 turns no. *33* Awg HF wire, 7.7 ohms, either side of center tap.
2. Feedback to base circuit; 21 turns no. *33* Awg HF wire, 0.7 ohm, either side of center tap.
3. Synchronizing circuit; 52 turns no. *33* Awg HF wire, 1.8 ohms.
4. Power amplifier driver; 65 turns no. *33* Awg HF wire, 2.4 ohms, either side of center tap.

Power-Amplifier Transformers

Cores: 4 mils grain oriented silicon steel tape, 1.0-inch ID, 1.625-inch OD, 0.438-inch height.

Windings:
1. Primary; 176 turns no. *26* Awg HF wire, 1.4 ohms, either side of center tap.
2. Secondary; 478 turns no. *28* Awg HF wire, 7 ohms.

Rectifiers in Synchronizing Circuit

100 milliamperes average forward-current rating, 200 volts peak inverse voltage rating, diffused junction silicon or equivalent.

Resistors

Graphical Evaluation of Magnetic Amplifier Performance Based on Constant-Voltage Reset Test

D. NITZAN
STUDENT MEMBER AIEE

Synopsis. A half-wave voltage-reset magnetic amplifier with a switching transistor in the control circuit is used as a core tester. Families of magnetizing current versus the magnitude of induced voltage with reset flux as a parameter are recorded. A graphical construction similar to the conventional one in the design of electronic amplifiers can yield the core behavior when operating in a 2-core magnetic amplifier, regardless of the magnitude of the control resistance.

THE CHARACTERISTICS of grain-oriented nickel-iron tape cores are described by Feth[1] in terms of the instantaneous values of the net mmf (magnetomotive force) F, the rate of change of flux $\dot{\phi}$, and the flux ϕ. It is assumed that the magnetic state of the resetting core is uniquely determined by these three quantities, provided the following restrictions are fulfilled: the core is initially in saturation, there are no radical changes in F, and there is a monotonic variation of $\dot{\phi}$. The relationship between F, $\dot{\phi}$, and ϕ is then assumed of the form

$$F=F_{avg}(\dot{\phi})+a_1\phi$$

in which F_{avg} is the average mmf corresponding to a full reset from positive to negative saturation. By resetting the core from positive to negative saturation by means of a variable amplitude and variable frequency square-wave supply, the average mmf F_{avg} versus $\dot{\phi}$ is plotted, and this curve is taken as F versus $\dot{\phi}$ at $\phi=0$. The curves of F versus $\dot{\phi}$ for other values of ϕ are determined from the calculated value of a_1.

In this paper a test method is suggested by which the family of F versus $\dot{\phi}$ curves are determined experimentally for any flux level ϕ. This family of curves will be referred to as the "core characteristics." The core characteristics are then employed to predict the operation of a 2-core self-saturating magnetic amplifier with any value of control resistance, including rectifier unblocking.

Constant-Voltage Reset Test

The circuit is shown in Fig. 1. This is a voltage-reset circuit with a synchronous switching transistor in the control circuit. During the positive half-cycle of normal operation the transistor is in the "on" position and the rectifier is blocked. By keeping the resistance R_c to a minimum

The author wishes to thank Prof. H. C. Bourne, Jr. for his valuable guidance and helpful comments.

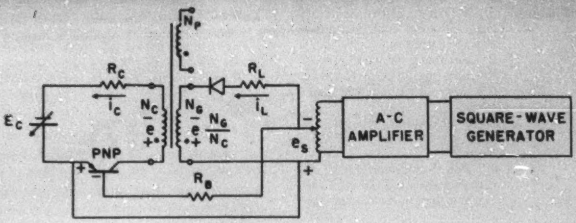

Fig. 1. Constant-voltage reset core test

value, the core is reset from saturation by a constant voltage source. At the end of the positive half-cycle the core reaches a flux level determined by ϕ and the frequency of the square-wave generator. During the next half-cycle the transistor is in the "off" position and the rectifier is conducting. The core is gated by the voltage e_s which is large enough to saturate the core before the end of the negative half-cycle. The value of R_L determines how far the core is driven into saturation. The number of turns N_c, N_G, and N_p may be small enough to enable jig operation.

Typical oscillograms of reset magnetizing current i_c and the induced voltage across the core are shown in Fig. 2. Note that the induced voltage during the negative half-cycle does not have a constant value due to the frequency response of the a-c amplifier. This fact does not invalidate the measurements to be described. The leakage current of the transistor is completely negligible.

The constant value of ϕ can be measured by an average-sensitive voltmeter with very high internal impedance connected across a pickup winding N_p. The corresponding value of F is determined by measuring the instantaneous value of i_c at the end of the reset, positive, half-cycle. This measurement was made by a calibrated oscilloscope, but probably can also be made by a suitable peak-sensitive meter. With a fixed value of E_c, hence constant ϕ, the frequency of the square-wave generator is slowly decreased until the core just reaches negative saturation. Denoting this frequency by f_{min}, resetting the core to any higher flux level ϕ is obtained by increasing the frequency to the value

$$f = f_{min}\frac{2\phi_s}{\phi_s - \phi} \tag{1}$$

This procedure is repeated for other values of ϕ. Evaluation of F versus $\dot\phi$ at $\phi = 0$ is obtained from the conventional measurement of the static hysteresis loop by means of a ballistic galvanometer. The resulting family of curves of a tested core (Magnetic Inc.; 1-mil tape; inside diameter = 1.0 inch; outside diameter = 1.75 inch; height = 0.5 inch; $l_{Fe} = 10.96$ centimeters; $A_c = 0.909$ square centimeter) is shown in Fig. 3. The curve corresponding to $\phi = \phi_s$ is obtained by extrapolating the curves ϕ versus F to $\phi = \phi_s$. The variations in slopes among the curves stem from effects such as macroscopic eddy currents which introduce terms of the nature of $\phi\dot\phi$.

Graphical Construction to Predict Magnetic-Amplifier Performance

Several core testers have been devised in order to obtain the information with which the performance of a 2-core self-saturating magnetic amplifier can be pre-

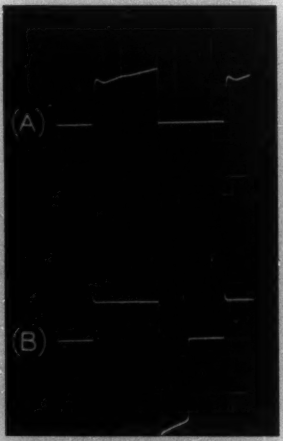

Fig. 2. Oscillograms of reset magnetizing current i_c and induced voltage $N_p\dot\phi$ in a tested core

B—Bridge circuit
C—Center-tap circuit

dicted.³ Unfortunately, due to the interaction between the two cores, good correlation is limited to extreme conditions of control impedance, e.g., the use of the data from Roberts' constant-current flux-reset core tester³ when R_c is very large.

An attempt is made here to predict the operation of a 2-core self-saturating magnetic amplifier with any value of control resistance by a graphical construction based on the core characteristics. The three types of this circuit are shown in Fig. 4. It is first assumed that the gate rectifier of the resetting core is completely blocked during the whole reset half-cycle. This can be achieved by switched transistors for any value of R_c. Later on this restriction will be removed. Under this condition the common equivalent circuit diagram of the doubler, bridge, and center-tap circuits is shown in Fig. 5. The gate circuit resistance R_o is equal to the sum of the resistances of the load, gate winding, conducting rectifier (*s*), and supply source e_s. Assuming steady-state operation, during mode *I* core 2 gates from $\phi=\phi_r$ at $t=0$ to $\phi=\phi_s$ at $t=\alpha/\omega$ under the voltage

$$e_{2I}=e_s-2i_{mI}R_o \tag{2}$$

and core 1 resets from $\phi=\phi_s$ at $t=0$ to $\phi=\phi_\alpha$ at $t=\alpha/\omega$ under the voltage

$$e_{1I}=e_s-Ne_c-i_{mI}(N^2R_c+2R_o) \tag{3}$$

in which i_{mI} is the instantaneous magnetizing current during mode *I*, referred to the gate circuit and $N=N_G/N_c$. It is assumed in equations 2 and 3 that the difference between the magnetizing currents for the resetting and gating cores produces negligible voltage drop through R_o compared to e_s. During mode *II* the voltage across core 2 is

$$e_{2II}=e_{\text{sat}} \tag{4}$$

and the voltage across the resetting core 1 is

$$e_{1II}=e_{\text{sat}}-Ne_c-i_{mII}N^2R_c \tag{5}$$

in which e_{sat} is the small voltage induced in the saturated core as a result of the variations of its net mmf and i_{mII} is the instantaneous magnetizing current of the resetting core in mode *II*, referred to the gate circuit. The inclusion of e_{sat} is especially important when R_c is small.

For the graphical construction that follows the core characteristics in terms of *F* versus ϕ are referred to the gate circuit in terms of i_m versus *e* by the following conversion factors:

$$i_m=F/N_G \tag{6}$$

and

$$e=N_G\phi \tag{7}$$

An alternative way, which would probably be used in design procedure, is to normalize equations 2 through 5 in terms of volts per turn, mmf, and ohms per turn squared. In this way the conversions indicated by equations 6 and 7 are eliminated and the same plot of core characteristics can be used for any circuit parameters.

SQUARE-WAVE EXCITATION

The case of square-wave excitation and direct-control voltage is discussed first. In this case $e_s=E_s$, $e_c=E_c$ and $e_{\text{sat}}=0$. Equations 2, 3, and 5 become

$$E_s=e_{2I}+2i_{mI}R_o \tag{2A}$$

$$E_s-NE_c=e_{1I}+i_{mI}(N^2R_c+2R_o) \tag{3A}$$

and

$$-NE_c=e_{1II}+i_{mII}N^2R_c \tag{5A}$$

The control voltage $E_{c(0)}$ corresponding to $\alpha=0$, i.e., the minimum value of E_c at which the core remains in saturation is determined from equation 5(A) by letting $e_{1II}=0$. The magnetizing current $i_{mII}=I_{mo}$ is the value of i_m at $e=0$ and $\phi=\phi_s$. At full reset ($\alpha=\pi$) equation 2(A) permits determination of the variation of i_{mI} and e_{2I} versus time by a graphical construction similar to the conventional

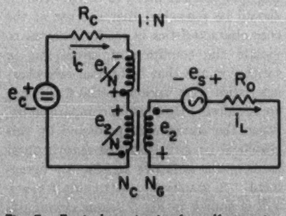

Fig. 5. Equivalent circuit of a self-saturating magnetic amplifier with ideal rectifier blocking

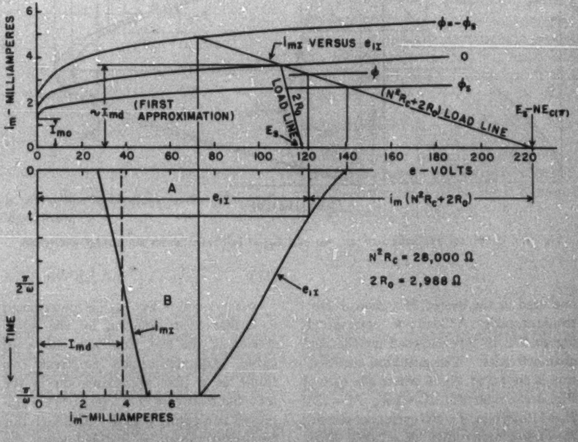

Fig. 6. Graphical evaluation of e_{1I}, i_{mI}, and I_{md} at full reset under square-wave excitation

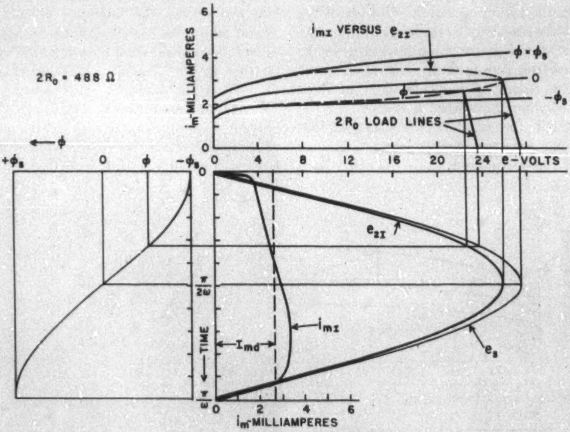

Fig. 8. Graphical evaluation of e_{2I}, i_{mI} and I_{md} at full reset under sinusoidal excitation

one used in the design of a class *A* electronic amplifier: A "load line" corresponding to $2R_o$ is superimposed on the core characteristics. This graphical construction is shown in Fig. 6 where the core of Fig. 3 is employed; $N_G=550$; $N_c=275$; $E_s=119.5$ volts; $f=400$ cycles per second; $R_o=1{,}494$ ohms (Ω); $R_c=7{,}000$ ohms. The average value of i_{mI} from $t=0$ to $t=\pi/\omega$, denoted by I_{md}, is determined as a first approximation by the intersection of the load line with the $\phi=0$ curve. Another reason to treat this result as a first approximation is the fact that reset core characteristics are employed in a gating period. Although this treatment might be justified when the core is not underdesigned, and thus yield a very good approximation, a more consistent evaluation of I_{md} is obtained by a graphical construction based on equation 3(A), as shown in Fig. 6. Based on the first approximation of I_{md} obtained previously, NE_c is assumed to be equal to $-I_{md}N^2R_c$. A load line corresponding to $(N^2R_c+2R_o)$ is drawn from the point corresponding to E_s-NE_c on the *e* axis. Here again a second approximation of I_{md} may be determined by the intersection of the load line with the $\phi=0$ curve. A more exact evaluation of I_{md} can be obtained from a point-by-point integration and evaluation of e_{1I} versus time. At a selected time *t* the voltage e_{1I} and the flux ϕ should satisfy the relation

$$\frac{A}{A+B}=\frac{\phi_s-\phi}{2\phi_s}$$

in which *A* and *B* are the areas under the curve e_{1I} versus time from $t=0$ to *t*, and from *t* to $t=\pi/\omega$ respectively. After e_{1I} versus time is determined, the waveshape of i_{mI} from $t=0$ to $t=\pi/\omega$ is easily plotted directly from the core characteristics, as shown in Fig. 6. The average value of this waveshape is the final value of I_{md} and its product with $-NR_c$ yields the control voltage $E_{c(\pi)}$ corresponding to $\alpha=\pi$.

If the firing angle α is between 0 and π, a cut-and-try graphical construction is employed. The amount of work involved depends on the degree of accuracy sought. As a first approximation the corresponding value of $-NE_c$ is

$$-NE_c\cong N^2R_c\left(I_{md}\frac{\alpha}{\pi}+I_{mo}\frac{\pi-\alpha}{\pi}\right)\qquad(8)$$

The graphical construction for mode *I* is similar to the previous one. The reset flux ϕ_a at the end of mode *I* is selected to be slightly above the reset flux ϕ_r at the end of mode *II*. The latter is calculated from the expression

$$\phi_r=\phi_s\left(1-2\frac{\alpha}{\pi}\right)\qquad(9)$$

The graphical construction during mode *II* is based on equation 5(A) with a load line corresponding to N^2R_c. Here it should be remarked that the use of the core characteristics in mode *II* seems to violate the condition of initial flux in saturation and that additional core characteristics with various initial flux levels are required. However, a comparison between the waveshapes predicted by this graphical construction and experimental oscillograms indicates satisfactory agreement. A graphical construction for $\alpha=\pi/2$ is shown in Fig. 7 (same circuit parameters as for Fig. 6). Let mode-averaged magnetizing currents be defined as

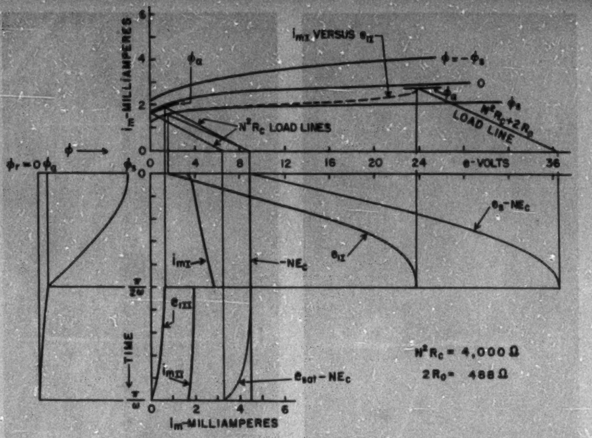

Fig. 9. Graphical evaluation of e_1 and i_m at $\alpha=\pi/2$ under sinusoidal excitation

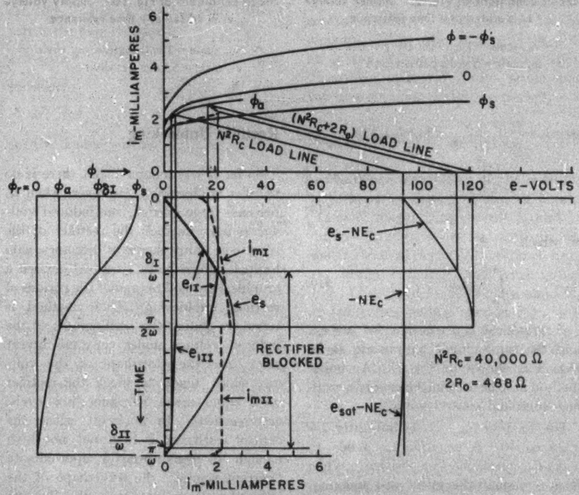

Fig. 10. Graphical determination of the periods of rectifier unblocking under sinusoidal excitation in a bridge circuit

$$I_{mI}=\frac{1}{\alpha}\int_0^\alpha i_{mI}d\omega t \qquad (10)$$

and

$$I_{mII}=\frac{1}{\pi-\alpha}\int_\alpha^\pi i_{mII}d\omega t \qquad (11)$$

The resulting values of I_{mI} and I_{mII} should agree with the assumed value of $-NE_c$ according to

$$-NE_c=N^2R_c\left(I_{mI}\frac{\alpha}{\pi}+I_{mII}\frac{\pi-\alpha}{\pi}\right) \qquad (12)$$

In addition, the ratio between the area under e_{III} to the area under e_{II} should equal to $(\phi_a-\phi_r)/(\phi_s-\phi_a)$. If necessary, a correction to the assumed $-NE_c$ and ϕ_a is made and a similar graphical contruction is repeated until these conditions are satisfied. Practically it was found that two trials were adequate.

Sinusoidal Excitation

The case where e_s is sinusoidal is more involved because both e_s and e_{sat} vary with time. A graphical construction to predict the waveshape of i_{mI} at full reset, and hence I_{md}, is based on equation 2 and is shown in Fig. 8 (core of Fig. 3; $N_G=550$; $N_C=275$; $e_s=\frac{\pi}{2}$ 17.5 sin ωt volts; $f=60$ cycles per second; $R_o=244$ ohms; $R_c=1{,}000$ ohms; d-c control voltage). The variations of ϕ with time is obtained by integrating equation 2

$$\phi=-\phi_s+\frac{1}{\omega N_G}\left[\frac{\pi}{2}E_s(1-\cos\omega t)-2R_o\int_0^{\omega t} i_{mI}d\omega t\right] \qquad (13)$$

The total flux change completed by $t=\pi/\omega$ is

$$\Delta\phi_r=2\phi_s=\frac{1}{\omega N_G}\pi(E_s-2I_{md}R_o) \qquad (14)$$

Note that in contrast to the case of square-wave excitation the locus of i_{mI}

Vol.
Pt. 1
195

versus e_{2I} is not a straight line but curved as shown in Fig. 8.

For a firing angle $o<\alpha<\pi$ a first estimate of $-NE_c$ is computed from equation 8 and the graphical construction for modes I and II is based on equations 3 and 5 respectively. The waveshape of e_{sat}, equation 5, is independent of R_c and can be obtained from the "butterfly loop" of the sinusoidal-current core tester.[2] Integration of equation 3 yields ϕ versus time during mode I

$$\phi_I=\phi_s-\frac{1}{\omega N_G}\left[\frac{\pi}{2}E_s(1-\cos\omega t)-NE_c\omega t-\right.$$
$$\left.(N^2R_c+2R_o)\int_0^{\omega t}i_{mI}d\omega t\right] \quad (15)$$

The flux $\phi_I=\phi_\alpha$ at $t=\alpha/\omega$ is

$$\phi_\alpha=\phi_s-$$
$$\frac{\frac{\pi}{2}E_s(1-\cos\alpha)-[NE_c+I_{mI}(N^2R_c+2R_o)]\,\alpha}{\omega N_G} \quad (16)$$

Similarly ϕ versus time during mode II is obtained by integrating equation 5

$$\phi_{II}=\phi_\alpha-\frac{1}{\omega N_G}\left[\int_\alpha^{\omega t}e_{sat}d\omega t-\right.$$
$$\left.NE_c(\omega t-\alpha)-N^2R_c\int_\alpha^{\omega t}i_{mII}d\omega t\right] \quad (17)$$

From equations 2 and 17 $\phi_{II}=\phi_r$ at $t=\pi/\omega$ is

$$\phi_r=\phi_\alpha-\frac{\pi-\alpha}{\omega N_G}(E_{sat}-NE_c-I_{mII}N^2R_c)$$
$$=\phi_s-\frac{1}{\omega N_G}\left[\frac{\pi}{2}E_s(1-\cos\alpha)-2I_{mI}R_o\alpha\right] \quad (18)$$

in which

$$E_{sat}=\frac{1}{\pi-\alpha}\int_\alpha^\pi e_{sat}d\omega t \quad (19)$$

A graphical construction for $\alpha=\pi/2$ and the same circuit parameters as for Fig. 8 is shown in Fig. 9. A similar method may be used in the case of a rectified-sinusoidal control voltage.

Up to $t=\pi/2\omega$ $e_{sat}>0$, but after $t=\pi/2\omega$ $e_{sat}<0$. A negative e_{sat} tends to make e_{1II} equation 5, less positive. When R_c is very small this effect will make e_{1II} negative during the end portion of the cycle. During this period the core has already started to gate along the minor loop corresponding to the reset flux. This amounts to an extension of the core characteristics into the negative region of ϕ, starting with positive F and ending with negative F. The voltage e_{sat} has an appreciable effect on decreasing $|E_c|$ but has a negligible effect on the total flux reset, in other words, a shift to the right of the transfer characteristic. This phenomenon reaches the point where it has maximum effect when the firing angle is equal to $\pi/2$.

Rectifier Unblocking

So far it was assumed that there is no rectifier unblocking. However, when R_c becomes large enough, the induced voltage e_1 may unblock the rectifier of the reset core, and the reset becomes gate limited. Finzi and Critchlow[4] devised a graphical method to predict the periods of rectifier unblocking. Their method is based on sliding the oscillograms of the induced voltage under constant-current reset, over the waveshape of the voltage which tends to block the rectifier until equal areas, i.e. same flux levels, are reached. In a circuit where the control resistance is high but not high enough to constitute an approximate "current source," the waveshape of the induced voltage may look like the one under constant-current reset but is certainly not identical with it. Under this circumstance the afore mentioned method cannot be applied, unless proper oscillograms of the induced voltage have been supplied.

The use of the graphical construction in conjunction with the core characteristics yields the waveshape of the induced voltage regardless of R_c. This method, therefore, can be used to predict the periods of rectifier unblocking with any value of control resistance.

Referring to the gate circuits of the re-

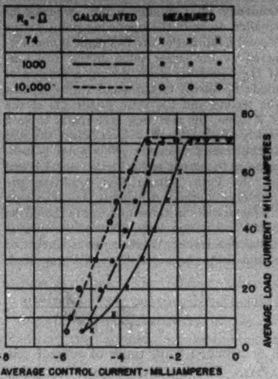

Fig. 15. Transfer characteristics of a bridge circuit

set core in Fig. 4, the blocking voltage across the gate rectifier is

$$e_r = e_B - e_1 \qquad (20)$$

in which

$$e_B = e_s - i_L R_L \qquad (21A)$$

for the doubler circuit

$$e_B = e_s - e_f \qquad (21B)$$

for the bridge circuit and

$$e_B = e_s + i_L R_L \qquad (21C)$$

for the center-tap circuit.

The symbol e_f stands for the forward voltage drop across the conducting complementary rectifier. The saturating rectifier stays blocked as long as $e_r \geqslant 0$. (The equivalent circuit for the forward characteristic of a silicon rectifier may be represented by a resistance R_f in series with a constant voltage E_u. In such a case the rectifier stays blocked as long as $e_r \geqslant -E_u$.) This period can be found graphically by subtracting e_1 from e_B. An example is shown in Fig. 10 for the bridge circuit with identical circuit parameters as in Fig. 9, except that R_c is ten times larger. The waveshape of e_{1I} versus time is plotted "backwards" from $t=\alpha/\pi$ towards $t=0$ until at $t=\delta I/\omega$, where $0<\delta I/\omega<\alpha/\omega$, $e_{1I}=e_B$. Similarly the waveshape of e_{1II} is plotted "forwards" from $t=\alpha/\omega$ towards $t=\pi/\omega$ until at $t=\delta II/\omega$, where $\alpha/\omega<\delta II/\omega<\pi/\omega$, $e_{1II}=e_B$. During the period $\delta I/\omega \leqslant t \leqslant \delta II/\omega$ the rectifier stays blocked. It is obvious from equations 21 that the worst case of rectifier unblocking is in the doubler circuit, especially in mode *II*, whereas the center-tap circuit has the least rectifier unblocking, shown schematically in Fig. 11.

The expression for i_1 and e_1 during the periods of rectifier unblocking must be determined in conjunction with the rest of the circuit. During these periods the control current $|i_c|$ must increase by the amount $|Ni_1|$ in order to satisfy the constraints of net mmf of the resetting core. This effect, as is well known, would shift the transfer characteristic to the left.

Experimental Verification

Checking the validity of the resulting waveshapes of Figs. 8, 9, and 10, oscillograms of magnetizing current i_m and induced voltage e_1 were photographed under identical circuitry conditions, using the bridge circuit. These oscillograms, Figs. 12, 13, and 14, show close similarity to the corresponding ones in Figs. 8, 9, and 10, respectively. Note that there is slight phase shift in i_m and a slight delay time in the switching of the complementary rectifiers caused by e_{sat}.

Repeating the graphical construction for other values of α and R_c results in calculated transfer characteristics which are compared with experimental ones in Fig. 15.

Conclusions

The inherent nature of a ferromagnetic core is expressed by its core characteristics which are obtained from a constant-voltage reset test. The core characteristics enable one to predict the variations of F, $\dot{\phi}$, and ϕ with time for any value of R_c by means of a graphical method. The resulting information helps to estimate the performance of the designed magnetic amplifier, including rectifier unblocking. This method has been demonstrated for the 2-core self-saturating magnetic amplifier with square-wave and sinusoidal excitation. The amount of the cut-and-try work involved depends on the required accuracy. If the cores are underdesigned the same method can be applied, except for a slight modification: At $t=\pi/\omega$ the full reset flux ϕ_π is higher than $-\phi_s$, and hence $(\phi_s-\phi_\pi)$ should supersede $2\phi_s$ wherever full reset is considered.

Discussion

G. C. Feth (General Electric Company, Schenectady, N. Y.): Use of the "constant-voltage reset test" described in this paper to obtain information on the instantaneous values of mmf, flux, and time-rate of change of flux in a core, resetting from saturation, should yield somewhat more complete and accurate information about the core characteristics than that contained in the parameters of the core-reset functions which were described in reference 1 of the paper. In evaluating such parameters, some accuracy is sacrificed in condensing the data so that an analytical formulation is possible; but the resulting analytical formulation is then readily utilized in a digital computer for speedy solution of problems, avoiding the more time-consuming graphical constructions. It should be emphasized, however, that regardless which of the two methods of obtaining data on the core characteristics is used there is still difficulty in calculating the control characteristic of the 2-core full-wave self-saturating amplifiers, center-tap, doubler, bridge, with sinusoidal excitation voltage or with square-wave voltage and capacitive load except when the amplifiers are controlled essentially from a current source. This is true because after the load current in the saturated core has reached its crest and decreases toward zero a sizeable voltage is induced in the control winding in a direction to prevent further resetting of the unsaturated core. That core then experiences a varying mmf which usually, except for nearly current-source control, ranges from the resetting branch of the hysteresis loop, through the static loop to the ascending branch of some minor loop.

Any information which may be obtained about the core from the constant voltage reset test does not apply here; hence any meaningful analysis in terms of that information is precluded. Moreover, although the amounts of flux change involved may be but a few per cent of ϕ_s, the control current may range from its maximum absolute value to a value of opposite sign with magnitude perhaps half its maximum. This control current excursion may last as long as one half of the half-cycle, and with no means of predicting the exact waveform, no accurate appraisal of the average control current can be made.

D. Nitzan: The author wishes to thank Dr. Feth for his interesting comments about some points which, it seems, are not emphasized enough in the paper. In evaluating the inaccuracy found in the analytical representation of the core characteristics in reference 1 compared with the core characteristics used in this paper, two factors should be distinguished. The first one stems from the assumed core model according to which F varies linearly with ϕ. The second factor depends on how closely the measured F_{avg} is approximated by the chosen functional form. A solution using a digital computer is certainly faster than by the graphical construction. However, which one is preferable depends upon the operational costs and upon the availability of the computer and the degree of accuracy required. An alternate way to insert the core characteristics into a computer program is by tabulation of the measured curves.

The effect of the load current in the saturated core on the resetting core is taken into account by adding the voltage source e_{sat}, which is independent of R_c, to $-NE_c$. If the operating point on the load line in mode *II* is within the first quadrant of the F-ϕ plane, core 1 would continue to reset and the information obtained from the constant voltage reset test of Fig. 1 is certainly useful. To fulfill this condition the control circuit does not necessarily have to constitute a current source. A wide range of finite values of R_c/N_c^2, especially when α is large, is under this category (see, for example, Figs. 9 and 13). Note that the tendency of a smaller $-NE_c$, when R_c is smaller, to shift the operating point to the second quadrant of the F-ϕ plane is counteracted by the larger slope of the load line. If the operating point during a portion of mode *II* moves to the second quadrant or the second and the third quadrants of the F-ϕ plane, the resetting core starts to gate slowly along the minor loop before the end of the reset half-cycle. This point is indicated in the paper and is further emphasized by Dr. Feth. Under this condition the graphical method still holds, but the core characteristics in these quadrants should be based on minor loops test with various initial flux levels. Further investigation to obtain these characteristics is still required.

Correlation of Measured and Calculated Substation Ground Grid Resistance

A. L. KINYON
MEMBER AIEE

IN THE past, substation ground grids have been designed by rule-of-thumb methods. There is reason to believe that as a result of this, many were greatly overdesigned whereas others gave a sense of security that was questionable.

In recent years methods have been developed which permit a more scientific approach to grid design. Using these methods, and with adequate knowledge of soil resistivity, it is possible to predict, at least approximately, the resistance to earth of the total grid before actual construction.

Several methods have been developed by various authors[1–6] for computing grid resistance for a given resistivity and grid geometry. Although some approximations are involved in relating most practical grids to the geometrical forms assumed by these methods, the results will generally be sufficiently accurate for practical purposes.

However, the resistivity value utilized in these formulas is often the source of errors of considerable magnitude since the formulas are valid only for soils of uniform resistivity, a condition not ordinarily encountered in most soils to any appreciable depth. Consequently, the resistivity value established at a given site by the survey becomes an important factor in obtaining accuracy in the proposed design.

Resistivity values measured in the field, using conventional instruments, represent an average or apparent resistivity of a geometric solid of earth, the dimensions of which are dependent upon the test conditions chosen. Such a solid may contain several individual layers or portions, each of which may have a resistivity vastly different than that of other parts.

Reasonably successful work has been done in the calculation of resistance using a single resistivity value which, in turn, is determined from those of several soil layers. The methods require extensive field measurements and laborious calculations and are therefore impractical except for unusual cases.

In general the complications involved make this a problem for which it would be highly desirable to find a reasonably accurate solution based upon the direct use of the apparent resitivity as measured in the field. It appeared that some progress may be made toward such a solution by approaching it from the study of various trends observed within the field test data taken over a period of years.

Method of Test

Resistivity Measurements

The resistivity measurements were made by the "four point" method using a conventional ground resistance instrument. Briefly, this consists of driving four probes into the earth in a straight line, at equal spacings, circulating a current i between the outer two probes C, and measuring a potential v across the inner two probes P (see Fig. 1).

The instrument is so scaled and calibrated that the indication is read in terms of v/i or the mutual resistance in ohms directly. The resistivity ρ is then calculated from the equation (modified form for relatively short probes)

$$\rho = 2\pi AR \qquad (1)$$

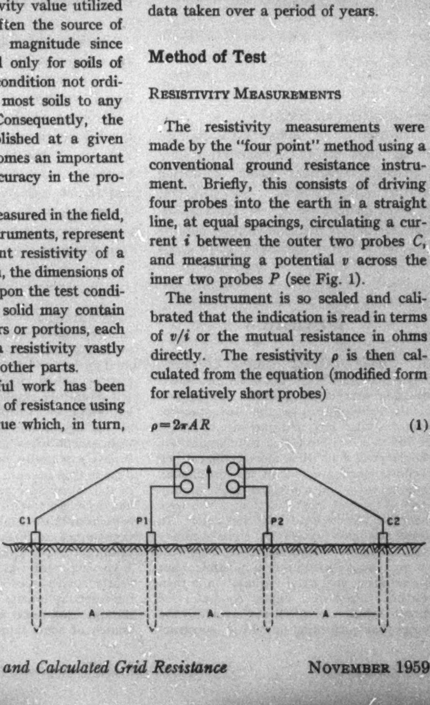

Fig. 1. Method for testing soil resistivity

Paper 59-805, recommended by the AIEE Special Instruments and Auxiliary Apparatus Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21–26, 1959. Manuscript submitted March 23, 1959; made available for printing April 27, 1959.

A. L. Kinyon is with the Bonneville Power Administration, Vancouver, Wash.

The author expresses sincere thanks and appreciation for the critical review and suggestions given by members of the Bonneville Power Administration Staff and by members of Task Force on Section 5.00 and 6.00 of the 1958 Subcommittee on Ground Resistance and Potential Gradient Measurements of the AIEE Special Instruments and Auxiliary Apparatus Committee. The material for this report is based upon a summary of the ground resistance and resistivity data accumulated during the past 18 years on the Bonneville Power Administration System.

Vol.
Pt. 1
1959

where

A = distance between the probes in cm (centimeters)
R = reading of the instrument in ohms
ρ = resistivity in ohms per cm cube

It has generally been assumed that, inasmuch as the grid and the ground rods were usually buried within the first 10 feet of depth, measurements encompassing this depth at the proposed substation site should be reliable for use in calculating resistance. Resistivity measurements were, therefore, made at the proposed site using 5-, 10-, and 20-foot probe spacings. The reading taken at any given spacing was considered to represent the average resistivity of the soil between the surface and a depth equal to the spacing. These data were then used for design purposes.

Resistance Measurements

Ground resistance of the installed ground grids were measured with a ground megohmeter. Sufficient data were taken to plot a complete curve of mutual resistance versus potential probe distance from the substation. This provided a graphic record for reference in future tests. These tests were performed immediately after construction and again approximately one year later after soil settling and seasonal changes had occurred. Subsequent tests were repeated at, approximately, 5-year intervals.

Information in the records which appeared to be of value was as follows:

1. Review of the data taken during the earlier years showed that measurements made with three different makes of instruments were in close agreement when measuring resistance but quite often in wide variance when measuring resistivity. Limited studies made at that time indicated that the errors were due to potential probe resistances. Some of the instruments used were null-type and were free from these effects but many of the measurements had been made with both the null and the "moving-coil ohmeter types."
2. Resistance of substations decreased with time because of weather effects and soil settling. This decrease may amount to 50% or more of the original value and occurred largely during the first year or two after construction. The resistance did not appear to vary greatly with seasonal changes after the first year or two.
3. Soil resistivity values obtained at 5-, 10-, and 20-foot spacings may change radically (500–1,000% or more) with seasonal weather changes. Usually these changes were slightly less pronounced at 20-foot spacings than at the 10- or 5-foot spacings.

As a result of the foregoing, additional data were obtained by taking the following steps:

1. Three types of instruments were tested to determine the effects of high probe resistances.
2. To eliminate the difference in measured and calculated resistance caused by a possible difference in moisture content when the resistivity survey was made and when the resistance measurement was made, resistivity measurements were again made in the proximity of substations during one season at the same time the periodic resistance measurements were conducted.
3. Using the previously mentioned data, an attempt was made to correlate measured resistance with calculated resistance values. Attention was also given the possibility of determining the relationship of the measured resistance to each of the resistivity values measured at the 5-, 10-, and 20-foot spacings.

Effect of Probe Resistance

Comparative tests were made on two null-type and one moving-coil ohmeter-type instruments by inserting resistance in series with the probes during resitivity measurements, under field conditions.

Resistance connected in series with the current probe circuit affected only the sensitivity of all instruments as presumed. Resistance connected in series with the potential probes caused no appreciable difference in the indication of null-type but caused a sharp decrease in the indication of the moving-coil ohmeter type (see Fig. 2).

Joint Resistivity and Resistance Measurements

Tests made at 47 substations during the 1958 season included resistance of the substation grid and resistivity taken the same day at one or more positions within the proximity of the grid. The resistance was measured with a ground megohmeter using the conventional method and plotting a mutual resistance curve from which the resistance was determined. Resistivity measurements included readings at 5-, 10-, and 20-foot probe spacings using the null-type instrument.

Comparison of Calculated and Measured Resistance

Several of the formulas developed for calculation of resistance from resistivity values were considered. The choice of formula appeared to be of much less importance than the value of resistivity used. The formula developed by Laurent was used primarily because of its applicability and its simplicity. This formula is

$$R=\frac{\rho}{4r}+\frac{\rho}{L} \tag{2}$$

where

R = resistance of the substation grid
ρ = resistivity of the soil in the proximity of the substation in ohms per cm
L = total length of buried conductor in cm
r = radius of a circle having an area equal to that of the substation grid

This equation is based upon the assumption that the grid is located at or very near the surface of the ground. The grids measured generally consisted of a buried conductor around the perimeter with sufficient cross-mesh to ground all equipment. They were buried approximately 1 foot to 18 inches deep with a scattering of ground rods driven 6 to 10 feet deep.

The resistivity data assembled from tests at the 47 substations showed wide variations between the values at 5-, 10-, and 20-foot spacings. Ordinarily, the resistivity decreased in value with increased probe spacing. However, at a few stations the value remained fairly constant and at others it increased with increased spacing. Resistance calculations were made using an average of the 5-, 10-, and 20-foot resistivity values. Comparison of the calculated and measured resistance showed that about one half of the calculated values fell within ±300% of those measured, with the remaining results even more widely scattered.

* Instrument reading too low to be accurate.

Closer study showed that of the 47 stations only about one fourth could be considered relatively isolated and free from effects of overhead grounds, grounded neutrals, other adjacent grounded substations, city water systems, etc. Data from these isolated stations showed a closer than average relationship between the measured and the calculated resistance. The resistance values calculated from the resistivity readings taken at the 20-foot spacings at these stations were in closer agreement with the measured resistance than those taken at the 10- or 5-foot spacings.

These findings and other similar evidence indicated the existence of an average resistivity value between the surface and some depth greater than 20 feet which, when used in equation 2, would result in a resistance value more closely approximating the measured value than heretofore obtained.

Within the time available at the close of the testing season, additional resistivity measurements were made at 11 of the substations. These measurements were conducted at the 5-, 10-, and 20-foot spacings, then the spacings were progressively increased to a maximum of 200 feet where possible. Table I shows the measured resistance and the resistance as calculated from resistivity values at the various spacings for these 11 substations. The table shows that for most of the substations the calculated resistance values are extremely high in relation to measured values when using resistivity values measured at 5-, 10-, or even 20-foot spacings. Results at about one half the substations show that when resistivity values taken at 50- to 150-foot spacings are used, the calculated resistance closely approximates the measured resistance value. Results at the remaining substations showed that resistance calculated from resistivity at these wider spacings were usually as close or closer in agreement with the measured value than those which were obtained from readings at 20 feet or less.

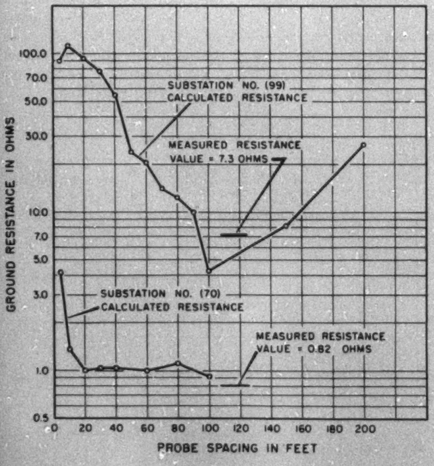

Fig. 3. Calculated ground resistance using resistivity values measured at various probe spacings

These 11 stations were chosen for their geographical location rather than other considerations. Several sources of error are present, examples of which are given in the following.

A minor source of uncertainty and possible error in the data resulted from the necessity of making resistivity measurements outside the substation enclosure rather than within the space actually occupied by the grid. Using the instruments described, resistivity values measured prior to placement of the grid cannot be duplicated after placement. A limited number of resistivity measurements made very near or immediately above buried grids have resulted in values which were considerably below those measured before the grid was buried.

Other sources of error which are present near energized substations are the effects of 60-cycle ground currents and their harmonics, which may enter into the instrument circuitry. Limited investigations indicate that such currents affect the accuracy of the instrument by the additional burden they impose rather than by combining with the odd frequency current supplied by the instrument.

An examination of equation 1 shows that with a given soil resistivity, spacing A can be increased to a value where reading R would be below the range of the instruments. These effects were in evidence at some of the stations even at relatively close probe spacings.

In equation 2, if the radius r is not accurate, the result will vary accordingly. At some of the substations, the overhead grounds are connected, city water lines are either connected or in close proximity, and grounded neutrals are carried from the station. All of these items tend to increase the effective area of the station and, consequently, the calculated radius r. Only a few of these 11 stations could be considered isolated and free from these interfering conditions.

Fig. 3 shows the calculated resistance plotted as a function of the probe spacing for two substations which were known to be relatively free from interference and at which the resistivity readings were

Vol.
Pt. 1
195

sufficiently high to permit relatively wide probe spacings.

Conclusions

The study indicates that improvements can be obtained in the accuracy of the calculated value of grounding grid resistance when utilizing the apparent resistivity as measured with conventional ground resistance instruments. The improvements depend upon a fairly comprehensive resistivity survey where soil resistivity varies widely at different depths near the surface.

It appears that the survey for a proposed substation grid should include a series of tests at two or more locations on the area, depending upon the proposed size. The investigations indicate that resistivity values tend to stabilize at spacings of 50 feet or more. Each series of tests, therefore, should include measurements at probe spacings beginning at 5 or 10 feet and increasing in increments of 10 to 20 feet until the spacings have reached about 100 feet for small to medium size substations, and 200 feet or more for large substations. It is suspected that the maximum spacing required to obtain stable resistivity values may approach the diagonal distance of the proposed grid, instrumentation permitting.

The data indicate that a stable value should be recognized as one which has become relatively constant for several consecutive tests at increased spacings or one which has reached an optimum low value at some spacing beyond which the value may tend to increase again.

It is apparent that refinements in determining the significance of intervening measured values and the maximum spacings and the recognition of the stable value will depend upon experience to be gained by field measurements. This may also depend upon progress in the improvement of instrumentation such as the provision for increased energy into the probe circuit and expansion of the lower range, or both.

The findings discussed in this report indicate progress and give rise to new questions. It is hoped that subsequent testing performed in this field in the future, both at installed grounding grids and at site prior to construction, will contribute to a greater understanding and a more accurate solution of the problem.

Discussion

R. F. Stevens (Bonneville Power Administration, Portland, Oreg.): Mr. Kinyon's paper sheds valuable new light on a problem that has received intensive recent study by two AIEE working groups. The problem is that of voltage grandients along the ground under fault conditions.

The first of these groups presented the report listed by Mr. Kinyon as reference 1 in February 1958. Subsequently, this material was revised and expanded into what has been called "A Guide to Safety in A.C. Substation Ground," which is now under consideration by the Committee on Standards for possible publication as a separate document. This guide approaches the problem primarily from the point of view of the designer.

Meanwhile, an AIEE Ground Resistance and Potential Subcommittee, of which John Parker is chairman and Mr. Kinyon is a member, is approaching the problem of both ground resistance and gradients from an instrumentation and measurement point of view, and will present its report a little later.

Now it is generally felt that a physician who has confidence in his methods should be willing to have them tried on his family. The same should doubtless apply to a utility engineer, like myself, who has worked on an AIEE project. We therefore started to check the safety of our Bonneville Power Administration ground grids by the principles established by AIEE Working Group 56.1. However, we met a stumbling block almost immediately when we tried to use the measured values of resistance and soil resistivity.

It is well known that the absolute potential to which a ground mat will rise can be computed as a simple product of short-circuit current times station ground resistance. The safety or danger at a station, however, is not usually a matter of this total potential rise, but of the magnitude of local potential differences which can be bridged by a man in or near the station. These local potential differences have no simple direct relation to the station ground resistance. They can conceivably be dangerously high where the resistance is relatively low, or within safe limits where it is very high. They are determined solely by ground current, grid geometry, and resistivity. Thus it is important to have meaningful figures on the effective soil resistivity at a station.

In the case of each of our substations, we had available one reading each for 5-, 10-, and 20-foot probe spacing. We also had ground resistance measurements taken by the fall of potential method, often on a different day from that on which resistivity was measured.

In some cases, the readings were reasonably consistent for the three probe spacings, showing the ground to be fairly homogeneous down to a depth of about 20 feet. In other cases, they varied considerably, and we faced the question as to which value to use in our computations.

As previously noted, the station resistivity does not enter into the computation of the local potential differences. However, by using the measured resistivity and known grid geometry, we were able to compute a value of station grid resistance by any one of various methods described in the literature and compare this with the resistivity as measured. Where agreement is good, this provides a partial check on the validity of both measurements. Where agreement is very poor, one measurement or the other must be invalid.

Actually, agreement was very poor in many cases, with calculated values often not merely differing by a few per cent, but being perhaps four or five times the measured values. Application of the methods of calculations prepared by Gross, Schwarz, Laurent, and others all involve approximations. However, the results using these different methods check fairly closely with each other, and the approximations which are involved cannot explain the gross differences between calculated and measured resistances.

The practical significance of the discrepancy was that nearly all the substations were safe from the ground gradient standpoint by a wide margin, regardless of which figure was correct. One or two, however, were apparently safe if we could believe the resistance figure correct and the resistivity figure therefore much too high; modification of the grid to provide a finer mesh might be desirable if it were the resistivity measurement which was representative of actual conditions.

Fortunately, Mr. Kinyon's work has done much to explain the discrepancies. Nevertheless, the matter of what resistivity measurements to take, and which test figure to use in calculations, is likely to remain one of the biggest elements of uncertainty when the designer attempts to apply the principles set forth in reference 1 of the paper and in the proposed AIEE guide.

Additional work still needs to be done, and we hope that Mr. Parker's subcommittee can provide us with further guidance.

The Winding Capacitances in Magnetic Amplifiers

INGE JOHANSEN
ASSOCIATE MEMBER AIEE

THE INFLUENCE of winding capacitance upon the performance of magnetic amplifiers is a matter of some concern. Although no systematic investigation has appeared in the literature, it is generally accepted in the art that such capacitances may be responsible for certain peculiarities in the transfer characteristic of the self-saturating magnetic amplifier. In this paper a lumped equivalent winding capacitance, connected across the winding terminals, is defined. An approximate, empirical formula is given for it for toroidal core windings. The concept of this equivalent capacitance is shown to be of some value in explaining the experimentally observed behavior of certain types of magnetic amplifiers.

The Equivalent Winding Capacitance

It is not obvious that the distributed capacitances of a winding can be replaced by an equivalent, lumped capacitance. In most cases the capacitance between turns within one winding is the most important term. The capacitances between different windings and from winding to ground or to the core will be treated later.

To start the analysis, a winding with uniform distributed turn-to-turn capacitance is considered. In Fig. 1 (A) each turn has the same capacitance to its two adjacent turns, but no capacitive interaction with other turns. When a voltage is induced in such a core winding, it is obvious that both the inductive network and the capacitive network separately will give the same linear voltage distribution along the winding. The networks can then be separated as shown in Fig. 1(B). This is easily justified by the fact that there is no voltage difference between the points A' and A'' and it is accordingly of no importance whether these points are connected or not. It is then possible to define a lumped capacitance that is equivalent to this idealized internal winding capacitance. This statement is valid whenever the capacitive network yields a linear voltage distribution.

Actually, the capacitive network of toroidal windings is not so simple, and it is unlikely to give a linear voltage distribution in itself. However, in magnetic amplifiers, the voltage distribution is dictated essentially by the magnetic flux, which approximately induces the same voltage in all turns. The winding capacitance, important as it may be, is a second order effect as far as the voltage distribution is concerned, and the assumption of a linear voltage distribution remains accordingly acceptable for further purposes in this paper. The equivalent winding capacitance for such a voltage distribution is defined here as a lumped capacitance across the terminals of the winding, affecting the core mmf (magnetomotive force) in an identical way as the actual distributed turn-to-turn capacitances do.

In Fig. 2 some of the turn-to-turn capacitances are indicated. Between the turns n and m there is a capacitance $C_{n,m}$ and a voltage $e(n-m)/N$, where N is the total number of turns, and e is the voltage across the terminals. If the terminal voltage varies by an amount Δe in the time interval Δt, the elementary capacitance $C_{n,m}$ causes a contribution to the core mmf, which is expressed by

$$\Delta(\Delta F)=(n-m)C_{n,m}\frac{n-m}{N}\,\frac{\Delta e}{\Delta t} \tag{1}$$

The contribution of the capacitances of all the turns to the turn n is

$$\Delta F=\frac{1}{N}\,\frac{\Delta e}{\Delta t}\sum_{m=1}^{N}(n-m)^2C_{n,m} \tag{2}$$

Finally, the total mmf, F, contributed by the turn-to-turn capacitances of the whole winding, is obtained by extending the same consideratinn to all the turns, that is, summing n from 1 to N. In this process all the turn-to-turn capacitances are counted twice, and the final expression for the mmf is

$$F=\frac{1}{2N}\,\frac{\Delta e}{\Delta t}\sum_{m,n=1}^{N}(n-m)^2C_{n,m} \tag{3}$$

A lumped capacitance, C_{eq}, across the winding terminals will have the same effect if

$$C_{eq}=\frac{1}{2N^2}\sum_{m,n=1}^{N}(n-m)^2C_{n,m} \tag{4}$$

From equation 4 theoretical values of C_{eq} could be obtained if the values of $C_{n,m}$ were known. For common toroidal windings this is not the case. Even if the turns were wound in an orderly way, the capacitance $C_{n,m}$ would be a rather complicated function of wire and core dimensions, and of m and n. In addition, the turns are wound randomly, and therefore equation 4 is not useful in obtaining a quantitative expression. Nevertheless, some interesting conclusions can be drawn, as shown in the following.

As a theoretical example, the case of a constant value for $C_{n,m}$ for all values of n and m is considered first. For this case equation 4 shows that C_{eq} will increase approximately proportional to the number of turns in the winding. As another extreme, the case when each turn has a capacitance only to its two adjacent turns is considered. Here the use of equation 4 shows that C_{eq} is inversely proportional to the number of turns. In the actual case of randomly wound turns, C_{eq} is likely

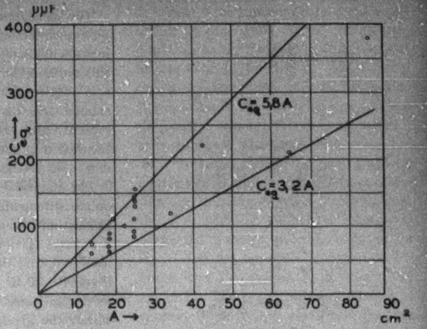

Fig. 4. The measured equivalent capacitance versus the inner surface of the winding

to be between those two theoretical extremes. Hence it is not surprising that actual measurements yield values of C_{eq} that are practically independent of the total number of turns.

It can be shown from equation 4 that C_{eq} is also equivalent to the distributed capacitances in terms of storage of energy. This is a more general property than the one implied by the original definition based on identities of core mmf's.

Equation 4 has been developed under the assumption that the winding has open terminals, but it is recognized that the same equivalent capacitance exists when an impedance is connected across the terminals. In this case the voltage distribution may become less linear, but experiments show that the assumption remains adequate for practical purposes. One interesting conclusion can be drawn at this point. The influence of the winding capacitance upon the core mmf will decrease with decreasing impedance connected at its terminals.

The foregoing discussion has been concerned with cores with one winding only. In practical magnetic amplifier circuitry, the influence of the other windings has to be considered. In Fig. 3 there are two windings on the core and the fundamental winding capacitances are shown. The presence of the second winding has influence in more than one way. To some extent it increases the turn-to-turn capacitances of the original winding, I of Fig. 3, in the same way as a metallic screen would do. The situation is complicated further by the fact that a voltage change in the windings will cause a current to flow through parts of both windings over the capacitances C_{13} and C_{24}. The mmf which results is due to currents in both of the windings. Thus, it is not enough to ascribe an equivalent capacitance to each winding, but the interwinding capacitances should also be considered. For the sake of obtaining useful results the analysis is limited to the case where winding I has many more turns than winding II. In that case the mmf contribution due to the current between 3 and 4, i.e., the part of the current flowing over C_{13} and C_{24}, can be neglected. The capacitance between two turns, C_{34}, will next be considered. Let N_1 be the number of turns between 1 and 2, and N_2 the number of turns between 3 and 4. The capacitance C_{34} will appear to be $k\ (N_2/N_1)^2C_{34}$ in parallel with C_{12}, as it will be transformed to winding I with the square of the ratio of the number of turns. The factor k depends on the mutual inductance between the windings. With the restriction $N_2<<N_1$, the term $k(N_2/N_1)^2C_{34}$ may be neglected in comparison to C_{12}. Thus, the main influence of winding II is the same as that of a metallic screen, and the equivalent capacitance of winding I depends only on its own design and on the location of the second winding. It should also be clear that the measured capacitance of a winding with few turns depends more on the other windings on the core than on its own design.

In the following only cases where $N_2<<N_1$ are considered. In the cases when the winding capacitance is important this will very often be true and the restriction will not limit the practical value of the derived results.

It will now be clearly shown that the winding with many turns is the important one. The empirical formula equation 6, presented later, shows that the value of C_{eq} for a given core is fairly independent of the number of turns. Ascribing the same capacitance C to two different windings 1 and 2 on the same core with number of turns respectively N_1 and N_2, it is easily shown that the contribution to the mmf from the capacitances is respectively CN_1^2de'/dt and CN_2^2de'/dt, where e' is the voltage per turn. Thus the quantity CN^2 is the significant one, and only the winding with the larger number of turns has to be considered.

A simple criterion can be suggested at this point to determine whether the winding capacitance is important or not in a practical design. Evidently this is the case when the mmf caused by C_{eq} is of the same order of magnitude as the change of signal ampere-turns, $N\Delta i_c$, required to control the amplifier over its whole range of operation. In order to make a rough estimate of the mmf caused by C_{eq}, it is evaluated as the product of the turns, N, times the current that flows in C_{eq} with the gate-voltage impressed on it. This implies that this current is discharged through the winding and the mmf thus produced will be added to the control-ampere turns. If the frequency is ω and the amplitude of the voltage per turn is E, then the maximum value of the capacitive ampere-turns is ωCN^2E. If the ratio $\omega CN^2E/N\Delta i_c$ is about 1 or larger, the consideration of the influence of the winding capacitance is justified.

Now it is noticed that the quantity $CE/\omega N\Delta i_c$ can be regarded as fairly constant for a given core, and thus

$$\frac{\omega CN^2E}{N\Delta i_c}=\frac{CE}{\omega N\Delta i_c}\ (\omega N)^2=K\cdot(\omega N)^2 \qquad (5)$$

This shows that the influence of winding capacitance increases roughly with the square of the product of the gate-voltage frequency and the number of turns in a given circuit.

Hitherto, the analysis has been concerned with the "internal" capacitance. The presence of other windings has been regarded to be of importance only to the extent that they increase the capacitance in the winding under consideration. However, the interwinding capacitances may also be of importance. This is so because each winding is connected to external networks, and current can flow in a circuit consisting of the interwinding capacitance, the windings themselves, and the external networks. A further discussion of this point is omitted here.

An Empirical Formula for the Equivalent Winding Capacitance

It has been stated already that an analytic expression for the equivalent winding capacitance is difficult to derive, and that its usefulness is doubtful. Therefore, attempts have been made to obtain an empirical expression. This has met reasonable success, when the accuracy requirements were not too high.

The measurements leading to the empirical expression were performed according to a method given by Terman.[1] With this method the condition of linear voltage distribution is preserved. The capacitance was measured with the core present, and the core was driven into saturation by an additional d-c source or it was short-circuited.

The empirical formula derived is based on measurements on windings with cores having inner diameter from 0.5 inch up to 2 inches. The wire was double enamel insulated, and the range of wire size was from No. 30 to No. 42, Awg (American wire gage) size. The formula is valid within the given range when the other windings have few turns, i.e., up to 20% to 30% of the turns of the winding considered. The radial thicknesses were at least equal to 25% of the available window space. A number of measurements yielded the astonishing simple relation that the capacitance is proportional to the inner surface of the winding, and is fairly independent of the number of turns and of the thickness of the wire. In Fig. 4 the equivalent winding capacitance C_{eq} is plotted versus the inner surface of the winding. It is seen that this capacitance may be expressed as

$$C_{eq} = \alpha \cdot A \ \mu\mu f \text{ (micromicrofarad)} \qquad (6)$$

where A is the inner surface of the winding in cm^2, and α is a constant within the range of 3.2 to 5.8. Hence, the equation has a certain ambiguity of ±30%, but this is quite good considering the fact that the windings in question were wound randomly.

Some comments can be made on the use of equation 6. In some cases the winding is wound randomly, but without overlapping. That means that there is a spacing between the beginning and the end of the winding. This reduces the capacitance somewhat. Either case is within the limit of equation 6, but account of this effect might be taken by choosing the value of the constant α within the over-all range stated, so that an accuracy better than ±30% can be achieved.

It is stated above that the winding has to be of a certain radial thickness. This is especially important when thin wires are used, as, No. 37 to No. 42. In such cases the winding capacitance will increase with decreasing thickness of the winding, and perhaps a better empirical expression should be sought that also accounts for radial thickness. In this work the number of measurements was too small to justify an attempt in this direction, but this effect should also be considered when choosing α within the range. On the other hand the position of the winding (outer or inner winding) has small effect on α.

The surprisingly simple equation 6 needs some analytical justification. The fact that C_{eq} is approximately independent of the number of turns has been discussed already. The fact that the wire size is unimportant can be explained in part by the fact that the ratio between net copper diameter and total diameter varies within narrow limits, between 0.7 and 0.8 for double enamel insulated copper wire in the range considered. Also, it can be understood qualitatively that the capacitance is proportional to some surface of the winding. This surface is equal to the length of a turn multiplied by the mean length of the winding. It is evident that the winding capacitance is proportional to the length of a turn, and an increase in the mean length of the winding will undoubtedly increase the capacitive interaction between the turns, which means an increase in the winding capacitance.

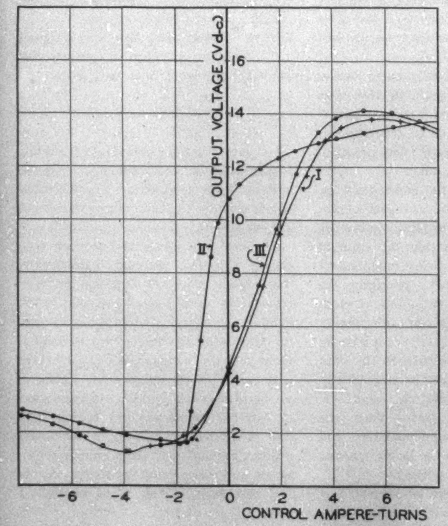

Fig. 6. Transfer characteristics for the half-wave amplifier. $E_g = 35$ volts, $f = 3.6$ kc. I: $N_c = 5{,}000$ turns, $R_c = 5.25$ megohms, $C_{eq} = 100\ \mu\mu f$. II: $N_c = 500$ turns, $R_c = 52.5$ kilohms, $C_{eq} = 100\ \mu\mu f$. III: $N_c = 500$ turns, $R_c = 52.5$ kilohms, $C = 10{,}000\ \mu\mu f$

Special Types of Windings

Only randomly wound windings have been discussed above. In some cases special windings are used to minimize voltages between adjacent layers and also to reduce the winding capacitance. The section winding is a type of such windings. Here the winding is divided in sections that follow progressively along the core, while each section is wound randomly.

Vol.
Pt. 1
1959

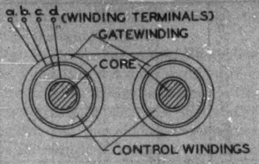

Fig. 7. Cross section of the core and windings

Equation 6 can be used for each section. The resultant capacitance may be obtained as the series connection of the capacitances of the various sections. Hence, it appears that C_{eq} decreases inversely to the square of the number of sections. This is an approximate reasoning, however, because the capacitive interaction between the different sections has not been taken into account. The presence of the core and neighboring windings will mainly provide this coupling, and when the winding is divided into many sections, this will be the dominating factor. For this reason dividing the winding into more than 4 to 6 sections is of no value. If further decrease in the capacitance is desired, it is necessary to increase the distance of this winding from the core and from the other windings, at the same time as the number of sections is increased.

Experiments on Magnetic Amplifiers

The purpose of this section is to show that the distributed winding capacitance can be replaced by an equivalent lumped capacitance, as defined in the first section, in the study of magnetic amplifier behavior. The experiments are based on the fact that two magnetic amplifiers that are identical in other respects, will behave in the same way when the product CN^2 is the same. If the concept of an equivalent capacitance is applicable, this will be the case regardless of whether the winding has distributed capacitance ($C=C_{eq}$) or whether it has little or no capacitance of its own, but is shunted by a capacitor at its terminals. Transfer characteristics of a magnetic amplifier circuit have been measured, where the winding capacitance was significant. This transfer characteristic is later referred to as characteristic I. The equivalent winding capacitance, C_{eq1}, was measured, and the product, $C_{eq1}N_1^2$, was calculated. Then the same amplifier circuit was duplicated with a winding having a fewer number of turns, N_2, so low that its equivalent capacitance ($C_{eq2}=C_{eq1}$) had a negligible effect on the transfer characteristic. The corresponding characteristic is referred to later as transfer characteristic II. Finally an external capacitance, C, was connected across the terminals of this second amplifier, and its value was chosen such that $CN_2^2=C_{eq}N_1^2$. The corresponding transfer characteristic is called characteristic III. Now if the predictions made in this paper are valid, transfer characteristics I and III should be fairly equal.

The influence of the winding capacitance, actual or simulated, upon the amplifier behavior can be seen by comparing I or III to II. In all cases the control winding was chosen as the winding which gives rise to the capacitive effects, since the number of turns could be changed easily without affecting the other parameters in the circuit.

Transfer characteristics I, II, and III were measured for a number of cases. The types of magnetic amplifier circuits that are examined are the half-wave amplifier, the doubler, and the bridge circuit; see Fig. 5. Fig. 6 shows the transfer characteristics I, II, and III for the half-wave amplifier. In this case it was difficult to obtain a truly smooth control current. However, care was taken to use the same value of R_c/N_c^2 in all measurements. It is seen that there is a good agreement between I and III, as predicted, and that the winding capacitance has a marked influence, as shown by the large difference between I and II. The winding capacitance causes a decrease in the slope of the transfer characteristic and a shift to the right. Some care was required in order to obtain good agreement between I and III on Fig. 6. Fig. 7 shows a cross section of the core and indicates the location of the two windings. When the control winding is randomly wound, as in this case, the turns with about the same potential as the terminal *c* will be distributed around the outer surface of the winding, and thus form a screen against the gate winding. When terminal *c* is connected to the grounded terminal of the signal source a capacitive interaction between the two windings is essentially avoided. The way the gate winding is connected is not very important, because the rate of change of the voltage is small compared to that in the control winding. The influence of the interwinding capacitance may be seen by interchanging the terminals *c* and *d*. This influence is by no means unimportant but can in many cases be eliminated.

Fig. 8 shows the transfer characteristics I, II, and III of the bridge circuit with low constraint. To obtain good agreement between I and III, the terminals *A* and *B* in Fig. 5(C) had to correspond to winding terminal *c* in Fig. 7. Good results are obtained since in the low constraint case both terminals have a constant potential in comparison to the induced voltages in the control windings. Transfer characteristic IV in Fig. 8 demonstrates the importance of the interwinding capacitance. In this case the

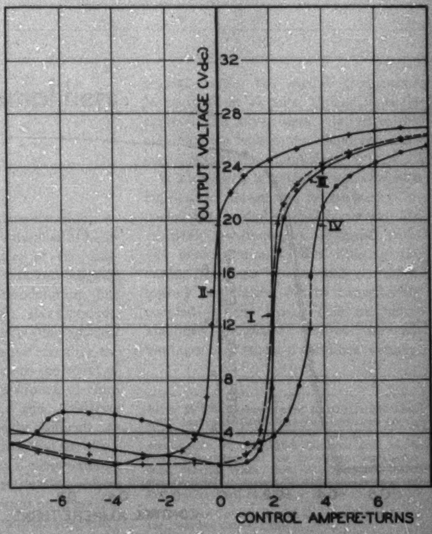

Fig. 8. Transfer characteristics for the bridge circuit. $E_g=35$ volts, $f=3.6$ kc. I: $N_c=5{,}000$ turns; $R_c\simeq 0$; $C_{eq}=100$ $\mu\mu$f. II: $N_c=500$ turns; $R_c\simeq 0$; $C_{eq}=100$ $\mu\mu$f. III: $N_c=500$ turns; $R_c\simeq 0$; $C=10{,}000$ $\mu\mu$f. IV: Identical to I, but the terminals on the control winding are interchanged

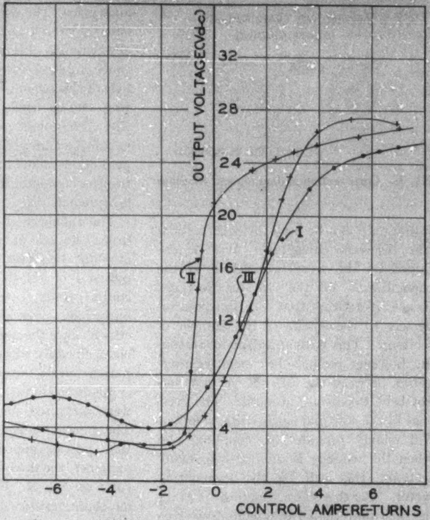

Fig. 10. Transfer characteristics of the bridge circuit. The same data as for Fig. 6

terminals were interchanged for both control windings. The transfer characteristics of the doubler and the center tap are quite similar to that of bridge circuit for the low constraint case.

Figs. 9 and 10 show the transfer characteristics I, II, and III of the doubler and of the bridge circuit for a high constraint case. In all cases R_c/N_c^2 has the same value. The agreement between I and III is not as good as before, because it is impossible to avoid capacitance interaction between the windings. Only one of the terminals of the signal source can have a constant potential in the high constraint case, and to avoid interwinding capacitive interaction a constant potential on each of the control windings would be required. However, in spite of the influence of interwinding capacitances, it seems that the internal winding capacitance is basically the most important. Figs. 9 and 10 show that the characteristics I and III have the same general behavior, although the quantitative agreement is not good. The center-tap circuit

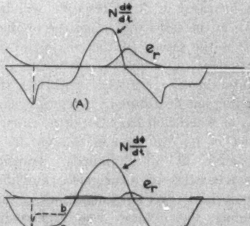

Fig. 12. The load voltage e_r and the core voltage $Nd\phi/dt$ in a half-wave amplifier

A—No influence from the winding capacitance

B—The winding capacitance has an important influence has a transfer characteristic similar to that of the bridge circuit.

Fig. 11 shows the transfer characteristics I and II of a doubler circuit with a control winding linking both cores. The characteristics in this case are almost identical, and the winding capacitances have accordingly no influence. This is in agreement with the predictions made since the capacitance is connected across the signal source directly. Experiments show that the winding capacitance has no influence regardless of the impedance of the control circuit. The bridge, the doubler, and the center-tap circuits behave almost identically, provided the number of control turns is large.

No experimentation has been performed to check on the validity of the "equivalent capacitance" concept during transients. Really, the steady state in itself is a succession of transients and the use of the equivalent capacitance, at least in "slow transients," seems justifiable.

It is not within the scope of this paper to describe why the winding capacitance has an influence on the behavior of magnetic amplifier circuits. Each circuit has several modes of operation. Unsymmetrical and subharmonic modes have been found which are not easily understood. Only the operation of the half-wave amplifier is examined in the following.

Fig. 12 shows the voltage e_r across the load and the induced voltage $Nd\phi/dt$. In Fig. 12(A) the winding capacitance is of minor importance, while it has a larger influence in Fig. 12(B). In case *a* the behavior can be understood by the description in reference 2. For case *b* the analysis is started as the flux is descending from positive saturation. Limiting the case to resistive loads, the current in the gate-winding will be positive, and the voltage induced in the winding is slightly larger than the impressed voltage. Up to point *a*, where the gate-voltage is equal to the induced voltage in the gate winding, the winding capacitance is charged negatively from the gate voltage. At point *a* the rectifier blocks. Instead of following the path *ab*, which indicates the induced voltage in the core under constant mmf, as in Fig. 12(A), the core voltage will follow *ac*, as the winding capacitance will discharge and supply the core with additional negative mmf. The area *abc* can simply be regarded as the contribution of the winding capacitance to the reset of the core. It is noticed that the winding capacitance in this case causes a larger reset. The contribution from the capacitance is, however, dependent on the firing angle and of the induced core voltage under the corresponding constant mmf. A shift to the right and a change in the slope of the transfer characteristic, as observed in Fig. 6, may then be understood.

This explanation gives the key to the understanding of the bridge and the centertap circuit. The doubler behaves in an entirely different way, due to the unblocking of the rectifiers during the reset period. In amplifier circuits with low constraint the foregoing reasoning is not valid. Here it is surprising that the slope is almost constant regardless of the winding capacitance, and the only influence is a shift in the transfer characteristic. No attempt has been made to explain this fact. It suggests, however, that a lumped capacitance across one of the windings could replace a separate bias winding.

Conclusions

In this paper a lumped equivalent winding capacitance C_{eq} has been defined. This definition has been limited to cases where the winding under consideration has a much larger number of turns than any other winding on the core. An empirical expression has been proposed for the winding capacitance which yields results accurate within ±30% or better.

Experiments show that in a number of cases the distributed capacitance has the same effect as an external shunt capacitance at the winding terminals. This enhances the practical usefulness of the concept of C_{eq}.

Capacitively Coupled Magnetic Amplifiers

H. WILLIAM COLLINS
ASSOCIATE MEMBER AIEE

AMPLIFICATION of a-c signals with magnetic amplifiers is generally more difficult than d-c amplification. The conventional full-wave circuits, such as the doubler circuit and the bridge circuit, can yield high performance only by demodulating a-c signals and amplifying the resultant direct current. These circuits remain, in effect, d-c amplifiers and suffer from several shortcomings. For example, the sensitivity is limited by the forward voltage drops of the demodulating elements, the output is affected by d-c drifts of the control characteristics, and the component duplication and ineffeciencies of push-pull circuitry must be used to obtain phase sensitivity. The work of Ramey has led to the development in recent years of a number of high-speed magnetic amplifiers of the half-wave type. These circuits can amplify a-c signals without demodulation, but they also have certain shortcomings. The power gain per stage is generally less than the gain of full-wave circuits, the amplifiers remain subject to the effect of zero drift caused by unbalance of component characteristics, and low-level sensitivity is particularly difficult to obtain. Geyger has shown that the effect of amplifier zero drift on a-c servomotors (or other frequency discriminating output elements) can be eliminated by operating half-wave circuits at a carrier frequency several times the signal frequency.[1] None of these circuits, though, entirely achieves the advantages relative to d-c amplification techniques which are associated with true a-c amplifiers.

If a magnetic amplifier is operated at a high-carrier frequency, its frequency response is extended so that it can amplify relatively low-frequency a-c signals without demodulation. After filtering the carrier-frequency pulses, the signal-frequency modulation can be capacitiviely coupled to the load. This magnetic-amplifier technique realizes the advantages of a true a-c amplifier, namely:

freedom from the effect of d-c drift, consequent increased sensitivity, inherent phase reversibility, and accurate reproduction of the input waveform.

Capacitively Coupled Circuit

A capacitively coupled magnetic amplifier using a full-wave bridge crcuit is shown in Fig. 1. The high-frequency power can be supplied by a frequency multiplier[2] or a transistor inverter.[3] The carrier frequency should be at least 10 times the maximum signal frequency that is to be passed; otherwise, the amplifier gain is unduly reduced by the residual delay of the amplifier and it is difficult to filter the carrier-frequency pulses without attenuating the signal-frequency power. Magnetic amplifiers can be successfully operated in the radio-frequency range.[4] The limitation on the pass band of a high-frequency magnetic amplifier is, in practice, set by the maximum operating frequency of a satisfactory power supply. Both frequency multipliers and transistor inverters have ruggedness and reliability commensurate with magnetic amplifiers and are suitable for this application. Appreciable power can be obtained from these devices at a maximum operating frequency of about 20 kc.

A capacitively coupled amplifier is biased at approximately one-half output (see Fig. 2) and the incoming a-c signal modulates the average output about this quiescent level. Capacitor C_1 filters the carrier-frequency pulses, and a smooth d-c having a signal-frequency modulation is produced across the output. The quiescent d-c passes through R_1 and L_1. This path should be a rather low impedance to d-c and, for maximum output power, a high impedance to signal-frequency power as provided by inductor L_1. Capacitor C_2 couples the signal-frequency power to the load and blocks the d-c component. An amplified replica of the a-c input signal is thereby produced in the load.

Except for the use of a carrier-frequency power supply, the circuit operation is analogous to the fundamental a-c vacuum-tube technique. The advantages of capacitively coupled magnetic amplifiers relative to the standard magnetic circuits are listed as:

1. Drift-free. The effect of zero-signal drift caused by component variations is eliminated, and a major practical limitation on magnetic-amplifier sensitivity therefore removed.

2. No demodulator. A-c signals can be amplified without demodulation by a high-gain full-wave circuit. Not only is a critical circuit element eliminated, but the corresponding forward voltage drops which limit sensitivity are also removed.

3. Signal sensitivity. A-c signals can be amplified which are several orders of magnitude smaller than possible with standard magnetic-amplifier techniques.

4. Phase sensitive. The 2-core circuitry is inherently phase sensitive. The duplication of components in push-pull circuitry is not required nor is there a d-c component in the output.

5. High speed. The amplifier begins response within 1/2 cycle of the carrier frequency and reaches full response in a fraction of 1/2 cycle of the signal frequency.

6. High gain. The use of a high-carrier frequency allows a greatly increased figure of merit to be realized.[5] In amplifying low-frequency signals, e.g., 60 cps (cycles per second), many cycles delay of the carrier frequency are tolerable and high power gains per stage are obtainable.

7. High stability. Because of constancy of the differential permeability and inherent voltage stability, the circuitry has excellent gain stability in addition to freedom from zero drift.

8. Linearity. Excellent linearity is achieved.

9. Small size. A high-supply frequency results in greatly reduced component size and weight for a given power rating.

10. High fidelity. Except for a very slight ripple, waveforms within the pass band of the amplifier are accurately reproduced in the output.

Nomenclature

A_p = power gain as defined by equation 2
A_p' = power gain at the amplifier-break frequency

Design Considerations

The maximum average a-c output power of a capacitively coupled magnetic amplifier is much less than the maximum instantaneous d-c power which the amplifier must supply. Note from Fig. 2 that the peak a-c output voltage is one-half the maximum d-c output voltage and that the maximum undistorted sinusoidal voltage has an rms value of $\sqrt{2}/4 = 0.353$ times the peak d-c voltage. The nonlinearities at the ends of the control characteristic limit the maximum excursion which will yield an undistorted output. The net result is that the maximum average a-c power delivered by a capacitively coupled amplifier operating in the linear region is less than 1/10 the instantaneous d-c power which the amplifier must supply at peak output current. The control power to produce the reduced average flux excursions, though, is similarly decreased and the power gain of the capacitively coupled amplifier remains the same as that obtainable with the d-c amplifier of equivalent response time. The power obtainable from a high-frequency supply is, in practice, limited, and therefore it is difficult to construct capacitively coupled amplifiers with high output power. Since capacitively coupled magnetic amplifiers are characterized by limited output power combined with excellent stability and a-c sensitivity, this technique is most applicable for low-level amplification. Major applications appear to be servo preamplifiers, strain-gage amplifiers, and, by the use of a chopper, low-level d-c amplifiers.

Referring to Fig. 1, capacitors C_1 and C_2 affect the frequency response and power gain of the amplifier. Capacitor C_1 should be large enough so that there is negligible attenuation to the lowest a-c signal frequency. Capacitor C_1 must remain small enough so there is negligible attenuation of the highest signal frequency. The response of a single-stage capacitively coupled amplifier can be expressed by the following transfer function:

$$E_o/E_c=\frac{K_v\,\dfrac{jwT_1}{1+jwT_1}}{(1+jwT_2)(1+jwT_3)} \qquad (1)$$

The break point on an attenuation versus frequency plot caused by T_1 (the coupling capacitor) should be below the lowest signal frequency of the desired amplifier pass band. The break resulting from T_3 (the filter capacitor) should be above the highest desired signal frequency. As the signal frequency approaches the carrier frequency, T_3 must become relatively smaller. As a result less filtering of the carrier pulses is achieved and an undesirably high "hum" level is pesent. In many applications where a frequency-discriminating-output device is driven (such as another magnetic-amplifier stage or a servomotor) the presence of this ripple, which is twice the carrier frequency, is not detrimental. In other applications though, such as driving a meter, this spurious output appears as a zero-signal error. At high signal frequencies it may be necessary to use an additional low-pass filter stage (such as series inductor in the output) to obtain increased discrimination between the signal frequency and the carrier ripple. In practice the carrier ripple can easily be held to less than 1% of full output with signal frequencies as great as 0.1 of the carrier frequency.

Power Gain and Frequency Response

According to the figure-of-merit concept, the power gain of a full-wave magnetic amplifier varies inversely with response time. In order to evaluate the power gain of a full-wave magnetic amplifier, the effective input impedance must be known. The effective input impedance of a magnetic amplifier operated as a d-c amplifier is simply the total series resistance of the control circuit. When a magnetic amplifier is subjected to a continually varying signal, the input impedance has an inductive as well as a resistive component. A magnetic amplifier with a multicycle delay responds exponentially to a change in control and can be properly represented by a series L_c-R_c circuit. The output voltage of a given amplifier is proportional to a constant times the control current. The control current for a given control voltage is a function of the input impedance.

$$E_o=KI_c=K\,\frac{E_c}{R_c+jw_sL_c}=K\,\frac{E_c/R_c}{1+jw_sT_2} \qquad (2)$$

In this discussion power gain is defined as follows:

$$A_p=\frac{E_o^2/R_L}{E_cI_c} \qquad (3)$$

It will be noted from equation 2 that as R_c is made small relative to w_sL_c, the input impedance becomes purely reactive and the real power consumed by the control circuit approaches zero. This condition is of only academic interest as the control source must still possess a volt-ampere capability which determines the output power. Hence, the realistic method of specifying the required control signal is in terms of volt-amperes ($E_c \times I_c$).

At a given signal frequency, maximum gain is achieved when R_c is small and the control source essentially works directly into the winding inductance. That is, if the input impedance is minimized, the least possible control voltage is required to force the control current which produces a given output. Thus, a given output is produced with minimum volt-ampere signal and maximum power gain. Sufficient copper can easily be placed in the control winding of a magnetic amplifier so that the control-circuit resistance is small relative to the winding reactance (w_sL_c) at power-frequency signals. In practice the control-circuit impedance can be reduced to essentially the value of the reactance and the condition of maximum possible power gain can be obtained. This design condition corresponds to operation of the amplifier at a frequency beyond the break point determined by T_2 in equation 1. As a result of operating beyond the break point, the relative gain (20 log E_o/E_c) is falling at a rate of 20 per decade of frequency. This rate of decrease is shown in the upper curve of Fig. 3. If the control source works directly into the winding reactance, maximum possible power gain is always achieved, but the amplifier obviously does not have a flat-frequency response which is required in many applications.

A flat-frequency response can be obtained by moving the break point ($1/T_2$) beyond the maximum desired signal frequency. This is done by making the control-circuit resistance greater than the reactance at the desired signal frequency. The relationship between gain and signal frequency for various ratios of control-circuit resistance to reactance is shown in Fig. 3. The curves do not consider the attenuation caused by the amplifier filter or coupling capacitors, as it is presumed that their break points can be placed outside of the desired pass band. These curves demonstrate that, in applications where the signal frequency varies, the gain can be held constant at the expense of additional control power.

At signal frequencies where the reactance is the dominant component of the input impedance, the input impedance increases directly with signal frequency. Under these conditions the voltage gain varies in inverse proportion to the signal frequency. Because of increasing input impedance, the power gain likewise varies in inverse proportion to the voltage gain. In other words, the power gain varies as a function of signal frequency directly with

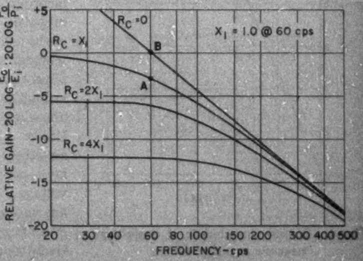

Fig. 3. Relative gain-frequency response as function of control circuit impedance

voltage gain, rather than as the voltage gain squared, as occurs in the case of an amplifier of constant input impedance. In determining the relative power gain from Fig. 3, the relationship 20 log P_o/P_c or 20 log E_o/E_c must be used. For example, if R_c is increased from zero to a value equal to X_c at 60 cps, both the 60-cps voltage and power gain are attenuated by 0.707. It will be noted from Fig. 3 that quite flat frequency response can be obtained without excessive gain attenuation. That is, if the control resistance is made equal to twice the control reactance at a given signal frequency, the gain is flat within 1 db (decibel) to that frequency, yet the power gain is only halved relative to the maximum possible value.

The figure of merit of a magnetic amplifier (M) in terms of power gain per second of response time is a valuable means of relating the power gain and transient response of a full-wave magnetic amplifier. The maximum power gain which can be obtained under sinusoidal a-c control at various signal frequencies can be determined from the figure of merit by the following relationships. Considering only the effect of the amplifier time constant (T_2), it can be seen from equation 1 that the gain is down by a factor of $\sqrt{2}$ at the frequency were $w_sT_2=1$. This frequency corresponds to the break point of the amplifier and is shown at point A in Fig. 3. The signal frequency of a given amplifier at which this break point occurs is

$$w_s'=\frac{1}{T_2} \qquad (4)$$

The steady-state gain is reduced by a factor of $\sqrt{2}$ at the break frequency.

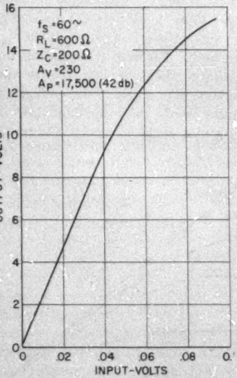

Fig. 4. Control characteristic of single-stage magnetic amplifier, 60 cps

$$A_p'=\frac{MT_2}{\sqrt{2}}=\frac{M}{\sqrt{2}w_s'} \qquad (5)$$

Maximum possible power gain will be obtained when the control resistance is small relative to the reactance at a given signal frequency, and this gain is $\sqrt{2}$ times the gain obtained when the break point occurs at this frequency. Reduction of R_c toward zero corresponds to changing the operating condition of the amplifier from point A to B on the curves of Fig. 3. The amount of increased gain is evident. The maximum possible gain (when $R_c=0$) obtainable at any signal frequency can, therefore, be expressed:

$$\text{Maximum } A_p=\frac{\sqrt{2}M}{\sqrt{2}w_s}=\frac{M}{w_s} \qquad (6)$$

This expression states the limiting case of maximum power gain and applies when w_s is large relative to w_s'.

The power gain at any signal frequency can be expressed as follows in terms of the figure of merit and the time constant.

$$A_p=\frac{M}{w_s'(1+jw_sT_2)}=\frac{MT_2}{(1+jw_sT_2)} \qquad (7)$$

This equation is accurate at a maximum signal frequency of about 0.1 the carrier frequency and over the frequency range where attenuation of capacitors C_1 and C_2 is negligible.

Amplifier Stability

The figure of merit of an audio-frequency magnetic amplifier[5] is in the range from 10^6 to 10^7. Equation 6 indicates that a power gain per stage in amplifying a 60-cps signal can be as high as 26,000 (44 db). The practical power gain which can be obtained from an amplifier is closely related to the stability of the amplifier. Several features indicate that a capacitively coupled magnetic amplifier is basically a very stable device.

Numerous tests have shown that the core gain (differential permeability) of a magnetic material does not display aging and is quite constant with varying ambient temperature. The major change in magnetic core materials is a lateral shift of the control characteristic with ambient temperature variations. Capacitive coupling eliminates the effect of this shift, as long as operation is maintained in the linear region of the control characteristic. Unlike a vacuum tube or a transistor amplifier, the gain of the magnetic amplifier is not a direct function of the supply voltage. Even though the supply voltage varies, a given control signal causes a given flux change. Therefore in a capacitively coupled magnetic amplifier the same modulation around the bias point occurs, and the output voltage remains constant. If the amplifier operates from a transistor inverter, there is an additional reason for stability as the inverter has a constant volt-second output (frequency increases at the same rate as supply voltage) which is ideal for operation of a magnetic device. If an a-c magnetic amplifier is operated from a voltage source and has negligible control-circuit resistance, the gain will be independent of the differential permeability of the core material. This condition occurs because the core gain and the input impedance (reactance) vary in a similar manner. Thus the control current also varies in a manner which maintains a constant output. Stating this another way, the amplifier is voltage controlled and the control signal forces a certain flux excursion which produces a given output, regardless of the characteristics of the core material.

The net stability of a capacitively coupled magnetic amplifier has yet to be fully evaluated. The aforementioned factors indicate, though, that the device may offer much greater stability for a given gain than other amplifying elements Starting the converse, a magnetic amplifier may allow a much higher gain for a given degree of stability.

Single-Stage Amplifier

A capacitively coupled full-wave bridge circuit as shown in Fig. 1 has been constructed. The amplifier operates from a transistor inverter at a 60-volt supply and at a frequency of 10 kc. The system (inverter and bias supply) is driven by a 24-volt d-c supply. It was developed primarily to amplify 60-cps signals. The cores consist of 32 wraps of 1/2-mil *4-79* Mo-permalloy* on 1/2-inch-inside-diameter ceramic bobbins. The load winding has 1,800 turns and the control winding has 350 turns. Germanium diodes and tantalum capacitors are used in the circuit. The maximum d-c output power of the stage is about 4.0 watts. The inverter and amplifier components fit easily into the space of a 3-inch cube.

A control characteristic when amplifying a 60-cps signal is shown in Fig. 4. The small signal linearity of the amplifier is excellent. Although not clearly evident on the curve, the nonlinearity of the amplifier below 8-volt output is too small to separate from the normal error of 1% meters. The control circuit inductance of the amplifier is 0.53 henry which produces a minimum input impedance of 200 ohms at 60 cps. The effective input re-

B—Closed loop

actance has been determined experimentally by increasing R_c until the output is 0.707 of the value that existed with R_c very close to zero. At the 0.707 point R_c equals the effective control-circuit reactance. Working directly into the input reactance, the 60-cps voltage gain is 230 and the power gain, as defined by equation 2, is 17,500 (42 db). The maximum usable a-c output power occurs at about 16 volts and equals 0.4 watt. The amplifier is driven to full output with less than 0.1 volt and 50 μw (microwatts) of signal. About 0.1 volt of 20-kc ripple is present in the output waveform with only a capacitor, C_1, used as a filter. Variations in the 24-volt d-c supply of ±10% cause less than ±2% change in gain.

Multistage Amplifier

Since a capacitively coupled technique eliminates the effect of d-c drift, it is possible to modulate an amplifier over only a small portion of its control characteristic and still maintain excellent stability. Likewise, since there are no rectifiers or other demodulating elements in the control circuit of these amplifiers, drifts in the characteristics of these components do not affect the practical sensitivity which can be realized. The practical sensitivity of any amplifier is eventually limited by the noise level of the amplifier components. By eliminating the effect of d-c drift and the voltage drops of demodulating elements in a magnetic amplifier, the major obstacles which have limited magnetic-amplifier sensitivity are removed. It now becomes possible to approach the true noise level of a magnetic amplifier. The most probable inherent sources of noise in a magnetic amplifier are the Barkhaussen effect in the magnetic material, thermal noise in diodes and resistors, and the effect of stray fields on the magnetic cores.

In order to demonstrate the extreme sensitivity possible with a capacitively coupled magnetic amplifier, the stage discussed in the preceding section has been combined with two low-level stages. A circuit diagram of the complete amplifier is shown in Fig. 5. The low-level stages each use cores consisting of 10 wraps of 1/4-mil *4-79* Mo-permalloy on 1/2-inch-inside-diameter ceramic bobbins and operate at an 8.0-volt level. Great difficulty was met in stabilizing the amplifier with the three stages operating from a common inverter. The loading effect of the output stage on the inverter, as the stage was modulated at a 60-cps rate, caused a spurious signal to be injected into the lower stages and unstable operation resulted. To overcome this difficulty, the power supply consists of a low-power inverter which drives the two low-level stages and also switches a pair of power transistors which supply the power to the output stage. A small amount of d-c negative feedback is used around the low-level stages to obtain a margin of stability. The amplifier is working at a signal level where care must be taken in shielding the components from stray fields. The cores of the low-level stages are mounted in tube shields and the critical leads are also shielded.

A 60-cps control characteristics of the amplifier is shown in Fig. 6(A). The input impedance of the amplifier consists of 130 ohms resistance plus the winding reactance and equals about 200 ohms. The amplifier is driven to the top of its linear region with a 100-μv (microvolt) signal which corresponds to an input power of about 50×10^{-12} watts. The voltage gain is 90,000 and the power gain is 27×10^{8} (95 db).

Fig. 6(A) shows that about 0.4-volt output exist with zero-signal input. This output results from the carrier ripple, voltage pickup in the amplifier, and random noise generated in the first stage. This output is the noise level of the amplifier and, referred to input, is the equivalent 5 μv or 10^{-13} watts of signal. A major portion of the zero-signal output is 120-cps ripple which apparently is coming through the transistor inverter from its d-c power supply. The remainder of this output is random noise which mostly occurs in the frequency range from 10 to 100 cps where the gain of the amplifier is near maximum.

Negative feedback can be used around the amplifier and the well-recognized advantages of increased stability, increased linearity, increased input impedance, and reduced noise, are obtained. Fig. 6(B) shows the control characteristic of the amplifier when operating with approximately 16 db of feedback. The open-loop and closed-loop frequency-response curves are shown in Fig. 7. Because of the large amount of phase shift of the open-loop amplifier, it is necessary to use a compensating feedback network in

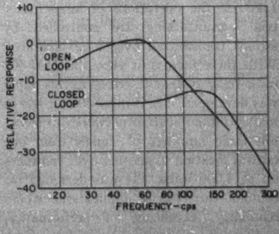

Fig. 7. Frequency response of 3-stage amplifier

order to obtain stable closed-loop operation. With feedback the amplifier is driven over the linear region with a 60-cps signal of less than 1.0 mv (millivolts). The voltage gain is about 15,000 and the power gain is 4×10^8. Considering the increased input impedance, the amplifier is driven over the linear range with 10^{-9} watts to produce full output. The use of high-supply frequency and capacitive coupling extends a-c magnetic-amplifier sensitivity by several orders of magnitude. In addition, a capacitively coupled amplifier possesses high speed, phase sensitivity, excellent stability, and good linearity. Low-level d-c signals also can be amplified and these features retained if a power-frequency chopper is used on the input of the amplifier.

Conclusions

A high-performance a-c magnetic amplifier can be constructed by using a high-carrier frequency and capacitively coupling the signal-frequency power to the load. This technique realizes the advantages of a true a-c amplifier which include freedom from the effects of d-c drift, consequent increased sensitivity, elimination of an input demodulator, inherent phase sensitivity, and accurate reproduction of the input waveform. A capacitively coupled magnetic amplifier possesses excellent stability, and when amplifying power-frequency signals, can achieve very high voltage and power gains. A 3-stage amplifier has been built which has an equivalent noise level of 5μv, or 10^{-13} watts, and requires a 60-cps signal of 50×10^{-12} watts to produce full output.

THE INCREASE in demand for communication service throughout the world has exceeded the rate of growth in population and the tremendous expansion of industrial activities.[1] Both civilian and military requirements have grown beyond the expectations of those associated with the communication field. Along with this need for increased capacities in communication networks, the need has developed for more reliable, higher quality communication service. Military operations and the defense of a country are dependent on the ability to communicate rapidly and accurately. Likewise the operations of large industrial organizations are controlled by signals transmitted over long distances. With these factors in view the *MM-600* radio relay system described in this paper was developed. It is intended for use in major communication networks to transmit large numbers of signals from one central location to another over distances up to 4,000 miles. It was designed for common-carrier-type applications where reliability, excellence of performance, and ease of maintenance are of paramount importance. New components such as travelling-wave tubes and solid state devices plus new concepts such as computer techniques have been integrated into proven methods to fulfill these requirements.

This radio system is a line-of-sight system operating in the radio frequency band 1,700 to 2,300 mc (megacycles). It utilizes frequency modulation and employs heterodyne repeaters at an average of 30-mile intervals to compensate for propagation loss. It is designed for satisfactory transmission of either a large number of message channels, of 4 kc nominal bandwidth, or one television signal on a single r-f (radio frequency) channel.

Facilities are provided for operating up to 12 r-f channels simultaneously. The r-f allocation plans, which have been adopted, follow recommendations of the International Radio Consultative Committee (CCIR); however, the flexibility of the system design permits deviations from these standard allocations for specific customer requirements. A typical plan is shown in Fig. 1. In general, because of the need for extremely reliable communication service, it is not desirable to operate a broadband channel without standby facilities. In the *MM-600* design, frequency diversity techniques are utilized to provide automatic protection against either equipment failure or selective fading in the propagation medium. Consequently, it is anticipated that in most applications one or more radio channels in each direction of transmission will be reserved for diversity uses.[2]

System Objectives

The capacity of each broadband channel is nominally 600 message channels or alternately one monochrome or color television signal. A baseband width of 2.5 or 3 mc, depending on the type of frequency division multiplex used, is required in the message application and a maximum of 6 mc is required for television of 625-line standard.

The bandwidth of the equipment for each r-f channel is 30 mc to the half-power points. It is anticipated that this large available FM (frequency modulated) signal bandwidth will permit increased traffic capacities after operating

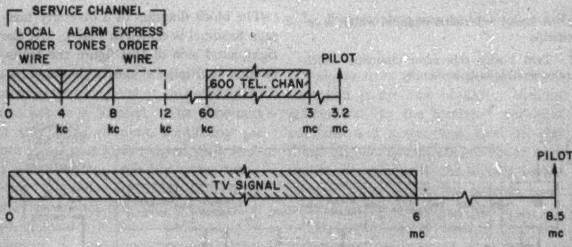

Fig. 2. Baseband allocation plan

experience has been gained and necessary refinements in design are made. The baseband frequency allocation plan is shown in Fig. 2. It will be noted that service channel signals, which are used in maintaining the radio system, can be transmitted on the same channel as the message traffic. This provision obviates the necessity for providing separate communication facilities such as wire lines or another radio system to handle this service.[3]

In establishing the system and unit design requirements for the *MM-600* system, all common kinds of message signals as well as television were considered. Satisfactory performance is realized for ordinary voice, telegraph, telephoto, data, and program. CCIR performance standards have been used as over-all system design requirements. These standards are defined in terms of a reference circuit 1,550 miles long. The basic system parameters were established primarily on message requirements which are, in general, more limiting than the television requirements. Over the reference circuit the allowable signal-to-noise ratio is 53 db (decibels) mean value in the busy hours in the absence of fading; 51 db mean value in any hour. These are the ratios of test tone level, 0 dbm (power in decibels referred to 1 milliwatt), to weighted noise (random circuit noise plus intermodulation noise).

The first value establishes primarily the linearity of the equipment and the second fixes the level of random circuit noise. The latter also requires the adequate provision be made for selective fading.

The basic characteristics of the system are summarized in the Appendix. By using the necessary values in this table, one may compute the random circuit noise in the worst channel of a 600-channel system at 2.54-mc baseband frequency. The ratio with weighting in a 1,550-mile system is 61.5 db. In this computation free space transmission is assumed and no advantage is taken of the fact that in a practical case a given telephone channel need not be transmitted throughout the full length of a system at the top edge of the baseband spectrum. If a 5-db degradation is assumed for the difference between free space loss and mean propagation loss and 2 db is assumed to be gained by shifting the location of the channel lower in the baseband, a net signal-to-noise ratio of 58.5 db is obtained. Further improvement may be achieved, if necessary, by the use of emphasis networks which increase the channel frequency deviation at high baseband frequencies.

Nonlinearity in a radio system results in the generation of modulation products from one or more message channel signals.[4] These products, which are primarily harmonics, and sum and difference signals, create interferences which are noise-like in character.[5] Because of the large number of signals transmitted, the linearity requirements of the system are very severe and many precautions have been taken to insure adequate performance. Reflections in the feeder system are minimized by the use of a well-matched antenna and by isolators at the radio bays. Modulators and discriminators which are linear over a wide band are employed, and delay equalizers are used to compensate for the phase distortion inherent in the r-f and i-f (intermediate-frequency) networks.

The major problems encountered in the transmission of video signals arise from the same sources as those in the message application. The signal-to-noise performance for a standard 525-line television signal over a circuit of reference length is 50 db. This is the ratio of video signal peak-to-peak (excluding synchronizing

signals) to rms random circuit noise. The energy distribution of this noise is essentially triangular: 6 db per frequency octave. Acceptable performance for this kind of interference is 41 db.

System nonlinearity is a major problem in television transmission for color signals for which the differential gain and phase characteristics of the system at the color subcarrier frequency, 3.58 mc, are critical. Emphasis networks are used to alleviate this problem.

Other important system requirements, such as those specifying baseband amplitude response and delay response, gain stability and allowable circuit interruptions, have been realized by the use of appropriate circuit designs and premium components. The equipment is designed to operate through a wide range of environmental conditions.

System Application

The *MM-600* system includes three basic types of repeater:

1. Terminal repeater
2. Drop repeater
3. Through repeater

A terminal repeater would normally be located near a communication center where access is required to a large number of the transmitted message channels. At this repeater all signals are demodulated to baseband frequencies. It is anticipated that in many installations there will be a demand for access to a small number of message channels along a radio path. To fulfill this need without a terminal repeater, the drop repeater is provided. Any number of message channels may be dropped and up to 60 channels inserted. The drop repeater therefore adds to the flexibility of the system.

The only function of the through repeater is to compensate for propagation loss. Access to the service channel is provided to facilitate maintenance and to permit unattended operation of the station. In fact all repeaters may be equipped for unattended operation. A typical arrangement of these repeaters in a system installation is shown in Fig. 3.

Standard system arrangements are designed for the more common applications and some of these are explained in the system description which follows. However, other traffic requirements can be satisfied with only minor modifications in the standard design. Some of these are:

1. A 1-way television channel which is reversible
2. Two 1-way television channels which are reversible independently
3. The occasional use of the message diversity channel for television transmission
4. The use of the message diversity channel as a television protection channel

System Description

Protection Arrangements

It is common practice to provide a separate r-f protection channel as a standby for one or more working channels.[6] For efficient protection a long circuit is divided into switching sections each of which may contain from 3 to 15 repeaters. Such an arrangement protects against equipment failure, facilitates maintenance, and provides frequency diversity. Diversity virtually eliminates periods of high noise if the difference between the protection channel radio frequency and that of the working channel is large.

The use of one protection channel for each working channel gives the greatest reliability and best performance as it is the simplest arrangement. Both channels carry the same traffic; the better of the two received signals being selected at the end of a switching section. All active units including baseband amplifiers may be protected if switching is performed at baseband frequencies. Typical stations using this principle will now be described.

Fig. 5. Diversity drop repeater for message traffic

ing the message pilot unit. The voice channel test tone level at this point may be as low as −50 dbm. The pilot unit has two equal outputs, containing the input signal plus a pilot signal, each feeding a transmitter assembly. One transmitter assembly, including a message amplifier, modulator, and a transmitter unit, generates a radio carrier at, say, frequency f_1' and the other generates a carrier at frequency f_5'. The method by which these carriers are generated will be explained in the description of basic units, but it should be noted that the frequency deviation for a voice channel test tone is 200 kc rms. The nomenclature used for frequencies corresponds to that of the allocation plan in Fig. 1, channels 1 and 5 being chosen as consistent with the use of one polarization per feeder.

In the receive direction the branching filter directs incoming signals of frequencies f_1 and f_5 to the appropriate receiver assemblies. Each assembly contains a mixer, i-f amplifiers, a demodulator, and a message amplifier. The baseband switch selects the better of the signals it receives from the two message amplifiers and passes one of these, without attenuation, to the receiving multiplex equipment at a test tone level of −15 dbm. If pilot signals are present on both inputs, the pilot with the highest signal-to-noise ratio is selected but an input without a pilot is always rejected.

The ferrite isolators used in the transmitting and receiving r-f circuits are essential to the operation of this system. They remove the need for critical adjustments in the radio equipment, e.g., matching of traveling wave tubes, while maintaining a good match at the side presented to the branching network. The mechanical design of the radio equipment has been simplified by the use of isolators as will be explained.

A Drop Repeater Station

The block diagram for the associated diversity message dropping repeater is shown in Fig. 5. Incoming and outgoing radio frequencies are transmitted by branching filters, band pass filters, and isolators identical to those used in the terminal station. An incoming signal at f_1' reaches the mixer preamplifier typically at a level of −30 dbm. The signal is converted to intermediate frequency, amplified, and reconverted to a radio frequency of, say, f_1. In the 2-frequency system shown the receive local oscillator feeds two mixer preamplifier units. Similarly the transmit local oscillator feeds two transmitters. The local oscillators are crystal controlled providing excellent stability in the frequency translation process. Since the receive and transmit local oscillator frequencies are independent at both repeater and terminal stations a wide variation in the value of the translation frequency is possible. The standard translation is 213 mc. Other applications exist, however, where operation in a 400 mc band as prescribed by the CCIR is not desirable. These applications require frequency translations as low as 80 mc and as high as 300 mc. The use of a 2-frequency system (two r-f frequencies per 2-way radio channel) is made possible by the use of an antenna system with excellent front-to-back ratio.

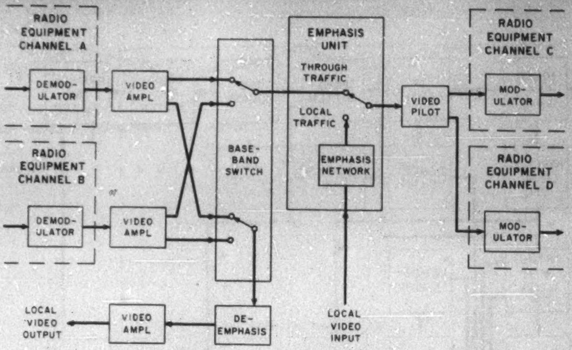

Fig. 6. Video facilities of a 1-way diversity terminal repeater

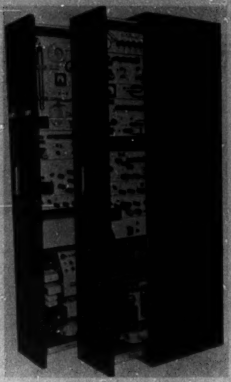

Fig. 8. Two-way terminal bay

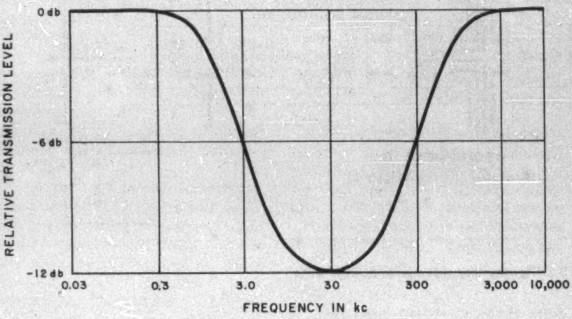

Fig. 7. Video emphasis characteristic

To provide for adding and dropping small amounts of traffic at repeater stations without the requirement for back-to-back terminal operation, a phase modulator is provided in the transmit local oscillator. When driven by a message amplifier this modulator is capable of adding to the outgoing carrier up to 60 voice channels in the 60 kc to 300 kc portion of the baseband spectrum. The received signals for these 60 channels are, of course, handled by the demodulator and receiving message amplifier. This low capacity drop traffic has the full advantage of diversity reception.

The service channel equipment for both terminal and repeater stations is designed so that one equipment assembly can serve the radio equipment for up to six 2-way radio channels. Service channel signals are distributed by the order wire combiner unit and are frequency modulated on the outgoing carrier by a second phase modulator in the transmit oscillator unit.[7]

Video Terminal Repeater

The organization of systems in which video traffic is transmitted is somewhat different from that illustrated in Figs. 4 and 5. The service channel signals, for example, are transmitted by a facility other than the video channel radio system. This removes the requirement for all demodulators and message amplifiers, at through repeater stations.

An illustration of the means by which video traffic is handled is shown in Fig. 6. This station is one in which diversified video traffic is received, used locally, and also retransmitted along the circuit. If desired, local video signals may be added. Other video station assemblies may be formed using the same equipment units. The emphasis network modifies the video signal such that signals below approximately 3 kc and above approximately 300 kc are transmitted at normal deviation. Signals inside this band are transmitted at levels approximately 12 db below normal deviation. This type of pre-emphasis reduces differential phase without deteriorating the ratio of video signal to hum. The characteristic is shown in Fig. 7. Video signals which pass through the station preserve the emphasis given to them at the source. Clamping is not used at any point in the system.

Description of Basic Units

Mechanical Design

The equipment uses cabinets which contain sliding racks. These racks are of standard width, holding 19-inch panels on which the basic units are built. A radio terminal, which is contained in two cabinets, is shown in Fig. 8. Four cabinets are required for a diversity terminal, excluding service channel supervisory equipment, and six cabinets are required for a diversity 2-way repeater including service channel and drop facilities.

A 2-way repeater is arranged so that one rack contains all the units which handle the through signal for one direction, i.e., a receiver and a transmitter. Between two such racks is a rack containing common equipment such as oscillators and service channel units.

Isolators and branching filters are mounted above the cabinets and connected to the pull-out racks by flexible coaxial cable. The branching filters are of waveguide construction but have coaxial outlets. The cabinet with two sets of branching filters can be installed in a room with only an 8-foot clearance from floor to ceiling.

Vol.
Pt. 1
1959

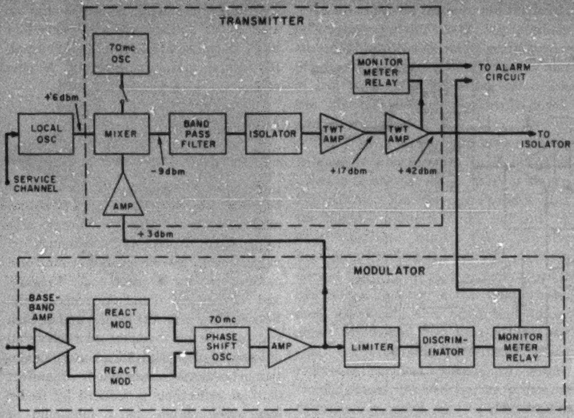

Fig. 9. Terminal transmitter assembly

The operation of the equipment may be monitored without the need for sliding an equipment rack out of the cabinet. For this purpose the cabinet front has meters indicating received signal and transmitted power as well as lights to indicate the status of controls.

More detailed information may be obtained by pulling out the rack. The equipment remains in an operating condition; all units being shielded for the protection of the maintenance personnel. In particular each rack and unit is provided with facilities for the measurement of tube currents and, by depression of the filament voltage, the emission capabilities of each tube may be ascertained. This is a facility for preventative maintenance which is of great value and particularly effective if records of previous measurements are kept. This facility will reduce operating tube failures and unnecessary replacement of tubes.

The use of individual unit rear covers allows circuits to be checked and repairs to be made in one unit mounted in the rack without accidental contact with other units. Also the removal of a unit is facilitated by the use of reliable plugs for signal and power connections.

The cabinet construction saves floor space while providing simultaneous accessibility to both sides of each unit. Cabinets may be mounted side by side and placed against a wall or may be placed back to back.

Terminal Transmitter

The radio transmitter block diagram is shown in Fig. 9. It consists of 3 units: the modulator unit, the transmitter unit, and the local oscillator unit.

The modulator unit performs the function of frequency modulating a 70 mc carrier. Included in the unit are a baseband amplifier, push-pull reactance modulators, and a phase shift oscillator. The frequency of the oscillator is very stable so automatic frequency control is not necessary. The stability is due to the balancing effect of the push-pull modulators. A 70-mc discriminator and meter are used to monitor the center frequency of the oscillator.

The slope of the conversion characteristic of a typical modulator varies less than 1% over a frequency deviation range of ±4 mc; the overload points being at ±12 mc.

The transmitter unit contains an i-f amplifier, a low level balanced crystal mixer, a band-pass filter for selection of the proper sideband, a ferrite isolator, and two traveling wave tube amplifiers.[8] These tubes have been specially designed for this equipment and are completely packaged. They are designed for extremely long life; requiring no mechanical adjustments and only minor voltage adjustments, upon installation.[9] Fig. 10 shows a view of this transmitter.

The mixer is an up-converter which obtains excitation from the local oscillator unit and signal from the 70-mc output of the modulator or, at repeater stations, the output of the i-f amplifier. The isolator is used between the band-pass filter and the first traveling wave amplifier to provide a good match for the filter. A 70-mc crystal-controlled oscillator, using transistors, is included in the transmitter and is automatically connected to the mixer should the i-f signal from the receiver in a repeater fail. This permits the transmitter to operate for the transmission of alarm signals.

Each local oscillator unit will provide sufficient output for either two transmitters or two receivers. Each contains a crystal oscillator and a multiplier chain. The transmitter local oscillator contains two phase modulator circuits, one at audio frequencies for the service channel and one for adding traffic channels at repeater stations. The audio-frequency modulator circuit consists of a ferrite line of variable-delay and the traffic channel modulator uses a conventional tube circuit. De-emphasis networks preceding each phase modulator produce the desired frequency modulation characteristic.

Terminal Receiver

The receiver is composed of four units: mixer-preamplifier unit, i-f unit, demodulator unit, and a baseband amplifier

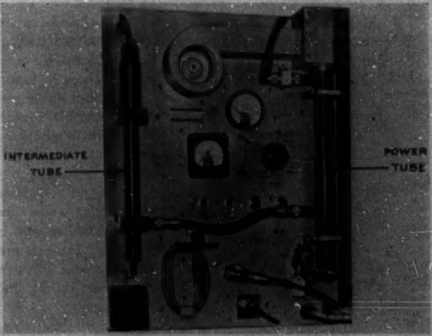

Fig. 10. Transmitter panel showing traveling wave tubes

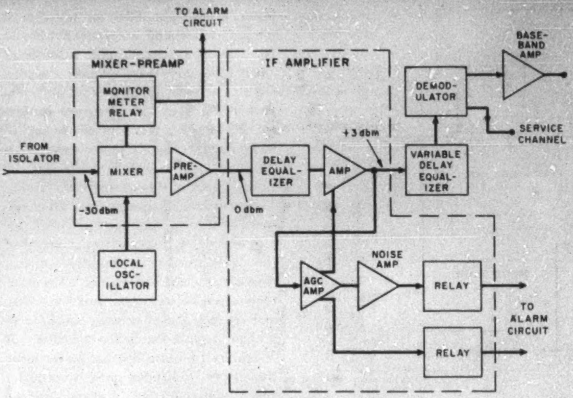

Fig. 11. Terminal receiver assembly

unit. The complete receiver block diagram is shown in Fig. 11.

The mixer-preamplifier unit contains an unbalanced crystal mixer and four stages of amplification at 70 mc. The first two stages use grounded grid circuits. A noise figure of between 8 and 10 db is obtained.

The i-f unit contains a fixed delay equalizer and seven stages of amplification using conventional double tuned interstage transformers.[10] The Q ratio of these transformers is designed to provide maximum band-pass stability with AGC action and tube changes. Additional circuits in this unit provide automatic gain control, and give alarm information should the receiver gain drop or the received signal fail. The signal failure circuit also operates a noise squelch and, at repeaters, turns on the 70 mc oscillator in the transmitter. Two outputs are provided, one for connection to the demodulator and one for connection to the transmitter at repeater stations.

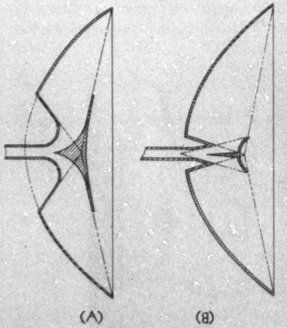

Fig. 12. Evolution of circular horn-paraboloid

A—Original
B—Modified

The demodulator unit includes a limiter driver tube, two limiter stages, a harmonic filter, and parallel discriminator drivers. The discriminator is a symmetrical arrangement of two tuned circuits which provides excellent balance and at the same time a single-ended output. Following the discriminator is a cathode follower for the base-band output and a 2-stage audio amplifier for the service channel.

The over-all gain of the receiver is sufficient to provide adequate limiting on signal strengths down to FM threshold.

Either one of two baseband amplifier units may be used. One is suitable for monochrome or color TV and the other, a simplified version, is suitable for message traffic only. Both amplifiers use negative feedback over three stages.

The baseband switching unit contains circuits for the selective amplification and detection of the radio pilot frequency present at each input. The switch is a transistor device driven by a trigger circuit and has a switching time of approximately 10 microseconds.[11]

Two types of d-c power supply are used: a low-voltage supply for the receiver circuits and a high-voltage supply for the traveling wave tube amplifiers. Silicon rectifiers are used in all critical circuits. Circuit breakers are used to protect the transmitter tubes against excessive helix current during initial adjustments of voltages.

All inter-unit connections at baseband frequencies and at 70 mc use 75-ohm coaxial cables, and all units are designed for high return loss at each input and output. R-f connections are made by 50-ohm cables.

Antenna System

Performance Requirements

Both the antenna and the feeder must be efficient in order that a good signal-to-noise ratio be obtained with reasonable transmitter power and antennas of modest size. Economic limits for these parameters were assumed to be 15 watts and 10 feet in diameter, respectively. Reflections within the feeder, and at each end, must be low to reduce color television differential phase and reduce intermodulation between voice channels.[12] The effect of these reflections is reduced by feeder loss which should be a minimum of about 0.4 db per 100 feet assuming an antenna of VSWR (voltage standing wave ratio) 1.06 maximum. The maximum permissible loss for good signal-to-noise ratio with an antenna of high efficiency is about 1.5 db per 100 feet.

The directional properties of the antenna must be controlled carefully. Very little energy must be radiated in the back direction as this energy interferes with transmission in the opposite direction.[13] Radiation at small angles off the main beam must be low to avoid "overshoot," a phenomenon by which a signal may bypass intermediate repeaters.

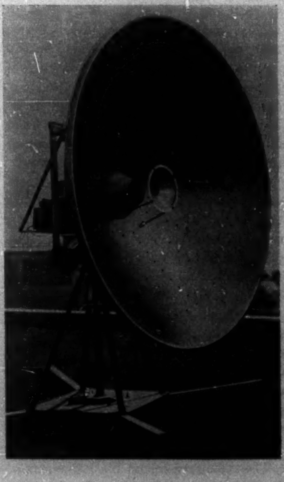

Fig. 13. Antenna

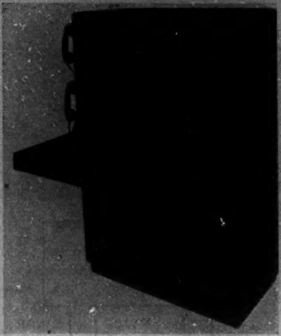

Fig. 14. Console containing all supervisory station service channel facilities

Also, the cross-polarized energy radiated in the direction of the main beam must be low to avoid interference with adjacent r-f channels of the CCIR frequency plan. For one antenna to serve three transmitters and three receivers on a common polarization it must have a minimum bandwidth of 400 mc.

Feeder Design

For 2,000-mc operation there are two types of feeder which may be used: "semiflexible" coaxial cable and waveguide.[14] In coaxial cable, freedom from the transmission of spurious modes sets the maximum useable standard diameter as $1^5/_8$ inches. This size has an attenuation of the order of 1.4 db per 100 feet but the magnitude of internal reflections suggest that its use be limited to systems, of 240-voice channel capacity or less. It is, however, suitable for monochrome television transmission.

The *MM-600* uses rectangular waveguide of outside dimensions 4.30 by 2.15 inches. Aluminum waveguide is used for ease of handling and had a measured attenuation of only 0.5 db per 100 feet. The feeder and the antenna are pressurized to a maximum of 2 psi (pounds per square inch).

Antenna Design

Conventional antennas, using a shallow paraboloid illuminated by a waveguide or coaxial horn, do not have the required VSWR over a ±15% band and have excessive back radiation. The horn-reflector antenna, which was designed specifically for radio relay use at frequencies of 4,000 mc and above, does have all the electrical properties desired but is large and heavy.[15–17]

An attempt was made to use the horn-reflector concept and modify it to produce an antenna with acceptable performance of larger aperture area, 80 square feet, and of less bulk. The procedure by which the *MM-600* antenna was evolved will now be explained.

The frontal area of the horn-reflector antenna is a sector of a circle but it is possible to use the whole circle as shown Fig. 12(A). For the same useful area the height is reduced to one half and the depth to one third. This "circular horn-paraboloid" is fed from the rear by a curved horn of coaxial cross section which blocks one quarter of the total frontal area. Reducing this large feed to increase the useful area also reduces the side lobes of the radiation pattern. Using reflecting surfaces instead of bends, simple shapes, derived by the principles of geometric optics, may be employed in the feed. The antenna, as shown in Fig. 12(B), then resembles a Cassegrain telescope. Further modifications from these shapes were found to be necessary to obtain good impedance match. For example the central pin was virtually eliminated. Fig. 13 shows the end product: a deep paraboloid $(f/d=0.2)$ of 10 feet in diameter. A window has been added to the mouth of the circular waveguide horn and behind the dish there is a transition from circular to rectangular waveguide.

The gain varies from 32.6 db at 1,700 mc to 36.5 db at 2,300 mc, the corresponding beam widths varying from 4 to 2.8 degrees. A VSWR of 1.03 at 2,000 mc is obtained.

The Service Channel

The maintenance of a long-haul communications system is a major operating expense. A comprehensive service channel system will decrease the cost of maintenance while increasing system reliability. Full facilities for unattended system operation may be provided by the service channel equipment to be described. The equipment arrangement is flexible and expandable to meet specific requirements.

The term "service channel" should be explained. It is used to denote all communication, data transmission and processing, display and control facilities provided for the maintenance of a radio relay system. Such a definition includes the communications means, which may be via a separate radio link, by wire lines, or over the relay system itself.

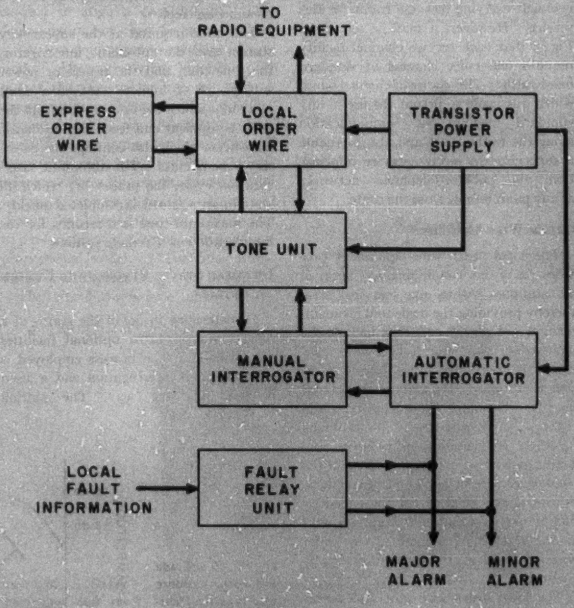

Fig. 15. Supervisory station

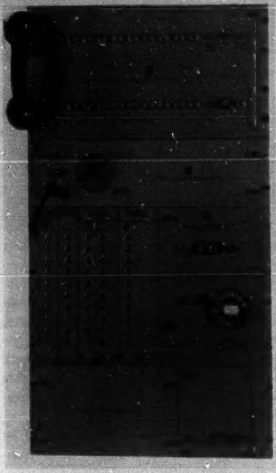

Fig. 16. Service channel equipment at a remote station

The design of the *MM-600* service channel does not include a special radio channel but uses one or more of the radio channels carrying message traffic for this service. However, it may be seen from Fig. 2 that each service channel facility requires one voice channel of standard bandwidth. This choice of channel bandwidth was made to permit the use of any standard medium for communication along the traffic route and also to enable a supervisor to receive service information via public telephone networks at any point remote from the route.

ORDER WIRE EQUIPMENT

The local order wire equipment provides party-line communication between all stations within one service area, thereby providing the basic tool for maintenance. A service area may include the main route plus spur links but is commonly 1 supervisory station plus 3 to 15 remote stations. The maintenance center may be at a point remote from the radio route; 4-way 4-wire hybrids are provided for these connections. Also 2-wire and 4-wire extensions are incorporated in the local order wire unit. Loudspeaker hailing and tone signalling may be added by plug-in units. Combining units are used if, for reasons of reliability, the order wire is carried over more than one radio channel.

The local order wire unit also serves as a distribution unit for the signals of other facilities including the express order wire which is intended for communication between maintenance centers. The express unit is similar to the local unit with the addition of translation circuits for the 8.3- to 11.7-kc band.

MINIMUM ALARM FACILITIES

It is a primary requirement that a supervisory station receive accurate information on the status of remote equipment. The degree of detail required will vary from system to system but a convenient design minimum must be set. The automatic reporting of four status conditions per remote station, which station is positively identified, was considered to be the minimum requirement. A "fail safe" design was considered mandatory so that no fault could occur without identification. These objectives were achieved by the use of the following basic principles:

1. Interrogation by the supervisory station.
2. Allocation of a separate tone channel by which each remote station receives the interrogation pulse and gives a coded reply.

The four status conditions may be called: no-alarm, major-alarm, minor alarm, and alarm system-alarm; the latter being the interpretation given to a meaningless reply.

The units required at the supervisory station are: the automatic interrogator, the tone unit, and the transistor power supply. At a remote station a fault relay unit stores the information from the radio equipment and feeds the automatic responder, which also contains the necessary tone circuits. The automatic interrogation cycle, the process by which all stations are scanned, is completed quickly. The maximum time is 6 seconds for the interrogation of 15 remote stations.

DETAILED STATUS REPORTS AND REMOTE CONTROL

To determine in detail the status of a remote station extra optional facilities are available. The process employed is called manual interrogation and is used in the following way. The station selected is withdrawn from the automatic interrogation cycle which continues to survey the other stations. A statement from the selected station is requested and by an electronic stepping process a maximum of 20 conditions is automatically reported and displayed visually at the supervisory point.

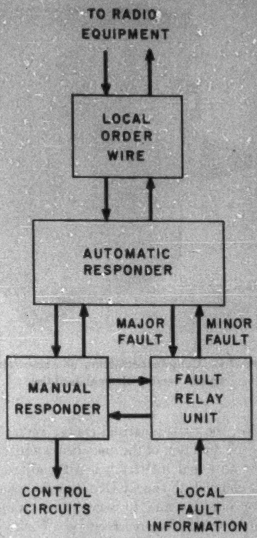

Fig. 17. Remote station

Remote control facilities are available as an extension of the manual interrogation process. After a control function is selected, a report from the remote station, confirming that the proper function has been selected, may be received and displayed. Then by the transmission of a special tone the control is executed. Confirmation of an order completed is of course obtainable at any time by manual interrogation.

The manual interrogator and responder units accept plug-in assemblies to provide continuous expansion of facilities for 1 to 15 stations each with 10 or 20 reports and 0 or 10 controls. Any of the num-

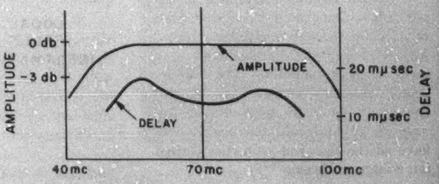

Fig. 18. Amplitude and delay response of a typical I-f network

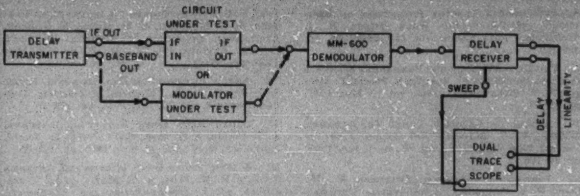

Fig. 19. Simultaneous measurement of delay and linearity

bers given above can be increased by the use of additional main units. A supervisory station equipped with maximum standard facilities is shown in Figs. 14 and 15. The corresponding remote station equipment, which can be incorporated in the radio bays, is shown in Figs. 16 and 17.

The service channel system, complete within itself, has many applications apart from the maintenance of radio relay systems. Extreme reliability is obtained by the application of sound basic operating principles to equipment which incorporates special long-life components including transistors and cold cathode tubes. No mechanical components are used for repetitive switching functions. Instead techniques taken from computer technology are employed.

The concept and planning of this system was a major achievement for which Mr. G. Birman should receive special credit.

Test Equipment

Test facilities are incorporated in the design of the radio equipment itself and some of these were described in the section on basic units. Special test points have also been included; for example, the feeder system includes directional couplers for the measurement of VSWR and station gain flatness. Sweep generators and amplitudes detectors for r-f and i-f use are essential items and other special equipments are needed.[18] Of particular interest and great importance is the group delay measuring equipment.

All r-f and i-f band-pass filters used in the radio system are designed to have maximally flat amplitude response and therefore do not have a phase characteristic linear with frequency. Group delay, the slope of this phase characteristic, is not constant and must therefore be measured and equalized. The amplitude and delay response of a typical i-f network is shown in Fig. 18. Considerable accuracy of equalization is required and delay measurements must be made on an operating system to ensure this.

The linearity of the transfer characteristic of a system must also be measured. In particular, modulators and demodulators require alignment by so-called derivative techniques. The delay equipment described incorporates all the circuits necessary for linearity measurements to be made simultaneously with delay measurements.

The delay and linearity measurement equipment is built in the form of two independent units. The transmitter unit supplies effectively distortionless signals and the receiver unit analyses the distortion introduced by intermediate equipment under test. This arrangement is illustrated in Fig. 19, which shows several important features. The transmitter unit has an i-f output, modulated by a 200-kc tone and swept across the i-f band, which is used to align a demodulator. This demodulator can then be used as part of the test equipment to measure i-f networks. Alternatively the baseband output of the transmitter may be used to measure the performance of a modulator and demodulator. For checking purposes the direct connection of receiver and transmitter units is also possible. The receiver measures the amplitude of the 200-kc tone to provide a linearity output, and detects the phase of the tone, with respect to a reference signal, to provide a voltage proportional to delay. The delay transmitter and receiver are shown in Fig. 20.

The signal-of-reference phase is derived from the input signal itself so that delay measurements can be made over 1-way multi-hop circuits. A sweep voltage for the oscilloscope is also taken from the input signal. The equipment is capable of measuring delay variations of 1 millimicrosecond and changes of slope of transfer characteristics to less than 1/2 of 1%.

Summary

The careful attention paid during the design period to user requirements and the completeness of the design make the *MM-600* system suitable for the varied needs of commercial and military high-capacity communication networks. Systems were under test in the laboratory in the beginning of 1958 and a 2-hop experimental field circuit has been operated since September 1958.

Appendix. Technical Specifications

Frequency band	1,700 to 2,300 mc
Length of system	4,000 miles
Relay station spacing	30 miles (average)
Type of modulation	FM
Maximum deviation	±4 mc peak
Type of repeater	heterodyne with 70 mc intermediate frequency
Transmitter output power	15 watt minimum (+42 dbm)
Antenna gain	34 db
Receiver bandwidth	30 mc
Receiver threshold	−79 dbm (10 db noise factor)
Fading margin (30-mile path)	49 db
Capacity of each r-f channel	600 voice channels plus service channel, or one television signal
Add channel provision at repeaters	60 voice channels, 60 to 300 kc

A High-Volume High-Speed Weather Information Distribution System

E. E. SCHWENZFEGER
ASSOCIATE MEMBER AIEE

THE PLANNERS of aircraft operations, both commercial and military, have always required up-to-date information regarding predicted weather along flight paths and at destinations. The need for more timely weather information has been increasing for some years. On the commercial side the need has grown because of the increasing density of air traffic and the economic drive for more efficient aircraft operations. For the military side, apart from the constant drive for greater efficiency, the need has also been growing because of the increasing complexity of operations.

The advent of jet aircraft has made the need urgent for more timely weather information. This urgency stems in part from the fact that a jet consumes such a large amount of fuel at low altitudes that a missed approach becomes a very expensive maneuver. The quality of weather information generally available today obliges the commercial operator to plan for the contingency of finding the end of the runway shut in after descending to an uneconomically low altitude. This planning calls for carrying sufficient extra fuel to permit regaining an economical altitude and reaching an alternate field or holding while waiting for the ceiling to lift. The extra fuel carried translates directly into a reduction in pay load. If timely weather information were available it could be transmitted to the plane before it descended to lower altitudes. In military operations good predictions regarding end-of-runway weather are especially important because jets returning from extended missions may have too little fuel left to permit any change of plan after reaching a low altitude. It will, of course, be appreciated that the foregoing is only one facet of a many-sided problem.

Weather system planners in the CAA (Civil Aeronautics Administration), U. S. Weather Bureau, and the Air Force Cambridge Research Center have been working on what may be called a 2-pronged attack on the problem. One prong calls for the development of sophisticated hardware for the rapid acquisition and dissemination of weather data. The other prong calls for the development of numerical methods employing computers for making forecasts. There are several numerical approaches which might be taken. One is a statistical method which requires reiterated solutions of a mathematical model utilizing constantly acquired data; another requires solutions of a thermodynamic model of the atmosphere and a third requires the solution of equations of motion. The equations for the third approach, which were furnished by D. R. Harris, Chief of Weather Bureau's Aero-Meteorological Investigations, are shown in the Appendix. These are offered only to give the flavor of the computation problem. These equations must be solved for each 100-mile grid point spread over the continent and adjacent waters. It is understood that a 24-hour forecast requires 144 solutions spaced 10 minutes apart for each grid point.

Because observation and forecast data are very perishable, rapid and efficient communication is a basic requirement in instrumenting the 2-pronged attack.

The communication system presently beging used to disseminate weather data is a conventional 75-word-per minute teletypewriter system. The system is composed of three services: Service A is for domestic aviation, Service C is for general weather service, and Service O is for international aviation. The demands made upon this system have for some years far exceeded its capabilities. A characteristic of the present system is that users at many receiving stations are obliged to receive a great deal of unwanted data in order to get what they need. In extreme cases the unwanted data run as high as 80% of the total received. Also, the system is inflexible in that when a user wishes to alter the program of received data he must put a request through Washington for the change; this requires several weeks to place in effect.

The Air Navigation Development Board in conjunction with the CAA asked the Bell Telephone Laboratories to make an engineering study and propose a system which would satisfy present-day and future requirements. This work was done under Signal Corp Contract *DA36-039 SC-64567* and was reported on under the title "Air Traffic Control Communications, Final Report, Task D Part 2—

Paper 59-812, recommended by the AIEE Data Communication Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21–26, 1959. Manuscript submitted March 23, 1959; made available for printing April 20, 1959.

Fig. 1. Proposed system

High-Volume Weather Information Communication System." Permission to discuss the proposed system in this paper has been granted by the Aviation Weather Division of the Federal Aviation Agency which now has the responsibility for this work. The military services, and particularly the Cambridge Air Research Center of the Air Force, took an active part in formulating these requirements, some of which are stated below to give the flavor of the communications problem.

1. The system shall be capable of accomplishing the collection and distribution of meteorological and NOTAM (Notice-to-Airmen) data on a national basis with a means of automatic interconnection with the weather and NOTAM system of contiguous countries and conventional teletypewriter systems within the United States.

2. The system shall be capable of accommodating the existing load on the Services A, C, and O teletypewriter networks, the USAF (United States Air Force) national teletypewriter networks and the special weather teletypewriter networks of the U. S. Weather Bureau. It is estimated that the load will increase to 1,500,000 groups per day in 1965 and to 2,050,000 groups per day in 1975. A group is a 5-character word plus a space.

3. The maximum message unit transit time of programmed data from origin to destination anywhere in the United States must be less than 10 minutes.

4. Provision shall be made for the receivers to determine their needs and be able to select and program data by types from a minimum of 500 selections. The ability to alter the selection on an hour-to-hour basis is a necessary feature.

5. The end product at receiving stations must be printed page copy with provision for feeding data directly, without human intervention, into numerical weather computing machines.

6. Consideration should be given to the possibility that the operating personnel at both receiving and transmitting stations will not always be experienced in the operation or adjustment of communication equipment.

General Description of the Proposed System

The system proposed to meet the above requirements is a high-speed distribution system, shown in Fig. 1, and is in effect based on the old telephone party line concept in which any or all subscribers could listen in on any or all conversations if they wished. It is a party line arranged for transmitting data and messages at the rate of 1,000 words per minute. There may be as many as 1,000 stations which transmit data and perhaps as many as 5,000 which receive them.

However, the proposed system is unlike the old telephone party line in that the transmitting station gets on the line only at the invitation of a master control station which is programmed by operating personnel to call in sending stations as required. Provision is made for the master control to give any sending station emergency access to the line. Stations, before sending data, identify themselves and the data they are going to send. This also departs somewhat from the old party line principle. Each receiving station is programmed, that is to say, instructed by its own local operating personnel to monitor the line and to attach its printer to the line automatically to receive desired data from transmitting points in which it is interested. The program at receiving stations may be arranged to select any number of transmissions from the line. This program may also be readily altered by nontechnical operating personnel to meet changing data requirements.

The telephone facilities which make up the long distance communication network of this country are arranged to connect towns and cities. Therefore, the circuit layout of the proposed system must consist of a series of lines fanning out arterially from interconnected hubs scattered about the country. The number and locations of the hubs present a problem of considerable magnitude to the circuit layout engineer because of the many economic and technical considerations involved.

Fig. 2 shows in schematic fashion the principles involved in laying out the system. It does not represent the actual layout which might be used.

The manner in which data are distributed over the network may be seen by considering the route by which data leave

a particular transmitting point, say Lincoln, Neb. The data flow in several directions from Lincoln to all points on its branch line. One of these points is Denver, Colo., which is a hub point on the backbone route. The data fan out to the rest of the country from Denver.

The proposed system is efficient in the use of the line in that only 5% of the time required for an average data transmission is utilized for control and selection functions. Also, in the proposed system, unlike the existing system, data sent into the line from any transmitting station are immediately available to any receiving station that wants them.

Comparative traffic-handling capabilities may be judged from the fact that the combined maximum hourly load of Services A, C, and O, which constitute the present system, could be handled in less than 15 minutes by the proposed system. Also, because it confers full flexibility in choice of data received, the proposed system delivers 20 times more useful data to the receiver. The twentyfold improvement grows out of the following considerations:

1. The transmission speed of the proposed system is 13 times greater than that of the existing system: 1,000 words per minute versus 75 words per minute.

2. All data received in the proposed system will be useful because only wanted data are selected by each receiving station. It is estimated that at least 25% of the data received by the average station in the existing system is unwanted. The ratio of effective transmission speeds is thus probably closer to 1,000 words per minute versus 56 words per minute.

3. A considerable but undetermined amount of data received in the existing system is obsolete because of switching delays encountered between transmitters and receivers. Switching delays do not occur in the proposed system because there are no centralized switching points to introduce delays. Thus the transit time for data from origin to destination is less than a second, which is many times better than the requirement which calls for a transit time of less than 10 minutes.

Operation of the Proposed System

Before describing the system components in detail it might be useful to consider first the operation of the proposed system.

would also be receiving stations but there would be in addition many receiving-only stations. Arrangements for transmitting-only stations would also be provided if desired. A combined transmitting and receiving station would include a data program-selecting device which would have the dual function of monitoring the line for both control codes and data program code. A data program code is a unique combination of characters which prefaces the data sent by each transmitter; it tells the data program selectors what type of data is being sent by which transmitter. Control codes are other character combinations used to start transmitters, indicate end of transmission, indicate end of program, etc. The selecting device would translate these codes and feed information to control logic circuitry. The logic circuitry would connect and disconnect the printer to and from the line to receive only the desired data which corresponds to decoded data program codes. It would also start the tape transmitter under command of a master control station and perform other functions as directed by decoded control codes.

There would be one master control station on the entire line. Its function would be to control the operation of the system. It would be programmed or instructed to start transmitters automatically and command them to transmit particular data at given times. The control station would also detect and correct certain malfunctions and call in operating personnel to deal with troubles it is unable to handle.

On the present Teletype weather network there are 8 scheduled and 27 unscheduled data collections (transmissions) which are made on a periodic basis. The collections are identified by designators such as:

SA for hourly aviation weather reports
SI for synoptic surface reports, collected four times daily, etc.

These designators would be retained in the proposed systems.

The transmitting stations would be identified by 3-letter CAA location designators, such as DCA = Washington, D.C., LGA = LaGuardia, SFO = San Francisco, etc.

The collection and location designators would be combined to form data program codes which would be recognized by data program selectors located at each station. The data program selector would be common to both the transmitting and receiving sections of each station. The specific devices which would recognize the codes are a series of plug-in devices, each coded to recognize and produce an output for a specific code. These devices are called cards and consist of an "and" gate on a printed wiring board.

When it is time for, let us say the SA collection, the master control station would get on the line and send SA space SA space SA space SA, the date, the time, carriage return, line feed, and a distinctive gate closing signal. This is a nonprinting character which is designated with the nonsense character ▷◁ to avoid confusion. Any transmitting station that had an SA card in its data program selector and also had its tape data selector switch set on SA would cock to transmit. The transmitter operator would set the tape data selector switch to correspond with the type of data he inserts in the tape reader.

All receivers having SA cards in their data program selectors would turn on printers on receipt of SA space. Printers would print

SA SA SA 180231Z (date and time).

The carriage would then return, the line would feed once, and the gate would close on the receipt of ▷◁.

The system would then be ready for the transmission and reception of the SA data collection.

The MC (master control station) would now call up transmitting stations in turn. This would be done as follows:

1. The MC would send SADCA.
2. All receivers with SADCA cards would connect their printers to the line.
3. The DCA (Washington, D. C.) transmitter would cut in and send DCA, its message, carriage return, line feed, and the gate closing signal, ▷◁.
4. All cut-in printers would print DCA and the message, then the carriage would return, the line would feed, and the printer would cut out.
5. When the transmitter sends the gate closing signal it would cut out.
6. When MC sees the gate closing signal it would know that the SA transmission from DCA is completed.
7. MC would send SAXXX (next station

in rotation) and steps 2 through 6 are repeated.

This process would continue until the end of the SA collection. At this point MC would send an end-of-program signal (EP>EP≡≡≡) which all receivers would interpret as a command to shut down the printers.

Table I gives the mode of operation in tabular form.

Detailed Description of the Proposed System

Transmission System

As stated earlier and as shown in Fig. 2 the proposed system would be composed of a backbone route interconnecting hubs with lines branching out to the stations. A typical segment of the proposed system is illustrated in some detail in Fig. 3.

In order to insure more reliable data transmission, the backbone route would consist of two channels, one regular and the other alternate. This is shown in Fig. 4. A level change detector would monitor the channels and automatically switch transmission to the spare in case of trouble, providing the spare were not also in trouble. This switch would only occur on the affected section of the route. Suitable alarms and indications would be provided so that sectionalization for trouble location would be nearly automatic.

The most probable source of noise in a system of this type would be the transmitting loops from the stations. Experience teaches that as few as 100 branch lines or loops can contribute an unacceptable amount of noise. Therefore, since the system might have up to 1,000 transmitting stations, it is clear that noise would present a problem. To limit the effect of noise contributed by transmitting loops, they would all be kept cut off except the one that is actually transmitting data. This would be accomplished by inserting a cut-off circuit in the transmitting leg just before it joins the backbone route.

Data would be transmitted serially on the line by frequency modulation at 1,000 bits per second, which equates to at least 1,000 words per minute. The number of words per minute is governed by the code selected; that is, the number of bits in combination required to form a character and, of course the number of characters in a word. For study purposes, a start-stop 4-out-of-8 code was selected. In this code each character is formed by a unique combination of 8 unit-length pulses, 4 of which are "mark" or "1" pulses and 4 of which are "space" or "0" pulses. Also, for synchronization purposes each character is preceded by a unit-length stop "mark" or "1" pulse. From this it will be seen that each character is composed of 10 unit-length pulses or bits. Also, since there are 5 characters and a space, i.e. 6 characters, per word the following arithmetic obtains:

$$\frac{1{,}000\text{ bits}}{\text{sec}} \times \frac{\text{characters}}{10\text{ bits}} \times \frac{\text{word}}{6\text{ characters}} \times \frac{60\text{ sec}}{\text{min}} = \frac{1{,}000\text{ words}}{\text{min}}$$

Combined Transmitting and Receiving Station

The modulated signals on the line would be detected at receiving stations by a demodulator which converts these signals to serial d-c pulses. This may be seen in Fig. 5.

The d-c pulses are fed into a circuit called a serial-to-parallel converter. This circuit accepts the serial pulses on a single lead and stores them until it has received the correct number corresponding to a character. The converter then spills out the stored bits as simultaneous pulses on the parallel leads, leaving it on the right side as shown in Fig. 5. The converter knows when to do this because the sequence of bits or pulses corresponding to a character is preceded and succeeded by start-and-stop pulses of unit length.

The parallel leads which are hot, i.e., carry pulses, in combination with those which are not hot, i.e., carry pulses, in combination with those which are not hot represent the transmitted character. Later it will be seen that this is the form in which the character was first presented to the system for transmission.

Data Program Selector

The parallel leads feed into the data program selector and station control logic. This circuit examines the leads as they become hot in various combinations for proper sequence of occurrence and uses this information to drive the logic.

For example, let it be assumed that Fig. 5 is the station at Washington, D.C., and that it has been programmed to transmit SA data when called up. When the MC transmits SADCA the parallel leads into the selector become hot in successive combinations which correspond to this, and only this, sequence of characters. The selector recognizes SADCA as a command to transmit SA data and gives information to the control logic, which in turn makes hot a lead corresponding to SA. If the tape data selector switch is

set on SA, the tape reader will start to send providing there is tape in the reader. When tape is in the reader it makes hot a lead which feeds back to the control logic where, combined with the information derived from the SADCA card, a lead is made hot to the modulator. This causes the modulator, before the tape is read, to send a momentary burst of high-level tone to open the transmission path to the backbone route through the transmitting loop cutoff circuit indicated in Fig. 4.

As another example of the Data Program Selector and Station Control Logic functions, consider its operation at a station other than Washington, D.C., when the MC sends SADCA. The selectors of stations interested in receiving SA data from Washington will have been programmed to do so by the insertion and coding of an address card that will give an output on SADCA. This output causes the logic to make hot leads, which in turn cause Gate No. 3 of Fig. 5 to open. As indicated in Fig. 5, when Gate No. 3 opens it extends leads from the Serial-to-Parallel Converter to the printers.

Programming the Address Cards

From the foregoing it is seen that the function of the Data Program Selector and Station Control Logic is to receive signals from the MC and to translate these signals into station operations in accordance with a program of instructions given it by operating personnel.

The basic circuit element in this program is a plug-in device mentioned earlier known as an address card. All address cards are physically the same. Each card has several inputs but only one output, and all inputs must be made hot before the output becomes hot. It will be shown that, by connecting the inputs of the cards in systematic fashion among a group of information-bearing leads, a unique output can be developed for every hot combination of these leads even though all cards are physically the same. Plug-in cards are used so that selector capacities may be readily fitted to station needs.

Consider a typical station. The operating personnel would know what data they wish to receive and what data they would be required to send. They would accordingly program their particular selector to accomplish this by connecting card inputs to leads which will become hot in response to codes received from the MC, and connecting card outputs to functions in the control logic, which in turn cuts in the printer or turns on the transmitter as required.

For example, assume as before that it is desired to receive the SA data from DCA. An input to the card is connected to a lead in the selector which becomes hot only when S is the first character in an address. Another input to the card is connected to a lead which only becomes hot when A is the second character in the address. This process is continued for DCA. As previously stated, a characteristic of the address card is that it will not produce an output unless all input leads have been made hot. Thus this particular card can produce an output only when the selector receives the address SADCA. In like manner, other cards may be coded to give unique outputs in response to other address and control codes.

The programming of the selector then reduces to coding a card for each data selection it is desired to make. It is probable that the greatest part of a program at a given station will remain fixed. Therefore, the most economical equipment arrangement would be to wire in the initial program. To permit nontechnical operating personnel to make changes in the program as desired, a number of cards, say 100, with patchable inputs and outputs, can be provided. With this arrangement momentary changes in the program could be accomplished quickly. A change in the wired program presents no problem except that it requires some technical skill. It would, of course, be possible to make the whole program patchable, but the cost of such an arrangement and the small additional flexibility thereby achieved makes this look unattractive.

High-Speed Page Printer

The Burroughs matrix page printer is recommended for use in this system because it is inexpensive, can operate in a range from 75 words up to 2,000 words per minute, and is closer to the production stage than any other suitable printer. Because the printer can operate at line speeds, the need for buffer storage at receiving stations disappears, which is a considerable advantage.

Tape Data Selector Switch

The purpose of the tape data selector switch shown in Fig. 4 is to permit the station operator to insert, let us say, an SA tape in the reader with the assurance that it will not be transmitted during an unscheduled or some other scheduled transmission. For example, at the Washington, D.C. transmitter this is accomplished by bringing the outputs of the SADCA, SIDCA, etc., cards, which start the reader, through contacts on the switch designated SA, SI, etc. When the operator inserts the SA tape he sets the switch on SA and thus only the output of card SADCA can start the reader.

Master Control Circuit

The function of the MC is to control the operation of the system, that is, to start transmitting stations at required intervals, monitor the data transmissions to discover and correct omissions of necessary control codes in the transmissions, record for maintenance purposes data which will assist personnel in detecting malfunctioning lines or apparatus, interrupt reguar transmission to permit emergency transmissions, etc. The MC is a combined transmitting and receiving station plus the additional equipment shown in Fig. 6.

The MC would be programmed by operating personnel to call automatically for transmission at desired intervals. The actual programming operation is no more than writing a schedule of collections (transmissions) as is done in the present weather system and then preparing a tape to conform with the schedule.

For example, a tape prepared for the SA schedule would be prepared as follows: SA space SA space SA space SA space, carriage return, line feed, gate closing signal, SADCA, SALGA, SA...etc.; ...EP>EP═══ (end-of-program signal). The program tape is then put in a reader which is controlled by a program timer. The tape is advanced and read under control of the timer and logic circuitry and is stopped at appropriate points for transmissions of date and time group signals by the logic.

A program equivalent to the combined schedules of Services A, C, and O can be put in less than 50 feet of punched paper tape. Because the tape will make but one pass a day, it is expected that a high grade of punched tape will give reliable service for more than 10 years. Punched tape also has an advantage in that it may be directly read by operating people while it is in the reader. This will permit them readily to determine the status of the program. Also, changes in the program are readily made by splicing.

Noise and Level Monitor

The purpose of this circuit is to observe continually the quality of transmission on the line. If the quality falls off to an unacceptable extent suitable indications are given to operating personnel.

Program Timer

The program timer controls the operation of the program tape reader. It also supplies date and time group information to the signal generator.

Signal Generator

This circuit generates date, time group, carriage return, line feed, and gate closing signals when required to do so.

Match Circuit

The purpose of this circuit is to check that called up transmitting stations put their data on the line. It does this by reading and storing the called address (DCA for example) from the tape reader and matching this against the address which the called station transmits. This latter address is read from the input to the data program selector. Failures to match cause appropriate trouble records to be made.

Timer Circuit

The timer circuit times certain operations and causes appropriate signals to be sent as required. For example, if a code match is not made in a specified time, this circuit causes the signal generator to send carriage return, line feed, and gate closing codes. Also, if the data program selector fails to receive carriage return, line feed, and gate closing codes at the end of transmission from a called-up station the timer waits a specified time and again causes the signal generator to send the required codes. This circuit also performs other timing functions which the system requires.

Alarm and Trouble Recorder

This circuit gives visual and audible alarms to assist operating personnel in checking and maintaining the system. It also includes an automatic trouble recording which will provide a permanent record to give personnel a statistical tool for locating intermittent malfunctioning system components.

LATE DISCUSSION

Discussion of "The Design of the Corner-Reflector Antenna," by H. P. Neff, Jr, and J. D. Tillman, published in Communication and Electronics, July 1959, pages 293–95.

James R. Wait (National Bureau of Standards, Boulder, Colo.): In discussing the ideal corner reflector consisting of two conducting planes which intersect along some apex, the authors state that "the only situation which is amenable to mathematical analysis is that in which the conducting planes are infinite in extent, and in which the angle between the planes is π/n, with n being any positive integer." I wish to draw attention to the fact that a general analysis is available which is valid for any corner reflector angle.[1,2] In fact, it is a series of precisely the same form as their equation 4. When the angle is specialized to π/n, it may be converted to a series of images.

The Use of D-C Overpotential Testing as a Maintenance Tool in the Industrial Plant

W. A. WEDDENDORF
MEMBER AIEE

ELECTRIC apparatus represents a large portion of the equipment required for productive activities in the industrial plant: generators to produce power; cables, transformers, and switchgear for transmission and distribution; and motors for transforming electric energy into mechanical power. Insulation, the critical part of electric apparatus, has a limited service life, a variable depending upon the deteriorating and contaminating factors associated with the operation of the equipment. Production interruptions and unnecessary damage from insulation failures represent an economic waste in industry. Needless replacement of insulation, primarily on the basis of age and visual inspection, without substantiating data of its being in questionable condition, further adds to economic waste. As an obvious deduction, there is a definite need for a test which will reliably evaluate the condition of insulation for continued service.

Considerations

An ideal maintenance test would express a definite difference between good, doubtful, and unsatisfactory insulation without reducing the over-all service life or having destructive effect on questionable insulation. To further complicate these utopian requirements the test should be simple to conduct and evaluate and should be one which could be performed by maintenance personnel. The test equipment should be small and ruggedly built so as to be portable and relatively inexpensive. At present there is no known single test method which can fulfill these idealistic requirements.

D-c overpotential testing seems to offer a promising start towards this goal in that the test is simple to conduct, and in recent years considerable experience has been gained in its use better to evaluate insulation. In sensing the demand for d-c test equipment, instrument manufacturers have marketed equipment with improved portability and greater ease of operation. While it is not the author's intention to present d-c overpotential testing as the answer to the insulation testing problem, there is no doubt but that its use would improve the effectiveness of most preventive maintenance programs.

D-C Overpotential Testing

The use of d-c for acceptance testing of new cable installations and subsequent periodic maintenance proof testing has been favorably received by industry. The a-c to d-c conversion factors, representing the differences in the searching qualities between an a-c and a d-c potential, have been established for the various cable insulating materials. Also, there is no question as to what percentage of factory test voltage should be applied for acceptance and proof test values. The duration of the test has, likewise, been established. These details, as related to suggested field testing, are practically spelled out in the general specifications of the IPCEA (Insulated Power Cable Engineers Association) and The Association of Edison Illuminating Companies. Within the proposed test values there should be no fear of detrimental effect on cable insulation.

In reference to the use of d-c overpotential methods in testing the winding insulation of rotating electric equipment, these details are not nicely tied together in a common package. The figures generally used to develop the periodic maintenance proof test value are an a-c to d-c conversion factor of 1.6 and an age factor of 0.65 applied to the a-c factory test of twice-rated voltage plus 1,000. Some engineers have found the 1.6 factor to be too low to develop equal searching qualities with d-c for certain types of insulations, suggesting a conversion factor of 1.8.[1] Others feel that their work in the laboratory has developed data to show that application of a d-c potential, such as used in the voltage-step method, may be detrimental to insulation.[2] With full appreciation of the concern from some quarters towards the general use of d-c overpotential testing, the author, nevertheless, is firmly convinced from a practical point of view that it has a definite application in the maintenance programs of industrial plants. In reality, the gain realized from its expanded use in industry demonstrates that d-c overpotential testing is here to stay, at least until replaced with something better. All engineers should investigate what d-c testing has to offer and make use of this new tool in improving the effectiveness of his maintenance operations.

Much has been written in recent years on the subject of insulation testing by d-c methods.[3] The referenced technical publication offers a complete bibliography and general coverage of insulation testing by d-c methods. It should be of interest in knowing there are groups within the Insulation Subcommittee of Rotating Machinery working on: 1. high-voltage d-c for maintenance testing, and 2. high-voltage d-c as an acceptance test. As a result of this work the AIEE may be in a position in the near future to recommend a uniform procedure for conducting d-c testing of rotating electric equipment. In the meantime, those interested in using this form of testing must establish their methods on the basis of experience, manufacturers' recommendations, and the work of others in this field.

Unfortunately, there have been limited data published on d-c testing relating to the type of equipment found in the industrial plant. The majority of the technical papers have been in connection with the larger high-voltage apparatus in the utility class. Obviously, the smaller equipment is equally as important to the operation of the industrial plant as the larger units are to the utility. Possibly, this brief résumé of the author's experience in this field will stimulate the interest of others in developing a better understanding of its application as well as to its limitations.

Testing of Primary Distribution Cable Circuits

Cable manufacturers high-voltage test all cable before it leaves the factory for assurance of quality construction. It would then be reasonable to assume that cable failures within a few years after installation are primarily due to: 1. damage

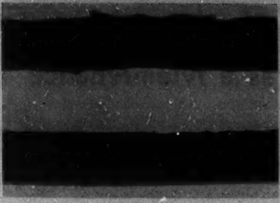

Fig. 1. Insulation failure of 5-kv rubber-insulated cable from sheath currents

in shipment or installation, 2. faulty installation, or 3. improper application. The plant engineer's first line of defense in assuring reliability of operation would be that of conducting a d-c acceptance test immediately after the cable is installed at 80% of the a-c factory test, using the proper a-c to d-c conversion factor for the particular type of insulation. At periodic intervals during the life of any vital cable circuit it could be maintenance proof tested at 60% of factory test for assurance of continued reliability of operation.

Table I gives suggested acceptance and proof test values of the common size and voltage ratings of ozone-resistant rubber-insulated cable used in industry. It should be of interest to know that a 600-volt 525–1,000-MCM (thousand circular mils) rubber-insulated ozone-resistant cable is factory tested at 10 kv a-c. This means that an acceptance test of 24 kv d-c for a period of 10 minutes could be applied immediately after installation. This proof test value is derived by using the 80% field test factor and an a-c to d-c factor of 3.0 for ozone-resistant rubber. Too frequently an important 600-volt cable circuit is placed in service after applying a 500-volt insulation resistance test. Obviously, the 500-volt test will not detect abnormalities which could cause service failures at a later date.

Many distribution circuits in industrial plants are of the 5-kv insulation class. In the conductor size 225–1,000 MCM, the recommended acceptance test would be 37 kv d-c. Along the same lines, the suggested periodic proof test would be 28 kv d-c. Again, the conventional 500- or 1,000-volt insulation resistance test would be far from adequate in assuring reliability of operation. Most cable manufacturers encourage acceptance testing before energizing a new cable installation in assuring reliable installation of a quality product.

Table II. Periodic Proof Testing of Cables

Related Circuit Voltage	Recommended D-C Test Voltage
0–1,000 volts	
#8 up to 500 MCM	10 kv
Over 500 MCM	15 kv
3,000 volts	20 kv
5,000 volts	25 kv
8,000 volts	35 kv
15,000 volts	50 kv

Frequently, the exact construction of the cable in an existing installation is not known, in which case the recommended d-c proof test value is based on the rated circuit voltage. Table II gives the suggested proof test on basis of circuit voltage.

Cable Failure From Improper Application

The 5-kv rubber-insulated cable of Fig. 1 failed from sheath currents due to an improper application for this nonshielded cable. The plant distribution system was comprised of several underground circuits operating at 4.16 kv. The same type of cable was used throughout and had been in service 5 years. A d-c proof test at 28 kv was suggested as a means of determining if other circuits were developing weakened areas from sheath currents. The employees were reluctant to use the suggested test value, so they elected to try a 10-kv test. The leakage current-time curve on the first circuit tested at 10 kv reflected a drooping characteristic shape, typical of good insulation, as shown in lower curve of Fig. 2. On retesting at 15 kv, the leakage current increased with time of voltage application, causing the test to be stopped after 4$^3/_4$ minutes for fear of a breakdown in insulation. This characteristic is shown in upper curve of Fig. 2.

Testing of other circuits reflected unsatisfactory conditions leading to a decision to replace all cable with that more suitable for the application. After pulling the single conductor cable from the ducts, areas of damage from sheath currents were found to verify the interpretation of the test data. Obviously, insulation resistance testing below 10 kv would have given false assurance of reliability of operation.

Proof Testing of Cable Circuits

In another plant the 4.16-kv distribution system was comprised of 13 underground circuits of 3-conductor 5-kv vcl (varnished-cambric lead-covered) cable in sizes ranging from 250 to 600 MCM. A metal-clad switchgear installation was made in 1951, about 500 feet from the old distribution center. The original circuits which had been in service for many years, were spliced and extended with new cable. A recent cable failure gave reason to question the reliability of the distribution system. This apprehension led to a recommendation to d-c proof test all primary circuits, conductor to ground at 16 kv.

The cable had conductor and belt insulation thickness of 0.109 inch and

B—Phase C leakage current-voltage characteristics
C—Phases A and B

0.063 inch, respectively, dictating a factory test between conductors at 23 kv a-c and between conductors and sheath at 58% of this value (13.3 kv), in accordance with the IPCEA specifications. The 16-kv d-c proof test conductor to ground was developed by applying the 60% service factor and a 2.0 conversion factor (for varnish-cambric insulation) to the 13.3-kv factory a-c test. Of the 13 circuits tested, five were shown as being unreliable, two in questionable condition, and six as satisfactory for continued operation.

Fig. 3 shows a plot of the leakage current characteristics for one of the circuits termed as being unreliable. The test was stopped at 10 kv on *C* phase and discontinued at 12 kv on phases *A* and *B*, because of the high leakage current of 1,000 microamperes. The steep slope of the curves was an indication that the test voltage could be approaching the breakdown value of the insulation. There was, however, no immediate apprehension of an unintentional breakdown of insulation as far as the test was carried, since the leakage current did reflect a slight drooping characteristic with time of voltage application. Through the use of d-c overpotential proof testing the insulating structure of the primary distribution circuits was evaluated in a nondestructive manner. All 13 circuits were returned to service with a suggestion that the cause for the unsatisfactory test results be investigated and corrected at the first convenient opportunity. The cause could be developing within the insulating structure. Operating conditions did not permit breaking down the weakened areas, thereby developing the cause of the high leakage current at the time.

Many examples could be cited from the author's experiences to show where d-c acceptance and proof testing of cable circuits was instrumental in preventing production interruptions associated with cable failures. Acceptance testing at the suggested values will most definitely ferret out weak insulating structures at splices and terminations which, if not detected, could lead to trouble. A particular mill was experiencing one or more cable failures a year on their 2,400-volt underground distribution feeders. The system was d-c tested at 23 kv (proof test for 3-kv ozone-resistant rubber insulation), breaking down the weakened areas which were found to be in the splices and terminations.

The point of emphasis is that these potential accident sources were corrected at a convenient time without incurring loss of production and at negligible cost. The expense involved was the cost of testing, the electrician's time, and materials required to remake many splices and terminations. The process in this mill was the manufacture of synthetic fibers where continuous power is very critical to plant operations. This testing was accomplished about 3 years ago, and it is encouraging to note that there has not been one case of cable trouble since that time. Others have found high-voltage d-c testing to be of considerable value for acceptance testing of new cables and routine proof testing of existing installations.[4]

Breakdown Test on Generator Winding

In the initial stage of extending d-c overpotential testing to insulation of rotating electric equipment, the writer conducted a breakdown test on a vertical 1,500-kw 2,400-volt 240-rpm water turboalternator. The 18-year old-class *A* insulated stator winding was to be replaced as preventive maintenance. One coil which recently failed at the edge of the slot from mechanical abrasion due to a loose lamination had been cut out of the electrical circuit.

The first step of the test was that of opening the Y connection and proof testing each phase independently at 6 kv with the other two phases grounded. The 6-kv maintenance proof test was developed by applying a 65% age factor and a 1.6 a-c to d-c conversion factor to the factory test value of twice rated voltage plus 1,000. Each phase developed very similar leakage current-voltage values which were linear throughout the 6-kv test range. A plot of these values is shown in the lower curve of Fig. 4.

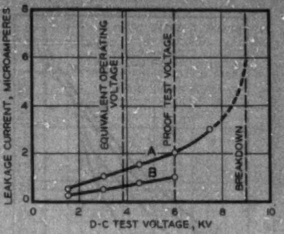

Fig. 4. D-c overpotential breakdown test on stator winding of 1,500-kw 2,400-volt 240-rpm vertical water turbogenerator

A—Breakdown test of complete winding
B—Proof test of each phase independently

The connection was made and the complete winding was tested to breakdown. The insulation of phase 2 broke down after reaching the 9-kv voltage step, in the area adjacent to where the one coil had previously been cut out. These test values are plotted in the upper curve of Fig. 4. The curve was linear through the 6-kv test but reflected a pronounced rise at 7.5 kv. It is evident from examining the curve that the test could have been stopped at 7.5 kv and the 9.0-kv breakdown predicted by extending the curve. This would probably have been more pronounced if smaller incremental voltage steps were used.

Phase 2 was isolated and the remaining two phases tested to breakdown in 1,500-volt incremental steps. Breakdown occurred in phases 1 and 3 on increasing the voltage to 15 kv. The steady state of leakage current were plotted as they were in Fig. 4, and again it appeared that the test could have been stopped at 13.5 kv and the 15-kv breakdown predicted by extending the curve. Probably, if the coils in the weak area of phase 2 could have been replaced without damage to other insulation, the winding would have had several more years of reliable useful life.

It would be well to note: 1. the linear characteristic of the leakage current in both curves of Fig. 4 through the 6-kv step, and 2. the high breakdown value in the unweakened phases, 1 and 2, of better than two times the suggested proof test value. It would seem, from a prac-

D—Retesting of phase C

tical point of view, that the 6-kv periodic maintenance test would not be detrimental to this class *A* insulation structure designed for 2,400-volt operation.

Proof Test on Generator Winding

The stator winding of a 3,500-kva 2,300-volt 150-rpm water turboalternator experienced six coil failures from various causes during a 9-year period following rewinding. D-c proof testing was suggested as a means of evaluating the condition of the insulation for continued operation.

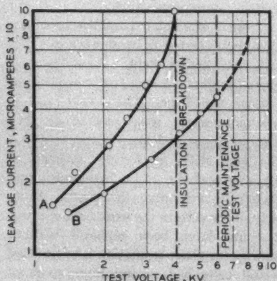

Fig. 6. Periodic d-c overpotential testing of overaged stator winding insulation on large 2,400-volt synchronous motors

A—1,050-hp 2,200-volt 600-rpm synchronous motor
B—2,100-hp 2,300-volt 514-rpm synchronous motor

The Y connection was opened and each phase was d-c tested independently by the voltage-step method in increments of 500 volts. The leakage current-voltage test values are plotted in Fig. 5. Phase *A* broke down without warning at 4 kv. The leakage current at 3.5 kv was 440 microamperes, showing an insulation resistance of about 8 megohms.

Phase *B* withstood 5 kv, the value agreed upon prior to conducting the test as being adequate to detect any defect which might cause an early insulation failure. The hydroelectric station, consisting of five similar machines, operates with a grounded neutral, limiting voltage above ground to about 1.3 kv. The 5-kv proof test value was considered to have adequate searching qualities for this application.

Phase *C* broke down without warning at 2.5 kv. The insulation failures in both *A* and *C* phases occurred at the edge of the coil slot. The coils which broke down were replaced. On retesting, phase *C* broke down at 3.0 kv, which could have been predicted if the test had been discontinued at 2.5 kv and the leakage current retest curve of Fig. 5 extended. The bad coil was replaced, and before the machine was returned to service, all three phase windings had withstood the 5-kv d-c breakdown test. The stator windings of the four other similar machines satisfactorily withstood the 5-kv d-c voltage-step test without incident.

The generator has now been in operation for more than a year since the weak coils detected by d-c testing were replaced. The machine has operated without incident during this period which is somewhat of a record, over previous years of operation. The present plans are to retest all five machines periodically. The testing is to be accomplished during periods of low water so that any weak coils which may break down can be replaced with no loss of power generation.

Evaluation of Motor Winding Insulation

The reliability of two large, slow-speed synchronous motors was questioned, primarily due to the age of the insulation, which was in excess of 25 years. One motor was rated 1,050 hp (horsepower) 2,200 volts, 600 rpm, and the other, 2,100 hp, 2,200 volts, 514 rpm. Both windings were of class *A* insulation. The stator winding construction of these two machines was very similar to that of the water turboalternators in the two previous cases; hence, this might be considered a comparable application for the use of d-c testing. A plot of the test data for these two motors is shown in Fig. 6.

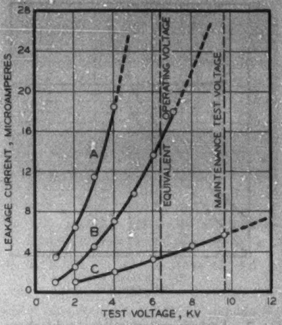

Fig. 7. Plot on cross-sectional paper of periodic d-c overpotential testing of 34-year-old insulation of 7,500-kw 4,000-volt 1,500-rpm turbogenerator

A—Test of April 1957
B—Test of January 1958
C—Test of April 1956

The stator winding insulation of the 2,100-hp motor withstood the 6-kv test. The final steady-state leakage current of 45 microamperes gave an insulation resistance of 130 megohms. The good insulation resistance value, plus the fact that the slope of the leakage current-voltage curve was not excessive, indicate reasonably good insulation. This motor can be continued in operation; however, d-c proof testing on an annual basis to develop trend in the insulation was suggested for greater assurance of safe continuous operation.

The stator winding insulation of the 1,050-hp motor failed at 4 kv. The tests on these two motors were conducted by an engineer from the local service shop. The data were furnished to the author for study and comment. It would appear the test on the 1,050-hp motor could have been stopped at 3.5 kv and the 4-kv breakdown predicted by extending the leakage current curve. The steepness of curve is forecasting warning of an imminent failure of weak insulation. In this manner the stator winding could have been evaluated by d-c testing as being unsafe for continued operation without damage to the insulation. The test was conducted at an opportune time and, although the insulation broke down, the motor was rewound with no loss of production.

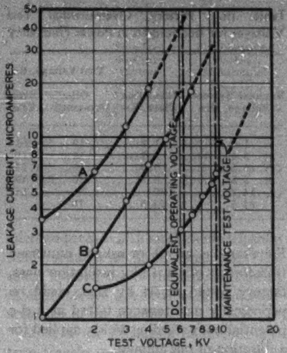

Fig. 8. Plot on log-log paper of periodic d-c overpotential testing on 33-year-old insulation of stator winding of 7,500-kw 4,000-volt 1,500 rpm turbogenerator

A—Test of April 1957
B—Test of January 1958
C—Test of April 1956

Method of Plotting Is Important to Interpretation

A 25-cycle 7,500-kw 4,000-volt 1,500-rpm turboalternator was to be retired from service in 3 years. Plant personnel were apprehensive of reliability of operation in extending the service of 33-year-old insulation. A d-c overpotential test was suggested as a means of evaluating its condition. The machine was taken out of service the night before so as to allow the winding to cool to room temperature. The generator was Y connected with two windings in parallel per phase. The six windings were isolated and each tested independently, recording and plotting the steady-state leakage current for each voltage step. The respective readings were found uniform in value indicating the insulation as being in similar condition throughout the machine. A set of current readings for one winding is plotted in lower curve of Fig. 7, identified as test of April 1956. When plotted on cross-sectional paper the curve was almost linear with moderate slope, an indication of reasonably good insulation. On completion of testing the winding was reconnected and the machine returned to service. An outage of 24 hours without inconvenience to production, plus the small cost of conducting the test, developed assurance of reliable insulation.

The machine had been out of service for several months due to mechanical trouble immediately prior to the subsequent test one year later in April 1957. It was anticipated that the leakage current readings might be higher because of moisture absorption. The values were found in excess of those anticipated, developing an extremely steep curve as shown in Fig. 7, identified as test of April 1957. The test was only carried to 4 kv on each winding for fear of breaking down the insulation. In preparing the report, the data for the April 1956 and April 1957 tests were plotted on log-log paper, as shown in Fig. 8. The shape of the April 1957 curve on log-log co-ordinates materially changes the interpretation. It is evident that the test could have been carried well beyond 4 kv without fear of breakdown. The two vertically separated parallel curves reflect a definite indication of similar quality of insulation, the displacement caused by increased leakage current due to moisture absorption.

An opportunity developed to retest the machine 9 months later, in January 1958. While the machine had not operated appreciably since April 1957, the general atmospheric conditions were less humid; hence, it was expected that the windings would contain less moisture. This observation was correct, as is apparent from the position of the curve in Figs. 7 and 8, identified as test of January 1958.

The author prefers to plot leakage current-voltage curves on log-log paper which tends to present the same relative dimensions of co-ordinates, which aids in the interpretation of slope. Experience would indicate that a rapid increase in leakage current with an increase in voltage in the first part of a test of dry insulation is an indication of deterioration. This is shown in test of April 1956 in Fig. 8 but not apparent in Fig. 7. It is obvious that the method of plotting the test data plays an important function in evaluating the results.

Should the Generator Be Rewound?

The operation of large rotating electrical equipment is normally vital to the production requirements in the industrial plant. Casualty insurance companies have learned from experience that overage insulation in this class of equipment presents an abnormal risk because of the high probability of failure, incurring costly damage to the object in addition to a large production interruption. While everyone recognizes that insulation has a limited service life, age alone should not govern when it should be replaced. In recent years, data from d-c overpotential testing have helped to resolve a difference of opinion between assured and insurer. This is one method of developing tangible data to show the insulation as being reliable for continued service or unsatisfactory to justify the investment of rewinding.

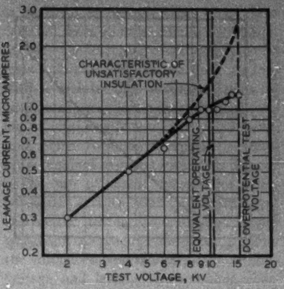

Fig. 9. D-c overpotential testing of 30-year-old stator winding insulation of 5,000-kw 6,600-volt 3,600-rpm turbogenerator

A question developed as to the need of replacing the 33-year-old stator winding of a 5,000-kw 6,600-volt 3,600-rpm turboalternator. The insurance company agreed to defer a recommendation for rewinding if data from a d-c overpotential test indicated the insulation to be in reliable operating condition. It was agreed that the manufacturer's recommended suitability for service d-c test voltage of $2.0E$ plus 800 would be used, developing a test value of 14 kv.[6]

The neutral connection was opened and all three phases were tested independently of each other. The respective voltage-step leakage currents for each phase were uniform in value and very small in magnitude. The recorded leakage current at 14 kv was only 1.2 microamperes, indicating an insulation resistance of 11,500 megohms. A plot of the test values for one phase is shown in Fig. 9. An interesting aspect is that the curve developed a drooping characteristic in approaching the maximum test voltage. Evidently, the small current being measured was not true leakage current but, instead, contained an appreciable absorption component. The explanation is that the absorption component must have been decreasing in magnitude faster than the leakage current was increasing to develop the drooping effect. The situation was aided by a voltage regulation problem inherent to the test set when dealing with small current values. Obviously, the recommendation for rewinding was deferred pending retesting at a later date, preferably on an annual basis.

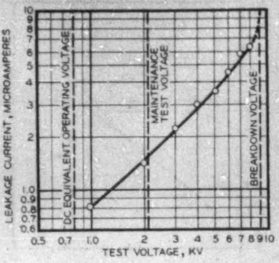

Fig. 10. D-c overpotential breakdown test of 28-year old stator winding insulation of 5,400-kw 480-volt 3,600-rpm turbogenerator

Breakdown Test on 480-Volt Alternator Winding

Permission was obtained to conduct a d-c breakdown test on 28-year old stator winding insulation of a 5,400-kw 480-volt 3,600-rpm turboalternator, which was to be replaced in changing the voltage rating. This was predicted on completing the test in a few hours so as not to interfere with rewinding operations, which placed limitations on what could be accomplished. The connections were opened to facilitate testing each winding independently; however, time was not taken to remove the current transformers from the circuit.

The test voltage was increased in incremental steps of 333 volts until breakdown, which occurred in *A*, *B*, and *C* phases at 13.6 kv, 9 kv, and 11 kv, respectively. Unfortunately, all three insulation breakdowns occurred within the current transformers. While the breakdown strength was not determined, each phase winding comprised of 28-year-old insulation satisfactorily withstood a d-c breakdown test of 9 kv, more than four times the suggested d-c periodic proof test of 2,100 volts. From a practical point of view, these data strengthen the author's conviction that there should be no fear of damage to insulation in reasonably good condition, within the suggested proof test range. The leakage current data developed from the test of *B* phase is shown plotted in the curve of Fig. 10. The curves for phases *A* and *C* were not shown since they would have coincided with *B* phase up to the 8-kv voltage step. A sharp upturn was not present in the leakage current curves to forewarn of an insulation breakdown within the current transformers.

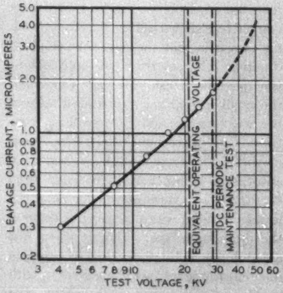

Fig. 11. Periodic overpotential testing of 7-year-old stator winding insulation of 15,000-kw 13.8-kv hydrogen-cooled turbogenerator

Use of D-C Testing in Following Trend of Insulation

The industrial plants have expanded their power generating facilities in keeping pace with increased power requirements to the point where it is not uncommon to find larger hydrogen-cooled generators being utilized. Many of the engineers in these modern plants are using d-c overpotential testing in connection with periodic dismantled inspections to follow the trend of the insulation with years of service. The data plotted in Fig. 11 were developed from testing a 15,000-kw 13.8-kv hydrogen-cooled generator after 7 years of operation. The test of 28.5 kv in accordance with the manufacturer's recommendation, was approached in incremental voltage steps of 4 kv. The leakage current of 1.7 microamperes at 28.5 kv shows an insulation resistance of 16,000 megohms on each winding, phase to phase and phase to ground. This high insulation resistance plus the general shape of the curve indicates very good insulation.

D-C Overpotential Testing Is Applicable to Transformers

Reference 6 suggests maximum values for periodic dielectric tests in the field using both a-c and d-c potentials. The a-c acceptance and periodic proof test values are respectively 75 and 65% of the factory test. For sake of discussion, an abbreviated listing of factory test voltages is shown in Table III.

Both American and National Electrical Manufacturers Association Standards state that "transformers may be subjected to periodic insulation tests using direct voltage from kenotron sets. In such cases, the direct voltage should not exceed the factory test rms alternating voltage."

Table III. Factory Overpotential Test Voltages for Transformers at Power Frequency

Nominal System Voltage, Kv	Insulation Class, Kv	Test Voltage, Kv Oil-Immersed	Test Voltage, Kv Dry-Type
1.2	1.2	10	4
2.4	2.5	15	10
4.8	5.0	19	12
8.32	8.7	26	19
14.4	15	34	31
34.5	34.5	70	

For example, an oil- or askarel-immersed transformer of the 15-kv insulation class, factory tested at 34 kv rms, could be periodically maintenance tested at a d-c potential not exceeding 34 kv, applied for a duration of one minute.

If the d-c test is to be applied to the transformer for a duration of 5 minutes, the value should not be more than 90% of the factory rms test value. In the case of the 34-kv test, the 5 minute duration of the d-c test would be 30.6 kv. The standards recommend that periodic direct-current overvoltage tests should not be applied to transformers of higher than 34.5-kv voltage rating, factory tested at 70 kv.

The plot of Fig. 12 was developed from a d-c test on primary windings of a 3,333-kva 3-phase 13,800/600-volt power distribution transformer. The final test voltage of 30.6 kv was held for a 5-minute duration to check the absorption characteristic.

The transformer had been in service 5 years. The test was requested by a prospective purchaser of the second hand transformer. The leakage current of 3.5

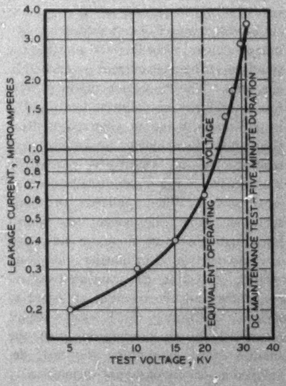

Fig. 12. D-c overpotential test on primary winding of 3,333-kva 3-phase 13.800 Y/600-volt askarel-immersed transformer

Table IV. Test Voltages of Switchgear

Rated Voltage of Switchgear	Standard 60-Cycle Factory Dielectric Test (Kv) (ASA—C37.20)	Suggested Periodic Maintenance Test (Kv)	
		A-C	D-C
2,400	15	11	16
4,160	19	14	20
7,200	26	19.5	27.5
13,800	36	27	38

microamperes at 30.5 kv showed an insulation resistance of 8,700 megohms. The sharp upward rise in the leakage current at about 20 kv was attributed to a characteristic of the askarel.

Most of the insulation failures of dry-type transformers are due to high-resistance carbonized paths caused by leakage currents from foreign deposits. Many plant engineers evidently do not realize that a dry-type transformer cannot be installed and forgotten. They must be cleaned at periodic intervals if a satisfactory life expectancy is to be obtained. The use of d-c overpotential testing, in conjunction with a cleaning and inspection program, will ferret out unsatisfactory insulation. In accordance with the standards, a 15-kv insulation-class dry-type transformer could be periodically d-c tested at 31 kv for one minute, or 27.9 kv for 5 minutes.

Maintenance Testing of Switchgear

Insulation resistance testing of the breakers and bus is generally made during periodic maintenance inspections with a direct reading instrument at 500, 1,000, or 2,500 volts, depending on the practice followed at the particular plant. The readings are generally recorded for comparison, since the trend is more important than a single reading. Insulation testing below operating voltage will primarily reveal the presence of conductive deposits and moisture as opposed deterioration or the developing of a detrimental condition leading to an impending failure. Testing at or above operating voltage has a better chance of detecting a harmful insulation condition which could lead to an insulation failure.

Dielectric tests of switchgear assemblies are made at the factory in accordance with voltages suggested in reference 7. The standard further states dielectric tests may be made at 75% of the standard insulation test values to determine the practicability of continuing equipment in service. This is a low-frequency voltage test for a duration of one minute. Usually it is more convenient to conduct the test with a d-c potential, in which case the general practice is to use a test voltage corresponding to the peak value of the a-c test voltage.

The standards for certain apparatus such as potential transformers may call for a lower test voltage than that suggested. If so, they may be disconnected during test.

Summary

Experience has shown overpotential testing of insulation to be one of the best known methods of verifying that it is in good condition for continued operation.[8] Some engineers suggest this test be made with an a-c potential, since the insulation is stressed with an alternating potential in service, the reason being that there does not seem to be a definite correlation between the searching qualities of the two tests. The author has no fault to find with a maintenance program which incorporates periodic a-c overpotential testing of vital equipment, the point being that some form of overpotential testing is required to detect insulation defects.

The use of direct current for overpotential testing offers definite nondestructive testing advantages. In approaching the predetermined test level by the voltage-step method, leakage current-voltage and leakage current-time characteristics are developed. These data can be interpreted, except in certain circumstances, as indicative of an impending insulation failure or give assurance to proceed with the testing. On completion of the test, much data will have been developed from which an experienced engineer can evaluate the immediate condition of the insulation and follow the trend from subsequent periodic testing.

In offering Accident Prevention Engineering Service to industry, the Mutual Boiler and Machinery Insurance Company has been actively engaged during the past 5 years in using d-c overpotential testing to evaluate the condition of insulation in vital electric equipment. The test projects discussed in this paper were taken from their files and are representative of a general cross section of the work. The early stage of the program was promoted at a time when in the author's opinion the possibility and the effect of an unintentional insulation failure under test was overemphasized as a detrimental factor. In the few instances of unintentional

Fig. 13. Stator winding damage form an insulation failure within a 1,000-kw vertical water turbogenerator

Fig. 14. Stator winding damage from an insulation failure within a 10,000-kw 13.8-kv turbogenerator

breakdowns, the failure usually occurred in the early stage of voltage build up, indicating that the insulation was on the rugged edge of failing in service. Most plant engineers have reconciled their thinking to conclude that it is a definite advantage to have an insulation breakdown at an opportune time under test than to experience a failure in service.

Fig. 13 exhibits severe damage to a 1,000-kw water turbogenerator from an insulation failure in service. The resultant electrical arcing not only made it necessary to replace the stator winding but, in addition, the core structure had to be dismantled and restacked to replace the burned laminations. As is frequently the case, the accident occurred during a period of ample water conditions when the power requirement was critical to production. The damage from electrical arcing, associated with an insulation failure in service, greatly extended the outage time.

The stator winding of the 10,000-kw 13.8-kv turbogenerator of Fig. 14 failed in service from an insulation breakdown, after many years of reliable operation. The power shortage from the outage of this generating unit curtailed plant operations. Repairs were expedited on around-the-clock 7-days-per-week operation in holding the production loss to a minimum. Periodic d-c overpotential testing will materially aid in preventing the type of costly accidents shown in Figs. 1, 13, and 14. Frequently d-c testing will reveal the need of maintenance which, if not corrected, may lead to an insulation failure.

Year by year, plant engineers are becoming more maintenance minded. Realizing that accidents are too costly to afford, they are in constant search for new means of accident prevention. The interest in all phases of plant maintenance is being focused on methods of nondestructive testing. D-c overpotential testing seems to offer the industrial plant's maintenance program a method for approaching a nondestructive evaluation of insulation. In the author's practical experience there has been no evidence to reflect damage to otherwise good insulation as the result of having been subjected to d-c proof testing, nor has there been any case where insulation has failed in service after testing to indicate the d-c voltage did not search out impending defects.

Design of Polyethylene-Insulated Multipair Telephone Cable

A. S. WINDELER
NONMEMBER AIEE

CABLES are designed to have special characteristics which will make them suitable for particular uses or purposes. In the case of telephone cable the purpose is primarily to transmit information at voice and carrier frequency during an expected life of approximately 30 years. To achieve this, certain mechanical and electrical characteristics must be built into the cable. Mechanical characteristics include such characteristics as resistance to environmental factors including heat, cold, wind, lightning, moisture, sunlight, and oxygen, as well as resistance to damage by rodents and insects, and by workmen. Other desirable mechanical characteristics involve factors of convenience of manufacture, installation, and joining.

The electrical characteristics include such factors as adequate dielectric strength and freedom from crosstalk and, of course, the all-important transmission properties. It is the purpose here to consider only the design of cable to obtain the desired transmission properties. In the case of multipair cable this reduces to adjusting the dimensions of the conductors and the insulation, so as to obtain the desired resistance, inductance, capacitance, and conductance of the cable pairs. From these four primary constants, the secondary parameters of nonloaded circuits, namely, the propagation constant and characteristic impedance, can be calculated. Moreover, with the primary constant data and the loading coil resistance, inductance, and spacing, the secondary constants of loaded circuits may be obtained.

Cost is, of course, one of the fundamental considerations of any cable design. This involves an evaluation of such factors as availability and cost of the material selected, reliability of supply and probably price trend, serviceability as compared with existing materials, etc. These considerations lie beyond the scope of the present article, which deals specifically with problems of design to obtain the desired electrical characteristics. The problem is then to determine the dimensions which will give the desired primary constants; this means determining the the way in which the primary constants vary as the dimensions are changed.

It is our purpose here to consider only the design of solid polyethylene-insulated multipair cable and to discuss only the voice frequency primary constants.

At voice frequencies the main interest here is in the capacitance and resistance of the pairs; this is because the secondary parameters of nonloaded circuits are dependent only on these constants and the frequency of transmission. In the case of loaded circuits the inductance of the cable pairs plays only a small part in

Paper 59-793, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21–26, 1959. Manuscript submitted April 6, 1959; made available for printing May 28, 1959.

A. S. Windeler is with the Bell Telephone Laboratories, Inc., Murray Hill, N. J.

The author is indebted to F. W. Horn for helpful discussions, to L. M. Rackson, E. O. Bauer, and E. Schultz for the electrical testing of cable samples, and to Mrs. B. M. Felderman for numerous computations.

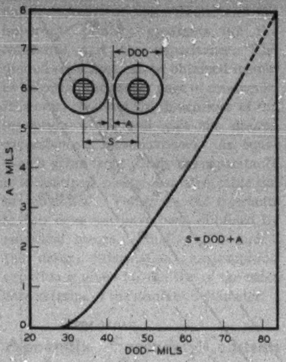

Fig. 1. **Interaxial spacing as a function of diameter over the dielectric**

determining the secondary constants. The effect is quite limited because the inductance of the loading coils far outweighs that of the cable pairs. With polyethylene-insulated cable, conductance has negligible effect in either case. This is true because of the remarkably low power factor of polyethylene. For convenient reference the equations[1] which express the secondary constants in terms of the primary constants are given in the Appendix.

Consider now the problem of determining the voice frequency resistance, inductance, and capacitance from the dimensions of the conductors, and the insulation. For this purpose a representative voice frequency will be taken as 1,000 cycles per second.

At this frequency, for the gages of interest, namely 19, 22, 24, 26 American Wire Gage, the a-c resistance of a cable pair is equal to the d-c loop resistance. For copper wires at 68 degrees Fahrenheit this becomes

$$R=\frac{0.1095}{d^2} \tag{1}$$

where

R = resistance, ohms per mile
d = conductor diameter, inches

Such simplicity is possible only because the skin effect, and certain proximity effects, so important at carrier frequencies, are negligible at voice frequencies for the wire sizes being considered.

For the same reason the equation for the inductance of cable pairs at voice frequencies is very simple, being the same as that of a pair of wires in free space,[2] namely

$$L=1.482\log_{10}\frac{2S}{d}+0.1609 \tag{2}$$

where

L = inductance, millihenrys per mile
S = interaxial spacing of wires
d = diameter of wires

The last term is the so-called internal inductance of the two conductors, which is a constant (0.1609 millihenry per mile) for all sizes.

One question which arises immediately is how to control the interaxial separation S, of the wires of a pair. Fortunately, S is dependent primarily on the diameter over the dielectric, generally referred to as the DOD. This dimension can be contolled quite precisely during the extrusion of the insulation over the conductor. For small values of DOD, normally associated with the finer gages, the value of S is exactly the same as the DOD. This simply means that the insulated conductors fit closely together with no space between them. For larger DOD values, normally associated with the heavier gages, there will be a small gap between conductors, as illustrated in Fig. 1. The extent of this gap depends upon the stiffness of the conductors and upon the tension and compression to which the core is subjected during manufacture and installation. Experience with solid polyethylene-insulated conductors demonstrates that the average value of S for a given DOD can be obtained from the empirical relation expressed by the curve in Fig. 1.

The problem of predetermining the capacitance is more difficult. To compute the pair capacitance one needs not only the dimensions d and S, but also the effective dielectric constant ϵ. The computation is further complicated by the fact that presence of the surrounding wires influences the capacitance of any pair. The surrounding wires form an electrostatic shield, the effective diameter of which is a function of S, the interaxial separation of the wires of a pair. This shield is indicated by the dashed circle in Fig. 2. The effective diameter of this shield is represented by the D. Any pair in the cable thus becomes effectively a shielded pair, the capacitance of which can be calculated by an equation developed a number of years ago by Mead.[3]

$$C=\frac{0.01944\epsilon}{\log_{10}\left(\dfrac{2S}{d}\,\dfrac{D^2-S^2}{D^2+S^2}\right)-0.1086\delta_{12}} \tag{3}$$

where C = capacitance in microfarads per mile, and δ_{12} is a series function of $d/2S$ and S/D. Values of δ_{12} for various values of $d/2S$ and S/D are plotted in Fig. 3.

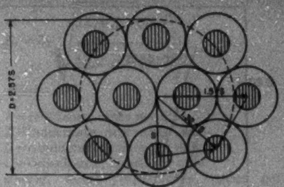

Fig. 2. **Cable pair with surrounding wires as an effective shield**

The relation between S and D may be arrived at by the following reasoning. Consider any pair in the interior of a multipair cable. It may be assumed that the two wires of this pair are surrounded by an oval layer of eight wires as indicated in Fig. 2. It is apparent from the geometry that the distance from the center of the pair to the centers of the two nearest surrounding wires is equal to S, while the distance to centers of the two farthest wires is $1.5S$. The centers of the four remaining wires are $1.32S$ distant from the center of the pair. These eight distances averaged gives $1.285S$ as the mean radius of the layer of wires. As a first approximation this may be considered to be one half the mean diameter D of the effective shield. The S/D ratio then becomes 0.389.

To obtain the dielectric constant ϵ, the remaining parameter involved in equation 3, reference must be made to the measured capacitance of cables for which the ratio of $2S/d$ is known (obtained, as mentioned, from inductance measurements). Data were obtained on eight cables of four different gages in the nominal 0.083-microfarad-per-mile capacitance range; see Fig. 4. The solid curve was calculated with the use of a dielectric constant of 1.80, which seems to fit the data fairly well. The dotted curves above and below the solid curve were calculated with the use of the dielectric constants of 1.90 and 1.70 respectively. These represent the extremes in deviation from the average. It is convenient to lump all variations into the dielectric constant, although some of the deviations may well be the result of variations in the S/D ratio. The S/D ratio for the curves in Fig. 4 was assumed to be constant at a value of 0.389.

The values of the dielectric constant and S/D ratio have been determined independently from capacitance measurements on a number of cables by the method described by Maupin[4] in which

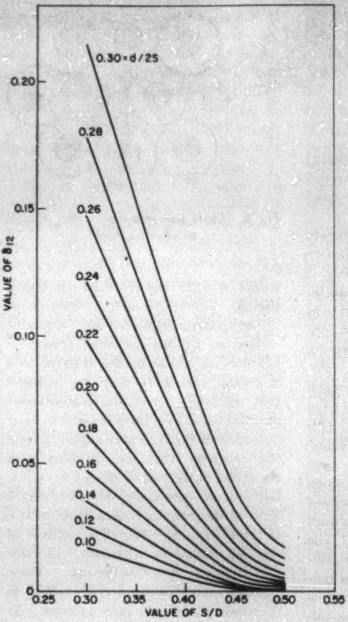

Fig. 3 (left). Value of δ_{12} as a function of $d/2S$ and S/D

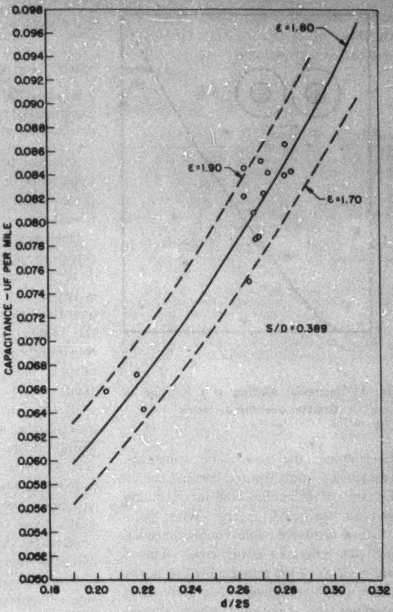

Fig. 4 (right). Capacitance as a function of the ratio of conductor diameter to interaxial spacing

measurements are made of the mutual capacitance and the direct capacitance to ground of cable pairs. These two quantities represented by C_{mut} and C_g respectively are functions of S, d, D, and ϵ, i.e.,

$$C_{mut}=f_1(S,d,D,\epsilon)$$

$$C_g=f_2(S,d,D,\epsilon)$$

Since S can be determined from the inductance measurements and d is known for each gage, the two equations can be solved for the two unknowns D and ϵ. The average value of S/D obtained in this manner is 0.376. Since this method of obtaining the S/D ratio is not very precise, this is considered a good check on the value deduced from geometrical considerations. The average value of ϵ obtained in this manner is 1.83, which is considered a good check on the value of 1.80, obtained from the data in Fig. 4.

It will be noted that ϵ appears to be constant for all values of $d/2S$. For the condition where S equals the DOD (fine gages and small DOD values) one would expect that the ϵ would increase as $d/2S$ is increased, since the ratio of the volume of insulation to the volume of air in the cable increases with an increase in $d/2S$ or an increase in d/DOD. However, the low-capacitance cables (small $d/2S$ or d/DOD ratios) are normally made only in the 19-gage size with the relatively large DOD of 75 mils. Referring to Fig. 1, it can be seen that with such a large DOD value the air space between the insulated conductors of a pair is relatively large (6 mils). This tends to counteract the effect of the small d/DOD ratio. The net result appears to be a constant ϵ over the range of $d/2S$ being considered.

In designing a cable to have a given capacitance one needs only to select the appropriate $d/2S$ ratio from Fig. 4. Knowing the value of d for the gage selected, one can calculate S. From Fig. 1, one can then determine the DOD to which the wire should be insulated.

To complete the design of a cable it is necessary to know one further parameter, i.e., the diameter of cable core to which a given number of pairs will build up. It is common practice in designing cable to allow a theoretical space or area for each pair in the cable. This theoretical area, measured in kilocircular mils (kcm) is known as the space per pair. For instance, it is known that 100 19-gage pairs having conductors with a DOD of 60 mils ($S=63.9$ mils) will form a core 1.17 inches in diameter. The total area involved here is approximately 1.37×10^6 circular mils or 1,370 kcm. This number divided by 100 gives the space per pair, which is 13.7 kcm.

The exact space which pairs of a given size will occupy depends upon the tensions and pressures encountered in the twisting, stranding, and cabling operations. The following empirical equation will, however, serve as a guide in selecting the number of kcm to allow for a pair of a given size, i.e., a given value of S.

$$\text{Space per pair}=3.35S^2\times10^3\text{ kcm} \qquad (4)$$

where S is the interaxial spacing in inches and is related to the DOD as indicated in Fig. 1. Having selected the space per pair one must multiply it by the number of pairs in the cable. This gives the total area of the core in kcm. This area is then coverted to circular inches and the square root extracted to obtain the diameter of the core in inches.

Conclusions

In designing cables to have certain transmission characteristics one must choose the dimensions of the conductors and the insulation so as to produce the primary constants which will give the desired characteristics. In the case of multipair cable at voice frequencies the important primary constants are the resistance and the capacitance. The desired resistance can be obtained merely by selecting the proper gage of conductor. However, choosing the dimensions of the insulation which will give the desired capacitance is more involved. An equation is given from which the capacitance of a multipair plastic-insulated cable can be calculated. Values for the constants in this equation have been obtained by empirical means. Finally, to complete the design information, an empirical equation is given for the size of the cable core in terms of the insulation diameter.

Appendix. Secondary Constants in Terms of Primary Constants

Nonloaded Cable

The propagation constant is

$$P=\sqrt{(R+j\omega L)(G+j\omega C)}$$

$$P\doteq\sqrt{j\omega RC}$$

approximately at voice frequency.

The characteristic impedance is

$$Z_0=\sqrt{\frac{R+j\omega L}{G+j\omega C}}$$

$$Z_0\doteq\sqrt{\frac{R}{j\omega C}}$$

approximately at voice frequency.

Loaded Cable

The propagation constant per mile is

$$P'=\frac{2}{N}\tanh^{-1}\sqrt{\frac{2Z_0\tanh\frac{NP}{2}+Z_C}{2Z_0\coth\frac{NP}{2}+Z_C}}$$

The mid-section characteristic impedance is

$$Z_0'=Z_0\sqrt{\frac{2Z_0+Z_C\coth\frac{NP}{2}}{2Z_0+Z_C\tanh\frac{NP}{2}}}$$

where

R = resistance, ohms per mile
L = inductance, henrys per mile
G = conductance, mhos per mile
C = capacitance, farads per mile
$\omega=2\pi f$, where f = frequency, cycles per second
$j=\sqrt{-1}$
N = number of miles per loading section
Z_C = loading coil impedance

Magnetic Amplifier Circuits—A Classification of Half-Wave and Full-Wave Nonreversible and Reversible Self-Saturating Circuits

DAVID L. McMURTRIE
MEMBER AIEE

THIS ARTICLE attempts to give an orderly, critical classification of a wide variety of self-saturating single-phase series-control magnetic-amplifier output circuits. It the article is successful, it will be clear that a confusing multitude of circuits appearing in the literature may be fitted into a very simple scheme. The relative merit of various alternative circuits for accomplishing different types of output will also become apparent.

The term "self-saturating" implies the use of a rectifier in series with each reactor winding in the output circuit. The more limited simple-saturable type of circuit is not dealt with. "Single-phase" circuits are circuits in which the supply voltages used are of a single phase. "Series control" results from the fact that the only power sources considered are voltage sources. With voltage sources, the reactor elements must act as variable impedance elements in series with the power source and the load. Where current sources are considered, the reactor elements must be used as variable impedance elements in shunt between source and load. The present treatment deals with output circuits only, omitting the details of control and bias. As is developed in the course of the article, there are important constraints which exist in the output circuitry independent of the manner of control, and it is possible to establish criteria for good output circuits independent of control arrangements. Moreover, once a degree of order has been established for output circuits, it is possible to study control arrangements applicable not just to single output circuits, but to classes of output circuits which will be identical insofar as establishing control and bias are concerned. Control and bias are not dealt with in the present article, however.

The manner in which the various half-wave and full-wave nonreversible and reversible circuits are derived is quite simple. The familiar half-wave (HW) circuit, the simplest form of self-saturating circuit, is used as a basic building block with which to construct the more complex reversible half-wave (RHW), full-wave (FW), and reversible full-wave (RFW) output circuits. The technique, with certain modifications that are explained in course, is a straightforward way of deriving even the most complicated circuits, many of which impress the uninitiated as hopelessly complex affairs arrived at in some mysterious inexplicable manner. The derivation technique also allows a quick search for equivalent or improved circuits which may be more economical in one or more of the components involved; i.e., reactor windings, rectifiers, and supply or load transformers.

From this point on the abbreviations mentioned before will be used, adding "AC" and "DC" where necessary to indicate the particular type of output. Thus an FWDC circuit will be a circuit having full-wave d-c output, and an RHWAC circuit will be one having reversible half-wave a-c output, and so on.

There is one serious stumbling block in the process of building complex circuits

D—Waveforms for a-c control, $N_L=N_c$

from the HW circuit (or in constructing them in whatever fashion). If there were no such stumbling block, the substance of the present paper would be somewhat trivial, and the ground would have been thoroughly covered long since. The unpleasant fact is that serious interactions often occur when HW circuits are combined to form more complex structures. Anyone who has worked with magnetic amplifiers has run into booby-trapped situations where the seemingly straightforward push-pull (or other) type of circuits were completely inoperable for the purpose intended because of unforeseen interactions. Treated as controllable synchronous switches, the HW circuits should work perfectly well to give the desired over-all circuit performance, but taken as actual reactors with definite flux-resetting requirements, the circuits are unworkable. It is the essence of the present paper that important output circuit interactions are recognized, measured, and classified, thus allowing a meaningful evaluation and classification of the whole range of single-phase self-saturating output circuits.

Nomenclature

e_b = bias voltage
e_c = control voltage
$e_s=E_m \sin \omega_s t$ = supply voltage
i_c = control current
$I_{co}=(NI)_o/N_c$
i_L = load current
N_c = control-winding turns
N_L = load or output winding turns
$(NI)_o$ = coercive ampere-turns
R_c = control-circuit resistance
R_L = load resistance
V_c = control-winding voltage
V_g = gate or load-winding voltage
V_p = prefire voltage $\equiv V_g$, $0<\theta<\theta_s$
$\bar{V}_p$ = prefire voltage, average value over half cycle
V_r = reset voltage $\equiv V_g$, $-\pi<\theta<0$
$\bar{V}_r$ = reset voltage, average value over one-half cycle
V_L = load voltage (reflected to primary in case of autotransformer output)
V_o = output voltage $\equiv 0$ when no output is being delivered, $\equiv e_s$ when output is being delivered (V_o and V_L are synonymous except for circuits using isolating or mixing resistors which consume a portion of the output voltage)
θ_s = core saturation angle in fire half-cycle
ψ = magnetic flux
ω_c = control-signal angular frequency
ω_s = supply or carrier angular frequency

HW Circuit

The simplest form of self-saturating magnetic amplifier is the HW circuit shown in Fig. 1. Knowledge of its manner of operation is assumed. The output and other waveforms are illustated assuming an idealized square-loop magnetic characteristic. An a-c control voltage is shown, but the control could as well be d-c or it could be a combination of the two, including a rectifier to yield the Ramey circuit, etc. The output obtainable is, as shown, nonreversible having

both a d-c and an a-c component. For convenience in later discussion, the gate or load-winding voltage V_g is resolved into two components, timewise, the reset voltage V_r and the prefire voltage V_p.

The block diagram notation which is to be used in constructing more complex circuits is shown in Fig. 2(A). Note that in the scheme used here, the HW block includes a voltage source. The arrow beneath the block indicates the direction of current flow through the rectifier, and the number *1* or *2* is used to indicate the half-cycle during which the voltage source has the proper polarity to produce positive current through the rectifier. Fig. 2(B) shows the notation to be used if the wish is to split an HW block into two equal parts as will be done often in arriving at bridge-circuit equivalents of the more complex circuits. The fact that in such cases the supply voltage and number of gate-winding turns are cut in half will be kept track of by using the prime as shown, and the double prime if the process is repeated. Fig. 2(C) shows the way in which superfluous voltage sources may be eliminated when HW circuits are combined. The process may be repeated several times in the case of multiple-HW-circuit combinations, Figs. 9(B) and (C) being one example.

Interactions Occurring When HW Circuits Are Combined

As mentioned in the opening paragraphs, certain important interactions may occur between individual HW circuits which are combined to yield RHW, FW, and RFW circuits. These interactions may be classified as follows.

Interactions in Output Circuit

Reset voltage constraints. In the basic HW circuit shown in Fig. 1, the magnitude of the reset voltage cannot exceed the supply voltage, i.e., $|V_r| \leq |e_s|$. If one attempts to impose a greater reset voltage, via the control source, current flows in the load circuit causing a corresponding number of ampere-turns in the control circuit. Provided $(N_c/N_L)^2 R_L << R_c$, $|V_r|$ will remain $\doteq |e_s|$, and the excess control voltage will appear across R_c. If R_c is very small, $|V_r|$ can be increased beyond $|e_s|$, but only at the price of large load and control currents with a subsequent loss in gain and efficiency. If two HW circuits are now put back-to-back as shown in Fig. 3, with control voltages applied to control circuitry not shown, it is not difficult to see that the constraint $|V_{r2}| \leq |e_s|$ holds only as long as core *1* is unsaturated and $V_L = 0$. Once either core saturates, it short-circuits the load winding on the opposite core. When core *1* saturates, then, necessarily, $V_{r2} = 0$ assuming ideal rectifiers and zero gate-winding resistances $R_1 = R_2 = 0$. Thus $|V_r| \leq |e_s|$. In terms of average values over a half cycle, $|\bar{V}_{r1}| \leq |\bar{e}_s| - |\bar{V}_L| = |\bar{V}_{p2}|$. Similarly $|\bar{V}_{r2}| \leq \bar{V}|_{p1}|$. In the steady state, $|\bar{V}_{r1}| = |\bar{V}_{p1}|$ and $|\bar{V}_{r2}| = |\bar{V}_{p2}|$. Hence $|V_{r1}| = |V_{r2}|$ which states that the reset voltages on the two cores must be equal. The prefire voltages must also be equal, and the load voltage on the two half-cycles must be equal. This may be called a condition of constrained balance. Considering just the block diagram of Fig. 3(A), it might have been possible to use this circuit for RHW output. For this type of output, one half of the output circuit must be "shut off" while the other half delivers output of one polarity and vice versa for output of the opposite polarity. The constrained balance condition just observed makes it impossible to shut off one half of the circuit while the other is delivering output. The circuit may be operated perfectly well for FWAC output but not for RHW output. As will be observed later, all back-to-back HW and FW circuits working directly into a common load to deliver reversible d-c suffer from this type of constrained balance. Without modification, these circuits are inoperable as reversible d-c output circuits.

One way in which the preceding constrained-balance condition may be modified is by adding the isolation resistors shown dotted in Fig. 3. Now the reset constraint on either core is $|V_r| \leq |e_s| - |V_L| = |e_s| - R_L|V_o|/R_L + R_1$. (As shown in the Nomenclature, a difference is noted between output voltage V_o and load voltage V_L. $V_o \equiv 0$ when no output is being delivered and $\equiv e_s$ when output is being delivered. V_L may be only a portion of V_o when isolating or mixing resistors are used or when output current bypasses the load and "circulates" through the load windings of other saturated cores.) Note that only one of the isolating resistors at a time is effective and that this resistor gains its effectiveness only by passing load current, thereby reducing the load voltage. If an attempt is made to increase the reset voltage (via the control circuit) beyond the limit mentioned, circulating current will flow and the reset may be increased by the voltage drop produced across the load and isolating resistors. However, this increase will be negligible if $R_L, R_1, R_2 << (N_L/N_c)^2 R_c$ and will be costly in gain and power in any event. It is important to notice that

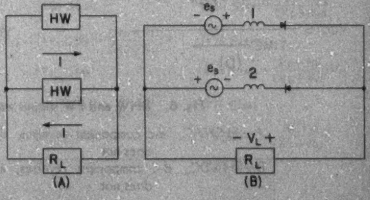

Fig. 4. Back-to-back HW circuit for RHW output
A—Block diagram
B—Schematic

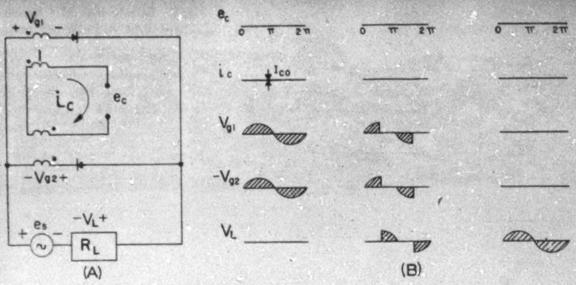

Fig. 5. FWAC circuit with control windings added

A—Schematic
B—Waveforms; any value of output obtained with zero input

even with the use of isolating resistors it will not be possible to shut off one half of the circuit completely while the other half of the circuit is conducting fully (over a complete half-cycle). In order to accomplish this the constraint would have to reduce to $|V_r| \leq |e_s|$, and this is impossible except in the limit $R_1/R_L = \infty$, in which case all the output power appears across R_1 and none across the load. Fig. 3(C) illustrates the situation. In practice, therefore, only a moderately successful compromise can be attained in which isolating resistors rob a sizable portion of the output power and still do not give full output.

Prefire voltage constraint. The reset voltage constraint just dealt with is only half the picture; the other half is the prefire voltage constraint. In the circuit of Fig. 3, as in the basic HW circuit, the prefire voltage of either HW circuit is $|V_p| \geq |e_s|$. Note the $\geq$ sign. The reset constraint is a matter of allowing reset voltage up to a fixed limit if reset excitation happens to be provided by a control winding. The prefire constraint above is a matter of *forcing* a certain minimum value of prefire voltage regardless of what goes on in the control circuit. The control circuit can imposed an even higher prefire voltage, but this is a rare occurrence. In Fig. 3 $|V_p| \geq |e_s|$ and $|V_r| \leq |e_s| - k|V_o|$, $k = R_L/(R_L + R_1)$. As discussed in the preceding section, one of the HW circuits cannot be completely cut off while its mate is fully firing, and full RHW output cannot be obtained, therefore, unless $|V_r| \leq |e_s|$. To this should be added the requirement for keeping one of the HW circuits shut off is that sufficient reset voltage area is allowed across its gate winding so that $|\bar{V}_r| = |\bar{V}_p|$ without forcing $|\bar{V}_p|$ to be reduced by saturation of the core before the end of the half-cycle. It is not always true that the prefire constraint is $|V_p| \geq |e_s|$. The basic criterion is that the maximum allowable value of $|V_r|$ be equal to or greater than the minimum mandatory value of $|V_p|$ when the core

needs to be completely shut off. In all the circuits to be analyzed it will be necessary to keep careful track of both the prefire and reset constraint conditions.

Consider the circuit of Fig. 4 used for RHW output. This is a circuit in which the two HW circuits reset on the same half-cycle and fire on the same half-cycle. Here the two halves of the circuit do not interfere with one another's reset ($|V_r| \leq |e_s|$ as though the halves were completely independent), but they do interfere with one another's prefire voltage. The prefire voltage on either core is $|V_p| \geq |e_s| + |V_o|$. For this circuit, therefore, one of the HW circuits cannot be completely shut off while the other is fully firing, and full RHW operation is impossible.

of control-circuit interactions. An example of control-circuit interaction is shown in the FWAC circuit of Fig. 5. Waveforms are given which show that any value of output may be obtained with zero-control signal under the assumptions of square-loop operation, ideal rectifiers, and zero control-circuit impedance. The condition is one of unstable equilibrium in which any small external disturbance will cause the output to run away either to zero or to full output. The prefire voltage of one core becomes the reset voltage of the other and vice versa, and thus the circuit can maintain any value of output without a control signal. The circuit exhibits unity-positive feedback through control-circuit interaction.

The ideal circuit with unity-positive feedback just described is uncontrollable and useless as an amplifier. In actuality, however, slight deviations from the ideal conditions discussed will decrease the feedback sufficiently to give stable, smoothly controllable operation. For example, if the control-circuit resistance is not zero, the reset voltage on one control winding (during any one cycle) will be slightly less than the prefire voltage on the other by the amount of the voltage drop in the control-circuit resistance, and the only stable value of output for zero-control signal will be full output. It is not the purpose of this paper to go further into the analysis of this circuit. The point to be made is that feedback can and does occur through control-circuit interaction when the control windings are connected in certain ways.

If the control winding on core *2* is reversed, the positive feedback feature disappears. The prefire voltage induced in the control circuit opposes rather than aids the proper reset of the other core. The control voltage (which must now be a-c in order to reset both cores in the same direction on alternate half cycles), must be sufficiently large to provide reset voltage and overcome the induced prefire voltages necessary to operate either HW circuit singly. The output (rectified average) is, of course, twice as great as for the HW circuit alone, simply because the output is full-wave rather than half-wave. In short, no net feedback is evident.

It is important to point out that the output circuit constraints previously discussed can be little modified by what transpires in the control circuit and then only at a price which it is desirable to avoid. For example, control-circuit interaction or feedback can do little to modify the detrimental constraints which disbar the basic circuit of Figs. 3 and 5 from RHW operation. It is profitable initially to study and to establish the workability and worth of output circuits independent of control and bias arrangements.

RHW and FW Circuits, Two Core Circuits

Two HW circuits are necessary for either RHW or FW output. Fig. 7(B) shows the simplest way in which two HW blocks may be combined to deliver power to a common load. If both of the HW circuits are made to deliver equal amounts of output on alternate half-cycles, the result is FW output, either FWAC or FWDC. Waveforms are shown in Fig. 6(D) and (E). If one of the HW circuits is kept shut off while the other continuously delivers output and vice versa, the result is RHW output. There is more than one type of RHW output. There are, in fact, three: RHWAC, RHWDC

and RHWACDC. These are shown in Figs. 6(A) through (C). Strong a-c and d-c components are simultaneously present in all cases, a condition inherent in the HW waveforms, but both components do not reverse together except in the RHWACDC case. In RHWAC, only the a-c component reverses while in RHWDC only the d-c component reverses. Two bias conditions are shown for the RHWAC and RHWDC waveforms. For one, the nonreversing component goes to zero with the reversing component. For the other bias condition, the nonreversing component is kept relatively constant as the reversing component goes through zero. (Only the a-c fundamental goes through zero in the latter RHWAC case.) In the RHWACDC waveforms one bias condition is shown in which both cores fire in the same half-cycle to give an output that begins as a spike at midcycle and widens out into a half sine wave. An important point to notice is that in the RHWACDC case, the two HW circuits reset (or tend to reset) on the same half-cycle and fire (or tend to fire) on the same half-cycle. For the other RHW and FW circuits the HW circuits reset on alternate half-cycles.

BLOCK DIAGRAMS

Fig. 7 shows the various ways in which two HW circuits may be combined to deliver RHW or FW output to a common load. The key of Fig. 7(A) indicates the manner in which each of the block configurations can be used for the different RHW and FW modes of operation. The simplest circuit is that designated type *I*, the type *II* circuit uses an autotransformer (or transformer) output. The autotransformer is inoperable for RHWAC and FWDC because the d-c component in the output saturates the autotransformer. RHWDC and RHWACDC operation are possible provided the d-c control frequency ω_c is actually a low frequency, $0<\omega_c<\omega_s$ where ω_s is the supply frequency. (Fig. 8 shows RHWDC and RFWDC operating with $0<\omega_c<\omega_s$.) The autotransformer must be wound to accommodate maximum output voltage and minimum signal frequency. Mixing resistors replace the autotransformers in the type *III* circuit. Mixing resistors are inefficient, giving a maximum efficiency of only 17.1% with $R_L/R_1=\sqrt{2}$. The type *IV* bridge circuit is equivalent to the type *I* is as made evident by the method of derivation.

If the types *I*, *II*, and *IV* circuits operated without difficulty to deliver all RHW and FW types of output, there would be little necessity for considering the mixing-resistor arrangement of the type *III* circuit or the isolating resistors shown modifying the other basic circuit types. Difficulty does arise, however, in the case of RHWDC and RHWACDC operation because of the type of output circuit interactions discussed previously. These interactions are summarized in the reset and prefire constraint equations of Table I, where data are easily derived using the reasoning already developed. Specifically, it was previously established that RHW operation is impossible for a circuit in which $|V_p|\geqslant|e_s|$ and $|V_r|\leqslant|e|_s-|V_o|$. For $|V_p|\geqslant|e_s|$ and $|V_r|\leqslant|e|_s-k|V_o|$, $0<k<1$, limited RHW output is possible, but short of $k=0$, one HW circuit cannot be shut off completely while its companion is delivering full output. For $k>0$, $|V_r|$ is restricted to such a small value that $|\bar{V}_p|=|\bar{V}_r|$ can hold (as it must in steady state) only if the core which is supposed to be shut off saturates before the end of its fire half-cycle. Similarly, only limited RHW operation is possible in a circuit in which $|V_p|\geqslant|e_s|+|V_o|$ and $|V_r|\leqslant|e_s|$, another case discussed previously. The situation is improved with $|V_p|\geqslant|e_s|+k\ |V_o|\ 0<k<1$, but full RHW output is not possible short of $k=0$.

HW BLOCK NUMBER	RFWAC OUTPUT	RFWDC OUTPUT

It is evident that isolation resistors used in series with each HW block to form type I' are only partially effective. There are equivalent type II' and IV' circuits with resistors in series with each HW block, but these are not shown. The type II'' and IV'' are fundamentally different with $|V_r| < |e_s| - (R_L - R_1)/R_L + R_1 |V_o|$ (RHWAC, RHWDC). For $R_1 = R_L$, $|V_r| < |e_s|$. The derivation of type IV'' is rather interesting. An attempt might be made to add a resistor in the type IV circuit as shown in Fig. 7(G), but there R_1 is of no benefit. With one HW circuit saturated, $V_L + V_{R1}$ is impressed across the other HW circuit exactly as though R_1 were immediately in series with R_L. In Fig. 7(H) the circuit is given a new twist and it can be seen that with one HW circuit saturated, $V_L - V_{R1}$ is impressed across the other HW circuit to create a new constraint situation. For $R_1 = R_L$, $V_L - V_{R1} = 0$, and the two HW circuits act independently. This is quite different from and much more beneficial than the action of the isolating resistors in the type I' circuit.

RHWAC CIRCUITS

Fig. 9 presents the detailed types I and IV output circuits selected from the block diagrams of Fig. 7. As reflected in Table I, these simplest and most efficient types offer no reset constraint problems and can deliver full RHWAC without difficulty. There is little cause, therefore, for using other types with isolating or mixing resistors. As has been mentioned previously, the type II circuit is inoperable for RHWAC because the d-c component in the output would saturate the autotransformer or transformer.

RHWDC CIRCUITS

Fig. 10 presents detailed RHWDC circuits selected from the several alternatives of Fig. 7. Table I reflects the disabling reset constraint of the simplest types I, II, and IV circuits used without isolating resistors. Of the circuits selected for Fig. 10, the type I' is relatively ineffective (this is one of the examples used in the section discussing reset constraints), and the type III is extremely inefficient (17.1% maximum efficiency). Types II'' and IV'' are the best choices. With $R_1 = R_L$, the interaction of the two component HW circuits is eliminated completely. The resulting circuit efficiency is 50%.

RHWADC CIRCUITS

Fig. 11 presents detailed RHWACDC output circuits selected from Fig. 7. The type I' circuit is relatively poor with

IIIA	$\lvert V_r\rvert \le \lvert e_s\rvert - \lvert V_0\rvert$	$\left\{\begin{array}{l}\lvert V_r\rvert \le \lvert e_s\rvert - \frac{R_1\lvert V_0\rvert}{R_L+R_1} \\ \lvert V_p\rvert \ge \lvert e_s\rvert - \frac{R_1\lvert V_0\rvert}{R_L+R_1}\end{array}\right\}$	$\lvert V_r\rvert \le \lvert e_s\rvert + \lvert V_0\rvert$	$\left\{\begin{array}{l}\lvert V_r\rvert \le \lvert e_s\rvert + \frac{R_1\lvert V_0\rvert}{R_L+R_1} \\ \lvert V_p\rvert \ge \lvert e_s\rvert - \frac{R_1\lvert V_0\rvert}{R_L+R_1}\end{array}\right\}$

Constraints hold for normal operation in which only one HW circuit at a time is saturated. Reset voltage $V_r = V_g$, $-\pi<\theta<0$. Prefire voltage $V_p = V_g$, $0<\theta<\theta_s$. $\lvert V_p\rvert \ge \lvert e_s\rvert$ if not stated otherwise

full output impossible short of $R_1/R_L=\infty$. The type *II″* circuit delivers full output at 50% efficiency for $R_1=R_L$ provided the control-signal frequency is $0<\omega_c<\omega_s$. The type *III* circuit is, as always, inefficient. The type *IV″* circuit is equivalent to the type *II″* without the restriction on ω_c.

FW Circuits

There is no difficulty in obtaining either FWAC or FWDC from any of the types in Fig. 7 except for the impossibility of obtaining FWDC with the autotransformer output of type *II*. The simplest and most efficient circuits, types *I*, *II*, and *IV*, are all equivalent. These are shown detailed for FWAC in Fig. 12. Types *I* and *IV* for FWDC are shown in Fig. 13.

RFW Circuits, Four-Core Circuits

RFW Block Diagrams

Four HW circuits are necessary for RFW operation. Figs. 14 through 20 show various ways in which four HW blocks may be combined to deliver RFW power to a common load. The key of Fig. 14 indicates the manner in which the block configurations can be used for either RFWAC or RFWDC. The simplest circuit is type *I* of Fig. 15(A). The type *II* circuits of Fig. 16 use an autotransformer or transformer output. It is not difficult to see that all the type *II* circuits are equivalent although differences arise when isolation resistors are added. Direct current cannot be passed through the autotransformer, of course, but RFWDC operation is possible where the d-c input is actually a low-frequency $0<\omega_c<\omega_s$. The autotransformer must be wound to accommodate maximum output voltage and minimum control frequency. In Fig. 17 mixing resistors have replaced the autotransformer in the type *III* circuit. Mixing resistors are inefficient giving a maximum efficiency of only 17.1% with $R_L/R_1=\sqrt{2}$ [7.1% with $R_L/R_1=3\sqrt{2}$ as in the case of Fig. 17(D)[. The type *IV* bridge circuit of Fig. 18 is

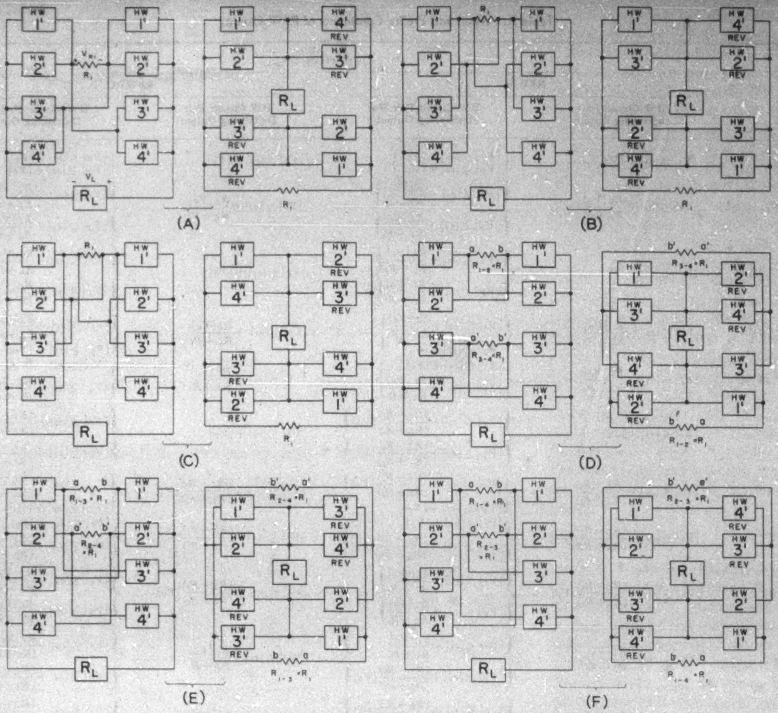

Fig. 19. RFW type IV'' and IV''' block diagrams, new twists to Fig. 18(C). Two drawings of same circuit in each case shown. In (D) through (F) one connection a–a', a–b', b–b', a'–b normally permissible

A–C—Types IVA''' through IVC'''1
D–F—Types IVD'' through IVF''

equivalent to the type *I* circuit as is made evident by the manner in which it is derived. The number of cores used in the bridge arrangement remains four since one core still suffices for a pair of windings when HW circuits are split in two as in Fig. 18(A).

If the basic types *I*, *II*, and *IV* circuits operated without difficulty to deliver both RFWAC and RFWDC, there would be little need to consider the addition of isolating resistors or the use of mixing resistors. Difficulty does arise, however. Types *I*, *II*, and *IV* circuits are completely inoperable for RFWDC. If the operation of the type *I* circuit is examined in detail following the reasoning developed earlier regarding reset and prefire interactions, it is not difficult to confirm the constraint conditions set forth in Table II. The constraints indicate that RFWAC operation offers no basic difficulty. The pair of cores delivering output (*1* and *2* for instance) have $|V_r| \leq |e_s| - |V_0|$ and $|V_p| \geq |e_s|$ which requires equal reset and equal output on successive half-cycles as in the type *I* FWAC circuit. The pair of cores not delivering output (*3* and *4*) have $|V_r| \leq |e_s| + |V_0|$ and $|V_p| \geq |e_s|$, and can thus be reset (using appropriate control circuitry) by an amount necessary to keep them shut off.

A completely different situation exists when the type *I* circuit or its equivalents are used for RFWDC output. When one pair of cores is attempting to deliver output, the other pair cannot be shut off. For the cores which should be shut off, $|V_r| \leq |e_s| - |V_0| = 0$ at full output. Thus the cores cannot be reset at all, and an intolerable situation exists in which pairs of cores are firing simultaneously and large circulating currents flow. No output of any kind is delivered to the load under these circumstances. What can be done to break up the unwanted interactions of the RFWDC type *I* circuit? In order to shut off one HW circuit pair when the other is delivering full output, it is necessary to make the maximum allowable $|\bar{V}_r|$ equal to or greater than the minimum mandatory $|\bar{V}_p|$. Then one of the HW circuit pairs can be shut off if the necessary reset voltage is provided in the control circuit. For the type *I* RFWDC circuit, the initial constraints on the pair of HW circuits which ought not to be delivering output are $|V_r| \leq |e_s| - |V_0|$ and $|V_p| \geq |e_s| + |V_0|$. Following the reasoning already developed, one way of allowing the pair to be shut off would be to make $|V_r| \leq |e_s|$, $|V_p| \geq |e_s|$ (if possible). Another equally good solution might be to make

Table III. Figure of Merit for RFWDC Circuits, Data from Table II

Circuit	HW Circuit Pair Not Delivering Output	
	$\|V_r\|/\|V_p\|$, $\|V_o\|=\|e_s\|$	$\|V_r\|/\|V_p\|$, $\|V_o\|=\|e_s\|$, $R_1=R_L$
I, IC″, II, IIC″, IIC‴, IV, IVC″, IVC‴	0	0
IB″, IIB″, IVB″	$R_1/2(R_L+R_1)$	0.25
I′, IA″, II′, IIA″, IID″, IV′, IVA″, IVD″	$R_1/(2R_L+R_1)$	0.33
IIB‴, IVB‴	$R_1/(R_L+R_1)$	0.50
IIE″, IVE″	$R_1/2R_L$	0.50
IIF″, IVF″	$2R_1/(2R_L+R_1)$	0.67
IIA‴, IVA‴	R_1/R_L	1.0
IIIA	$(R_L+2R_1)/R_L$	3.0

$|V_r| \leq |e_s|+|V_o|$, $|V_p| \geq |e_s|+|V_o|$. A partial solution can be obtained by placing a resistor in series with each HW circuit to form the type *I′* circuit. Limited but not full RFWDC output is then possible with $|V_r| \leq |e_s|-k|V_o|$, $|V_p| \geq |e_s|+k|V_o|$, $k=R_L/(R_L+R_1)$, as shown in Table II.

Various other ways of adding isolating resistors to the basic type *I* circuit are shown in Fig. 15. Figs. 16 through 19 show similar systematic modifications of varying merit for the basic circuit types. Types *I′*, *II′*, and *IV′* use four isolating resistors; *I″*, *II″*, and *IV″* use two; and *II‴* and *IV‴* use one. Types *II′*, and *IV′*, equivalent to *I′*, and *IIA″*, *IIB″*, *IIC″* and *IVA″*, *IVB″*, *IVC″*, equivalent to *IA″*, *IB″*, and *IC″*, are not shown. Many of these circuits appear scattered throughout the literature with scanty indication of their relative merit or equivalence to other circuits. The key to relative merit (and equivalence) is contained in the constraints listed in Table II. Once the restraints in the final column of the Table are established, it is simple enough to judge the relative effectiveness of the circuits for RFWDC operation. A figure of merit can be obtained by considering the ratio $|V_r|/|V_p|$ with $|V_o|=|e_s|$ (case of full output being delivered by the other HW circuit pair). This ratio is shown in Table III. It is not difficult to see that $|V_r|/|V_p|=0$ indicates a completely unworkable circuit. $0<|V|_r/|V_p|<1$ indicates a circuit from which limited but not full RFWDC is possible. $|V_r|/|V_p| \geq 1$ indicates that full RFWDC output is possible. Table III evaluates the RFWDC circuits for the case $R_L=R_1$. Note that the only circuits, other than the inefficient type *III* circuits, capable of giving full RFWDC output are the type *IIA‴* and *IVA‴* circuits.

The derivation of the type *IV* circuits is similar to that of the *IV* RHW circuits. In Fig. 18(C) an isolating resistor is added, but V_{R1} adds to V_L, and the effect is no different than that of putting R_1 directly in series with R_L. In Fig. 19(A), the reverse resistor connection causes V_{R1} to subtract from V_L. If $R_1=R_L$, $V_L-V_{R1}=0$, and all interaction between the two pairs of HW circuits is cancelled. Other possible isolationresistor combinations are explored in Fig. 19 and appraised in Tables II and III.

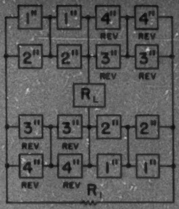

Fig. 20. RFW block diagram of bridge of bridges, equivalent to type IVA″

More complex forms of RFW circuits may be spun out indefinitely by splitting parallel pairs of HW circuits into bridge circuits in any of the preceding RFW block diagrams. One example is shown in Fig. 20 with the detailed circuit shown in Fig. 22(L). This circuit is sometimes seen in the literature despite its apparent complexity.

A word with regard to complexity is appropriate here. In all the RFW circuits shown so far and in the figures to follow, the minimum number of cores required is the same: four. Furthermore, the total volt-amperes ratings of the voltage sources, the windings, and the rectifiers (back voltage times forward current) is the same for all the circuits discounting whatever extra capacity must be provided for circulating currents and power dissipated in isolating and mixing resistors. Thus when the type *I* RHW or RFW circuit is split into a type *IV*

bridge circuit, the number of load windings is doubled but the number of turns in each winding is cut in half, the number of rectifiers is doubled, but the back-voltage ratings on each rectifier may be cut in half, etc. The bridge arrangement obviates the need of input and/or output transformers (or autotransformers) in some cases. In any event, the simplest circuit on paper is not necessarily the most suitable circuit in practice.

RFWAC CIRCUITS

Fig. 21 shows several detailed RFWAC circuits selected from the earlier block diagrams with redundant voltage sources eliminated. In all cases cores *1* and *2* deliver output of one phase while *3* and *4* deliver output of the other phase. The basic types *I*, *II*, and *IV* circuits operate very well for RFWAC, and there is ordinarily no need to consider circuits with isolating or mixing resistors. Types *I*, *II*, and *IV* are all equivalent as indicated in Table II.

RFWDC CIRCUITS

Fig. 22 shows a wide selection of detailed RFWDC circuits from the earlier block diagrams. In all cases cores *1* and *2* deliver output of one polarity while *3* and *4* deliver output of the opposite polarity. Only the types *IIA'''*, *IVA'''*, the bridge of bridges, and the highly inefficient type *III* circuits can achieve full RFWDC output as indicated in Tables II and III. The other circuits are less successful but usable, and many appear in the literature.

Conclusions

This paper attempts to bring together a comprehensive collection of self-saturating magnetic-amplifier output circuits. A method of derivation is used which is intended to include as many known circuits as possible and to give a process of arriving at complex circuitry that may be remembered when details of the circuits themselves may be in doubt or forgotten. A simple analysis technique is used which makes troublesome interactions a little better defined and therefore a little more understandable. If the presentation has been successful, the paper should be helpful both in the selection of the most suitable circuits for particular jobs and in the better understanding of magnetic-amplifier circuitry and operation.

Reference Data

It is beyond the scope of this paper to give precise and detailed credits for first usage of the various circuits presented. Rather than give cursory credits, the author chooses to omit completely all such references. For details of this nature reference 1 is one of the best single sources. It discusses a large number of circuits, has a good bibliography, and is particularly thorough in its documentation of original publications and patents. Reference 2 is a short survey which includes several types of magnetic amplifiers other than the type dealt with in the present paper. For even broader perspective, reference 3 gives a brief review and bibliography of nonlinear magnetic devices, of which amplifiers are but one class. Reference 4 is an excellent source for detailed analysis of self-saturating and other magnetic amplifiers and has chapters and bibliography devoted to circuits and applications.

A New Dynamic Impedance Matching Circuit as Applied to a Conference Repeater

O. D. GRANDSTAFF
MEMBER AIEE

MOST telephone conversations are made between two parties. Occasionally the conversation may involve three parties, where the third party talks on an extension telephone. Another form of group conversation involves the interconnection of several telephone lines for a conference call. Here the lines are connected together in a conference circuit at the telephone exchange in a manner to provide optimum transmission and impedance matching. Small conference groups can be coupled through repeating coils but larger groups and conference circuits employed on toll switchboards need an amplifier to maintain satisfactory transmission levels. Current practice is to use telephone repeaters for this purpose.

During the establishment of a conference call, lines are added successively to the conference circuit until the desired number of parties are connected. Also, some parties may disconnect before the conference is concluded. These changes substantially alter both the impedance and voice signal power requirements in the conference circuit. Dummy loads are usually connected when the party disconnects to improve the stability but precise compensation cannot be obtained by this method as the impedance of lines connected to a conference circuit may vary considerably. Therefore, for the new conference repeater an amplifier with special input circuits was required that could keep each line properly terminated and operate with good stability regardless of the number of lines set up for a conference call. Since modern transmission standards provide uniform transmission levels in both local and toll switchboards, no gain is required in the conference re-

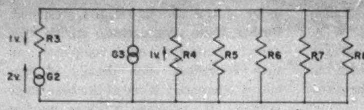

Fig. 2. Schematic of a telephone and conference circuit correctly impedance matched

peater but the original level must be maintained with any number of conference lines connected.

These requirements impose several problems in the conference repeater circuit. First, each line should be properly matched for impedance by the input of the conference repeater. A mismatch can adversely affect the antisidetone circuit of the telephone or the hybrid balance of a toll circuit repeater. Second, the amplifier must have the unique characteristic of delivering the same output level regardless of variations of load. A third requirement is that any party in the conference must be able to talk at will and all other parties hear him.

This conference repeater circuit is arranged to meet these requirements with as many as 12 lines. A new dynamic impedance matching circuit provides stable operation without need of a balancing network normally required in similar circuits where hybrids are used. The principles of operation of the conference repeater are as follows.

Fig. 1 shows the usual two party connection in a schematic diagram. Generator *G*1 represents the transmitter of the talking telephone. Resistor *R*1 is the internal impedance of the transmitting circuit. *R*2 is a load impedance representing the listening telephone. If the generator or talking telephone has an output of 2 volts, one volt is dissipated in the source *R*1 and one volt is dissipated in the load resistor *R*2. Under this condition the load impedance matches the source impedance and provides the ideal condition. Fig. 2 is a schematic of a conference repeater circuit where *G*2 represents the transmitter of the talking telephone; *R*3 its source impedance; and *R*4, *R*5, *R*6, *R*7, and *R*8 the load resistances of five listening telephones. These load resistors in parallel would normally cause a mismatch of impedance with the source impedance *R*3; but in this circuit a generator *G*3 has been added to produce a voltage across *R*4, *R*5, etc., of the same value that existed across *R*2 in Fig. 1. Therefore, if generator *G*2 generates 2 volts, one volt will be dissipated in resistor *R*3 and one volt will exist across resistors *R*4, *R*5, *R*6, *R*7, and *R*8 resulting in the same loading of the source as in Fig. 1. Under this condition the same current will flow from generator *G*2 of Fig. 2 as flows from generator of *G*1 Fig. 1. Also, each load resistor *R*4 to *R*8, will have one volt across it; the same as load resistor *R*2 of Fig. 1. In this manner the talking telephone is kept properly terminated and the several listening telephones receive full strength signal.

As long as generator *G*3 maintains the voltage across the load circuit, additional loads may be added or loads may be removed without altering the transmission level on the remaining circuits. In the conference repeater circuit, generator *G*3 is an electronic amplifier which uses an output circuit of the cathode follower type. It has sufficient inherent negative feedback that telephones may be added or removed with negligible change of its output voltage.

The diagram in Fig. 2 shows transmission only in one direction; from generator *G*2 and *R*3 to all the other loads. Since the requirements are that speech may originate from any telephone, the conference circuit must be a symetrical-type circuit arranged for any party to either talk or listen. This requirement presents a considerable problem since it involves 2-way voice transmission with an amplifier. Such an amplifier or voice repeater usually uses a hybrid circuit for detection of direction of power flow. In case of the conference repeater, hybrid circuits are not very practical because large impedance variations occur as several lines are switched onto or disconnected from the conference repeater. These variations cause excessive unbalance in the hybrid circuit which starts oscillation or singing in the circuit.

This conference repeater circuit uses a new method of detecting direction of power flow which does not require a balancing network. Line voltage and line currents are rectified by germanium diodes for comparison of their polarities to determine if the lines are carrying incoming or outgoing signals. Incoming currents control the amplifier but outgoing currents are prevented from having any effect on it. This is accomplished as shown in Fig. 3. Generator *G*4 and resistor *R*9 represent a talking telephone connected to line access circuit no. 1. Voice signals from *G*4 pass through transformer *TR*1, through capacitor *C*1, and resistor *R*11 to the main signal bus leads *A* and *B*. An amplifier, *AMPL*-1, has its cathode follower output connected to the *A* and *B* leads and functions the same as generator *G*3 of Fig. 2. The listening telephones such as *R*10 also are connected across the *A* and *B* leads. Load current flows from the *A* and *B* leads through resistor *R*12, capacitor *C*2, transformer *TR*2 to the load *R*10. A conference repeater may have several line access circuits like no. 1 and no. 2. All are alike and each may function at any time as a circuit for a talking or listening telephone. The signal voltage across leads *A* and *B* is applied through transformer *TR*5 to provide a voltage reference. During pos-

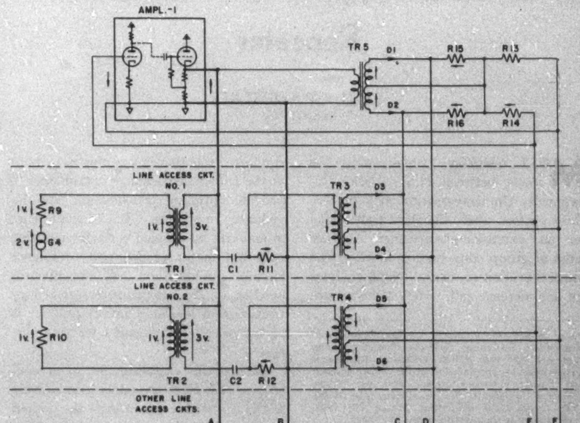

Fig. 3. Conference repeater circuit

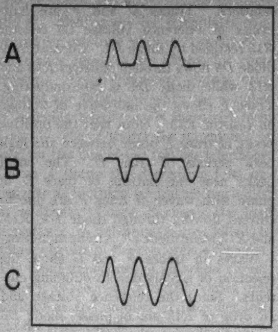

Fig. 4. Oscillogram of input signal

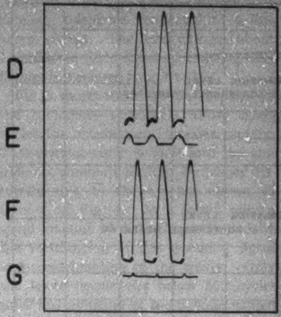

Fig. 5. Oscillogram of reference voltage and input signal

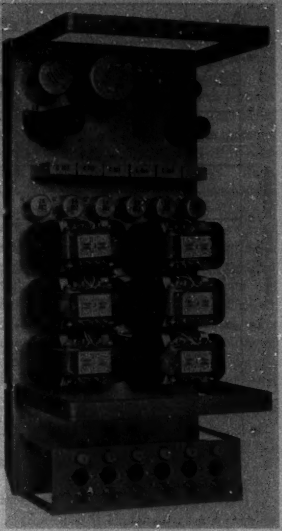

Fig. 6. Conference repeater for six lines

itive half-cycles of the *A* and *B* lead voltage, current flows through diode *D*1 and resistor *R*15 to the center tap of *TR*5. This causes positive half-cycles of the *A* and *B* lead voltage on resistor *R*15 while diode *D*2 prevents any reference voltage on *R*16.

The current references are obtained from resistors *R*11 and *R*12 which are small resistances approximately 5% of a line impedance connected to leads *A* and *B*. Signals flowing into or out of the *A* and *B* leads cause *IR* drops in these resistors of about 5% of the voltage across the *A* and *B* leads. The *IR* drop or voltage across *R*11 is proportional to the voice signal from generator *G*4. This small voltage is stepped up about 4 to 1 through transformer *TR*3 to have a better amplitude for diodes *D*3 and *D*4 and the input to the amplifier. On positive half-cycles of the *A* and *B* lead voltage, a secondary winding of *TR*3 causes current to flow through diode *D*3, resistor *R*16, and resistor *R*14, back to the winding of *TR*3. On negative half-cycles, current flows from the other winding of *TR*3 through diode *D*4, resistor *R*15, and resistor *R*13 back to the winding of *TR*3. The voltage drops developed across resistors *R*15 and *R*16 are of no consequence but the voltage drops across *R*13 and *R*14 are connected to the input of the amplifier. Resistor *R*12 has an *IR* drop proportional to the load current. The voltage drop is opposite in polarity to

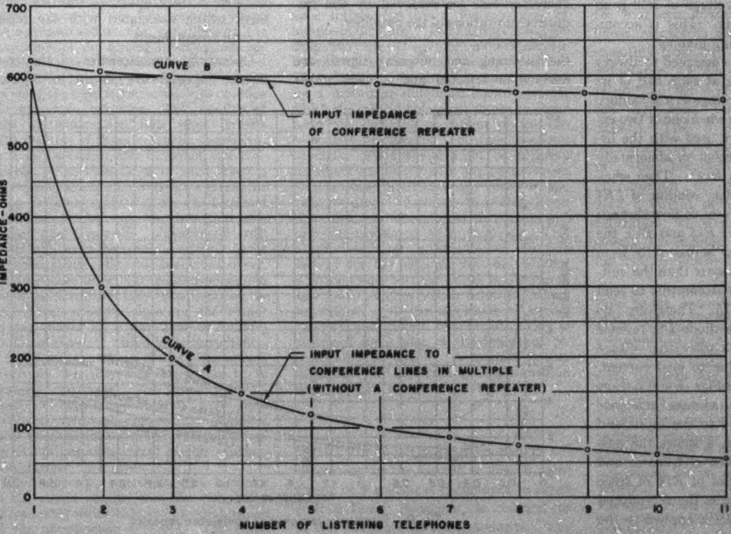

Fig. 7. Input impedance of conference repeater

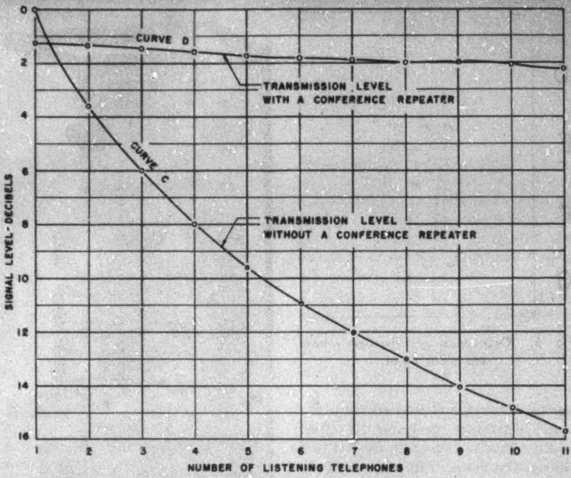

Fig. 8. Output level of conference repeater

that of the *IR* drop of *R*11, since it is due to current flowing out from the *A* and *B* leads. If this voltage were impressed on the input of the amplifier, it would subtract from the voltage applied to the amplifier from resistor *R*11, causing the input to be diminished and not be proportional to the incoming signal. Therefore, the circuit must function to prevent the outgoing signal voltage of *R*12 from reaching the amplifier. This is accomplished in the following manner.

Transformer *TR*5 is designed to always have a larger voltage at each half of its secondary than the voltage at a secondary winding of *TR*4 (even when one or two extension telephones are used with the listening telephone, causing an abnormally high voltage drop on *R*12). Then when voltage from a secondary winding of *TR*4 attempts to cause current to flow through diode *D*6 and resistors *R*15 and *R*13, the voltage drop already across *R*15 from transformer *TR*5 is greater than the voltage from *TR*4 that is attempting to send current through *R*15. Therefore, no current flows through diode *D*6, resistor *R*15, and resistor *R*13 when the voltage drop across *R*12 is due to load current.

The oscillograms in Figs. 4 and 5 show the relation of the vlotage reference waves and waves due to the input and output currents. Fig. 4 shows the positive half-cycles of *R*13 in trace *A* and the negative half-cycles of *R*14 in trace *B*. The sum of these is the reproduced signal of trace *C* which is applied to the input of the amplifier. Note the small notches, at the zero points of the cycles in trace *C*, caused by the addition of the rectified positive and negative half-cycles. These notches are kept to a minimum by use of gold-bonded germanium diodes for *D*3, *D*4, *D*5, and *D*6 and by circuit design with little phase shift. The notches are of high-frequency character and are removed by the frequency limitations of the amplifier.

The oscillogram in Fig. 5 shows how the incoming and outgoing signals are selected or rejected due to their phase relations. Traces *D* and *F* are half-cycles of reference voltage on resistor *R*15 rectified by diode *D*1. Current from diode *D*4 flows through resistors *R*15 and *R*13 while diode *D*1 is nonconducting. Trace *E* shows the half-wave of voltage on resistor *R*13. Note that the positive peaks of trace *E* occur between the high peak periods of trace *D*. The small peaks near the bottom of trace *D* in phase with waves of trace *E* are due to current flowing through diode *D*4, *R*15, and *R*13 while diode *D*1 is nonconducting.

Waves in traces *F* and *G* show the rejection of signals due to outgoing currents. Since the reference voltage and *IR* drop of *R*12 are in phase, diode *D*6 is conductive at the same time diode *D*1 causes large positive half-cycles on *R*15. The absence of positive half-cycles of the signal on trace *G* show how effectively signals due to outgoing currents are rejected. Only small notches remain which are lost in the amplifier like the notches in trace *C*.

A conference repeater equipped with six line-access circuits is shown in Fig. 6. The common amplifier is at the top of the unit. It is a conventional vacuum-tube amplifier using resistance-coupled triode voltage amplifiers to drive the cathode-follower output tube. One control, *R*6, sets the gain to provide the correct input impedance in the manner explained for generator *G*3 in Fig. 2. The access circuits are located in the middle of the unit. Equipment at the bottom includes a busy lamp, a test jack, and busy switch associated with the input of each access circuit.

Operating characteristics of the conference repeater are shown in Figs. 7

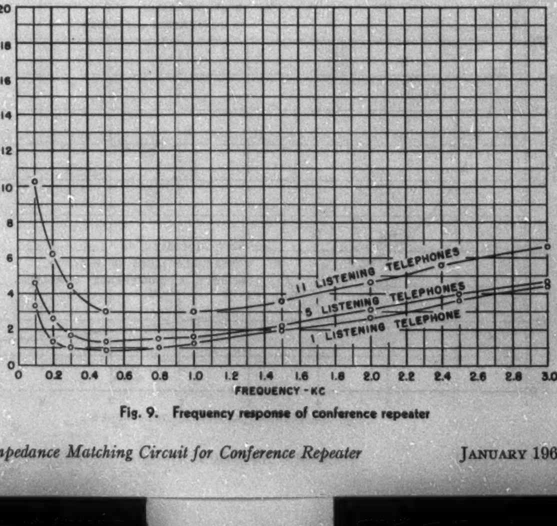

Fig. 9. Frequency response of conference repeater

and 8. Also curves for telephones connected in multiple without benefit of a conference repeater are shown for comparison. Voice frequency signals originate at one telephone while the number of listening telephones is increased from 1 to 11. Fig. 7 shows the impedance or load on the line of the talking telephone. Curve *A* shows the decreasing load impedance as listening telephones are added in multiple. Curve *B* shows the load impedance as telephones are added to access circuits of the conference repeater. The input impedance of an access circuit, while it is receiving a signal, varies only slightly as the number of listening telephones is increased.

Fig. 8 shows the signal level at the listening telephones in decibels. In curve *C* the level decreases rapidly as listening telephones are added in multiple. Curve *D* shows the level at a listening telephone connected to a line access circuit. The level changes about 1 decibel as the number of listening telephones is increased from 1 to 11.

Fig. 9 shows the frequency response of the conference repeater. Above 3,000 cycles the attenuation increases rapidly. This characteristic is built into the amplifier to eliminate the high-frequency distortion due to the notches shown in trace *C* of Fig. 4. As a result, only a small amount of distortion is caused by the rectification of the incoming signal and recombination of the waves. Only the lower frequencies below 500 cycles show any evidence of the notches caused by the recombination.

In a telephone conference, more than one person may speak into his telephone at the same time. Such coincidence of speech is more likely than where the group is assembled around a conference table. Nevertheless, the conference repeater can handle simultaneous speech; since each line-access circuit is always ready to receive incoming signals. To test simultaneous response, three persons were asked to read paragraphs from three unrelated subjects. Three other persons were instructed to listen and each to concentrate on his particular subject. Each one was able to understand completely the transmission of his subject.

The conference repeater provides equipment frequently needed for group telephone conversations. It can be used in toll and local offices or in private exchanges. It is easily applied to either manual- or automatic-type offices. Its constant-input impedance, fixed-gain amplifier, and inherent stability permit lines to be connected or disconnected without need of dummy loads or balancing networks.

Theory of Ferroresonance

JALAL T. SALIHI
ASSOCIATE MEMBER AIEE

Synopsis: The phenomenon of hysteresis occurring in a series nonlinear resonant circuit has interested engineers for a long time. The phenomenon is associated in literature with a resonance occurring at a critical value of applied voltage where the nonlinear inductance, variable with the magnitude of the forcing function, reaches a value so as to resonate with the fixed capacitor. This is probably the reason for using the term ferroresonance to describe the hysteresis behavior. The validity of such an explanation fails when circuits with reactors of sharp magnetic saturation, such as Deltamax and Orthonol, are considered. The inductance of such reactors may be approximated without appreciable error by linear regions of zero and infinite inductances. As will be shown in this paper, the hysteresis phenomenon still exists and even becomes more prominent as the magnetic saturation becomes sharper. On the other hand, the usual explanation given in literature fails when applied to such ideal circuits, since an inductance having values of either zero or infinity could not resonate with a finite capacitance.

Another explanation of the phenomenon given in the literature attributes it to negative resistance. The presence of regions of negative resistance have been confirmed through resort to graphical plots of equations derived. However, no direct mathematical proof of this explanation has yet been given.

The confusion concerning the behavior of the circuit results from the complexity of equations which hide the physical nature of the phenomenon involved. The equations derived in this paper are relatively simple and could be interpreted directly. This simplification is achieved by considering an idealized circuit consisting of a reactance with two regions of zero inductance interrupted by a linear region of infinite inductance. The analysis is further simplified by assuming a rectangular instead of a sinusoidal forcing function. The behavior of the circuit is thus expressed by a first-order difference equation, from which the critical points are shown to occur when the damping coefficient of the approximate differential equation becomes negative. Thus the concept of negative resistance associated with the phenomenon is confirmed mathematically without the need for graphical plots. It is also shown that the phenomenon of ferroresonance may be associated with feedback. This is expressed by a closed-loop diagram derived for the circuit. Another concept is introduced where the circuit is considered as a low-pass filter whose cutoff frequency depends on both the amplitude of forcing function and circuit parameters. This is expressed by a plot of the frequency response of the circuit. A method is also suggested for determining the transition time between the stable states.

THE HYSTERESIS phenomenon occurring in the circuit of Fig. 1, consisting of a nonlinear inductance in series with a linear capacitor, is referred to in the literature as ferroresonance. The phenomenon is explained as a resonance occurring at a critical value of the applied voltage where the inductance, variable with the applied voltage, reaches a value so as to resonate with the fixed capacitance at the frequency of the forcing function. Fig. 2 shows the ideal magnetization characteristic assumed. Figs. 3 and 4 show the correlation between the shape of magnetization characteristic and the hysteresis behavior. If the magnetic characteristic of the nonlinear reactor is assumed to be varied smoothly from one of gradually varying inductance to one of sharp magnetic saturation, the corresponding change in the hysteresis phenomenon will be smooth. The hysteresis phenomenon becomes more noticeable as the magnetic saturation becomes sharper. Thus the phenomenon of hysteresis associated with a circuit of very sharp magnetic saturation, which may be approximated closely by regions of infinite and zero inductance (curve *a*, Fig. 4), may be

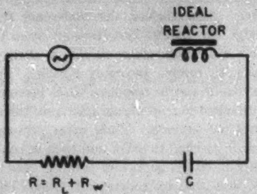

Fig. 1. Idealized basic ferroresonant circuit analyzed having an ideal reactor of zero winding resistance and the magnetization characteristic of Fig. 2

considered as a limiting case or an idealized ferroresonance. This is described by curve *a* of Fig. 3, such that, starting from zero, as the voltage is increased the reactor does not conduct until a critical voltage is reached at which the operation point suddenly jumps to P_1.

For any further increase in the voltage the current increases smoothly along the curve up to some point P_2. If the voltage is then reduced, the current reduces in the same manner to point P_1, where the voltage is again equal to its critical value. A further reduction in voltage is described by the path P_1P_3 along which the current reduces smoothly to point P_3 which corresponds to a second critical point at which a further reduction in voltage reduces the current abruptly to zero. The other two curves, *b* and *c* of Fig. 3, correspond to less ideal ferroresonance associated with the magnetization curves *b* and *c* of Fig. 4. As will be shown in this paper, the hysteresis phenomenon occurring in the ideal circuit is not a resonance, either instantaneous or average. This contradicts the explanation given in the literature, since such a circuit may be considered as a limiting case of less ideal ferroresonance circuits.

The basic ferroresonant circuit of Fig. 1 has been given considerable treatment due to both its practical and theoretical importance. The critical points at which the circuit becomes unstable were deduced either by graphical methods,[1] or from the knowledge of the behavior of one reactor by applying the principle of similitude,[2] or by fitting certain equations to measured relations.[3] In all these cases, a continuous magnetization characteristic of gradually varying permeability is assumed and a sinusoidal method of analysis is followed, where either the current or flux is assumed to be sinusoidal. The discrepancy between theoretical results obtained from a sinusoidal analysis and practical measurements increases as the saturation of the magnetic material of the core becomes sharper. The accuracy of the method may, of course, be increased by considering higher harmonics such as the third; however, consideration of harmonics higher than the third makes the sinusoidal approach to the analysis so tedious as to render it impractical.

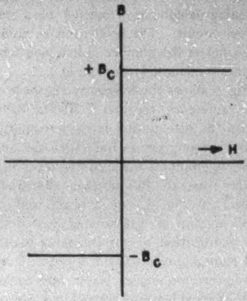

Fig. 2. Ideal magnetization characteristic assumed

In a previous paper by the author,[4] the steady-state behavior of an idealized ferroresonant circuit for the case of sinusoidal excitation was analyzed. The conduction angle was taken as an independent variable to which the various factors were related. The idealized equations were still so complicated that no direct mathematical explanation of the nature of the phenomenon could be seen. In this paper a rectangular excitation is assumed. This assumption simplifies the equation of the circuit appreciably so that the physical nature of the phenomenon hidden in previous analysis by the complexity of equations involved is exposed. Further, the dynamic equations of the circuit, from which useful conclusions may be made, are derived.

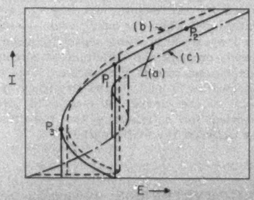

Fig. 3. Effect of the magnetization characteristic of the material used for the reactor of the series ferroresonant circuit on the steady-state behavior of the circuit

Method of Analysis and Assumptions

The idealized series resonant circuit of Fig. 1 consists of a nonlinear reactor in series with a fixed capacitance and resistance. The reactor is assumed to be ideal, having a magnetization characteristic composed of two linear regions of zero inductance interrupted by a linear region of infinite inductance as shown in Fig. 2. This circuit is referred to in this paper as the idealized ferroresonance circuit and the phenomenon of hysteresis occurring in this circuit as an idealized ferroresonance.

When an alternating forcing function is applied to the idealized ferroresonance circuit, the inductance of the circuit alternates between its zero and infinite value. During the intervals of infinite inductance, the circuit offers an infinite impedance to the flow of current. During the intervals of zero inductance, however, a current limited only by the capacitance and the resistance of the circuit flows. The angular interval through which current flows, referred to half a cycle of the forcing function, is called the conduction angle. The conduction angle is taken as an independent variable to which all the variables in the circuit are related. These variables are discontinuous functions of time. Thus, as a first step in the analysis, these variables are represented by artificial jump function. This function is of constant amplitude during each half-cycle of the forcing function and varies instantaneously to a new constant value at the beginning of the next half-cycle. Relating the variables thus expressed to the conduction angle leads to nonlinear difference equations. The nonlinear difference equations are approximated for small variations by linear difference equations. From these equations both the steady-state and the dynamic behavior of the circuit may be obtained.

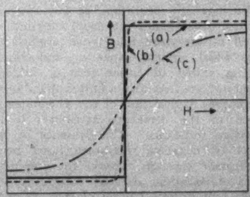

Fig. 4. Magnetization characteristic of the reactor of the series ferroresonant circuit corresponding to the steady-state behavior of Fig. 3

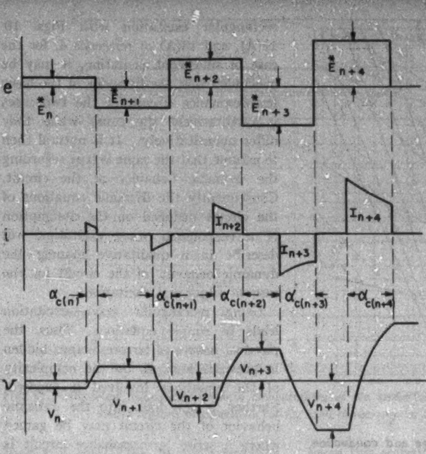

Fig. 5. Waveshape of current flowing in the idealized basic ferroresonant circuit of Fig. 1 and the voltage across the capacitor for a rectangular excitation voltage of varying amplitude applied to the circuit

The qualitative correlation of the characteristics derived in reference 4 for the case of sinusoidal excitation with the corresponding characteristics derived in this paper for the case of rectangular excitation gives an indirect proof of the validity of the analysis presented.

Modes of Operation and Circuit Equations

Let a rectangular voltage, of varying amplitude, be applied to the circuit of Fig. 1. The resulting current pulses and the voltage across the capacitor are given in Fig. 5, where α_c, V, i, and I denote the conduction angle, the constant voltage across the capacitor during nonconduction intervals, the instantaneous value of current, and the half-cyclic average value of the current, respectively. The subscripts n, $n+1$, $n+2$, ..., are used to assign these values to the corresponding nth, $n+1$, $n+2$, ..., half-cycle of the forcing function. During the conduction intervals, α_c, of each half-cycle of the applied voltage, the flux in the reactor is constant at its saturation value. Consequently, the induced voltage is zero and the reactor behaves as a resistance equal to its winding resistance. During the nonconduction intervals the flux in the reactor is changing. Consequently, a voltage will be induced across the reactor which behaves as an infinite inductance preventing the flow of current.

It is convenient to describe the behavior of the circuit in terms of three unknowns α_c, V, and I. Thus three difference equations are required to determine any of these unknowns. These equations may be derived as follows.

Equation 1

If Q_n and Q_{n+1}, are the charges across the capacitor during the nonconduction interval of nth and $n+1$ half-cycle, then:

$$Q_{n+1}=-Q_n+\frac{1}{\omega}\int_{\pi-\alpha n}^{\pi} i_n d\omega t=-Q_n+\frac{\pi}{\omega}I_n$$

since

$$Q_n=CV_n$$

and

$$\phi=\tan^{-1}(1/\omega CR)$$

then

$$\pi \tan \phi R I_n=V_n+V_{n+1} \qquad (1)$$

Equation 2

The differential equation of the circuit during the nth conduction interval is of the form:

$$Ri_n+\frac{1}{C}\int i_n dt=E^*$$

where E^* represents the amplitude of the rectangular excitation voltage. Solution of this equation is of the form:

$$i_n=K\epsilon^{-\frac{t}{CR}}=K\epsilon^{-\frac{1}{\omega CR}\omega t}=K\epsilon^{-\tan\phi\,\omega t}$$

Substituting the boundary condition

$$i_n=\frac{E_n^*+V_n}{R}$$

at

$$\omega t=\pi+\alpha_{c(n)}$$

the value of the constant K may be determined. The equation of current then becomes:

$$i_n=\frac{E_n^*+V_n}{R}\epsilon^{\tan\phi\,[\pi-\alpha_{c(n)}]}\times\epsilon^{-\tan\phi\,\omega t}$$

The half-cyclic average value I_n of the current may be obtained by integrating this equation between the limits

$$\omega t=\pi-\alpha_{c(n)}$$

to $\omega t=\pi$ which gives the second equation:

$$1-\epsilon^{-\tan\phi\,\alpha_{c(n)}}=\frac{\pi\tan\phi}{E_n^*+V_n}RI_n \qquad (2)$$

Equation 3

The differential equation of the circuit during the nth nonconduction interval is of the form:

$$N\frac{d\Phi}{dt}\times 10^{-8}=E_n^*+V_n$$

where

Φ = flux
N = number of turns on the core

Since $d\Phi=Ad\beta$, where A is the cross-sectional area of the core, one may write:

$$d\beta=\frac{E_n^*+V_n}{AN\omega\times 10^{-8}}d\omega t$$

Integrating this equation gives

$$\beta=K_1+\frac{10^8(E_n^*+V_n)}{AN\omega}\int_{\omega t_i}^{\omega t}d\omega t$$

At $\omega t=0$, $\beta=-B_c$ due to negative saturation, while at $\omega t=\pi-\alpha_{c(n)}$, $\beta=+B_c$, due to positive saturation. Inserting these conditions in the foregoing equation gives the third of the required equations, which is of the form:

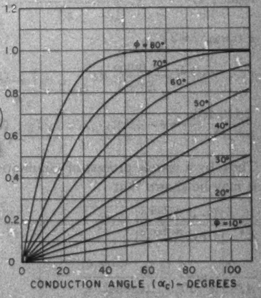

Fig. 6. Steady-state calculated relationship between conduction angle and constant voltage across the capacitor during presaturation intervals expressed as a fraction of the amplitude of the rectangular voltage applied to the basic ferroresonant circuit

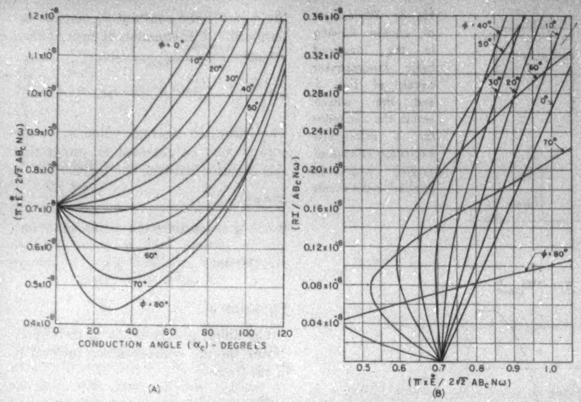

Fig. 7. Calculated steady-state relationships between (A) applied voltage and conduction angle and (B) applied voltage and half-cyclic average value of current, for a rectangular voltage applied to the basic ferroresonant circuit

$$\frac{2AB_cN\omega}{10^8(E_n^*+V_n)}=\pi-\alpha_{c(n)} \tag{3}$$

These three equations containing three unknowns give enough information to solve for both the steady-state and the transient behavior.

Steady-State Behavior

In steady-state operation

$$I_n=I_{n+1}=I_{n+2}\ldots$$

$$V_n=V_{n+1}=V_{n+2}\ldots$$

$$\alpha_{c(n)}=\alpha_{c(n+1)}=\alpha_{c(n+2)}$$

Thus the three equations derived reduce to

$$\pi \tan\phi RI=2V \tag{1A}$$

$$1-\epsilon^{-\tan\phi\,\alpha_c}=\frac{\pi\tan\phi}{E^*+V}RI \tag{2A}$$

$$\frac{2AB_cAN\omega}{10^8(E^*+V)}=\pi-\alpha_c \tag{3A}$$

Thus, by a simple process of elimination, it may be shown that

$$\frac{V}{E^*}=\frac{[1-\epsilon^{-\alpha_c\tan\phi}]}{[1+\epsilon^{-\alpha_c\tan\phi}]} \tag{4}$$

$$\frac{E^*}{AB_cN\omega}=\frac{1}{10^8}\,\frac{[1+\epsilon^{-\alpha_c\tan\phi}]}{[\pi-\alpha_c]} \tag{5}$$

$$\frac{RI}{AB_cN\omega}=\frac{2}{10^8}\,\frac{[1-\epsilon^{-\alpha_c\tan\phi}]}{\pi\tan\phi[\pi-\alpha_c]} \tag{6}$$

where $V/AB_cN\omega$, $E^*/AB_cN\omega$, and $RI/AB_cN\omega$ are the nondimensional values of voltage across capacitor, applied voltage, and the average value of current. Equation 4 is obtained by eliminating *RI* from equations 1(A) and 2(A), while equation 5 is obtained by eliminating *V* from equations 4 and 3(A). Equation 6 is obtained by eliminating E^*+V from equations 2(A) and 3(A). Fixing values of ϕ at 10, 20, 30, 40, 50, 60, 70, and 80 degrees, the nondimensional graphical relationship of Figs. 6 and 7 are obtained. Fig. 6 relates the voltage across the capacitor to the conduction angle as deduced from equation 4. Fig. 7(A) relates the applied voltage to the conduction angle as deduced from equation 5. Fig. 7(B) relates the voltage applied to the circuit to the average value of the current flowing. This is deduced from equations 5 and 6, where the corresponding values of voltage and current for any conduction angle may be calculated.

From a comparison of Figs. 6, 7(A), and 7(B) of this paper for the case of rectangular excitation with Figs. 10 11(A), and 13(A) of reference 4, for the case of sinusoidal excitation, it may be concluded that the behavior of the basic ferroresonance circuit for the two cases is qualitatively the same while they differ quantitatively. It is natural then to assume that the same is true regarding the dynamic behavior of the circuit. Consequently the dynamic equations of the circuit deduced on the assumption of a rectangular wave excitation will describe in a qualitative manner the dynamic behavior of the circuit for the case of sinusoidal excitation.

Using rectangular wave excitation leads to simple equations. Thus, the physical nature of ferroresonance hidden in previous analysis by the complexity of the equations involved is exposed. Further, a new look into the dynamic behavior of the circuit may be gained where a series ferroresonance circuit is considered as a low-pass filter whose frequency-response characteristic may be calculated from simple equations. From these characteristics the speed of response may be deduced.

Dynamic Behavior and Condition for Stability

The three difference equations involve nonlinear terms. These equations may be linearized for small variations about given operating points. To do this, equation 2 may be written as

$$1-\frac{\epsilon^{\tan\phi[\lambda-\alpha_{c(n)}]}}{\epsilon^{\tan\phi\,\lambda}}=\frac{\pi\tan\phi}{E_n^*+V_n}\,RI_n$$

where λ is a steady-state operation conduction angle about which the transient variation takes place. For small transient changes $(\lambda-\alpha_{c(n)})$ is small, and foregoing equation may be written as

$$1-\frac{1+\tan\phi\lambda-\tan\phi\,\alpha_{c(n)}}{\epsilon^{\tan\phi\,\lambda}}=\frac{\pi\tan\phi}{E_n^*+V_n}\,RI_n \tag{7}$$

By the process of substitution in equa-

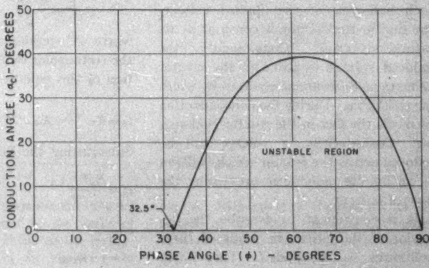

Fig. 8. Calculated critical value of conduction angle below which the basic ferroresonant circuit becomes unstable

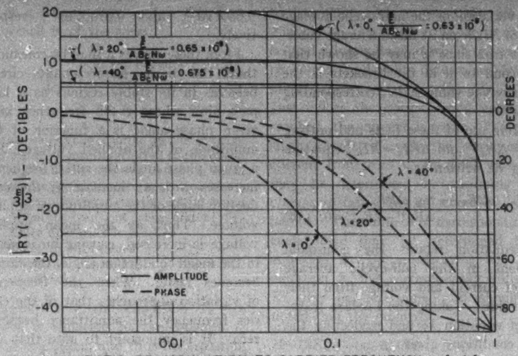

Fig. 9. Calculated frequency response characteristic of the basic ferroresonant circuit in the stable regions of operation for the case of rectangular excitation

tions 1, 3, and 7, the difference equation of the circuit is derived, which is of the form:

$$[K_3 - \pi \tan\phi]RI_n + K_3[RI_{n+1}] - [E_n{}^* + E_{n+1}{}^*] + \frac{4AB_cN\omega}{10^8}K_2 = 0 \quad (8)$$

where K_2 and K_3 are constants corresponding to a given steady-state operation conduction angle λ, and are given by

$$K_2 = \frac{\tan\phi}{\epsilon^{\lambda \tan\phi} + \tan\phi(\pi - \lambda) - 1}$$

$$K_3 = \frac{\pi \tan\phi\, \epsilon^{\lambda \tan\phi}}{\epsilon^{\lambda \tan\phi} + \tan\phi(\pi - \lambda) - 1} \quad (9)$$

Letting

$$I_{n+1} = I_n + \Delta I_n$$

and

$$E_{n+1}{}^* = E_n{}^* + \Delta E_n{}^*$$

equation 9 gives

$$K_3 \Delta RI_n + [2K_3 - \pi \tan\phi]RI_n - [\Delta E_n{}^* + 2E_n{}^*] + 4 \times 10^{-8} AB_cN\omega K_2 = 0 \quad (10)$$

for a constant applied voltage $\Delta E_n{}^* = 0$, and $E_n{}^* = E^*$. Thus equation 10 may be written

$$\Delta RI_n + \left[\frac{2K_3 - \pi \tan\phi}{K_3}\right]RI_n + \frac{2}{K_3}\left[\frac{2AB_cN\omega}{10^8}K_2 - E^*\right] = 0 \quad (11)$$

For slow variations this equation may be approximated by a differential equation of the form:

$$\frac{d}{dt}RI + \left[\frac{2K_3 - \pi \tan\phi}{K_3}\right]RI + \frac{2}{K_3}\left[\frac{2AB_cN\omega}{10^8}K_2 - E^*\right] = 0 \quad (12)$$

From this equation it may be concluded that the system is stable when the damping coefficient is positive. The condition for stability may be expressed as

$$\frac{2K_3 - \pi \tan\phi}{K_3} \geq 0 \quad (13)$$

Substituting for values of K_3 given by equation 9 in this equation the condition for stability becomes

$$[\epsilon^{\lambda \tan\phi} + \lambda \tan\phi - \pi \tan\phi + 1] \geq 0$$

At the boundary of the stable region $\lambda = \lambda_c$, thus

$$[\epsilon^{\lambda_c \tan\phi} + \lambda_c \tan\phi - \pi \tan\phi + 1] = 0 \quad (14)$$

From this equation the critical value of steady-state conduction angle corresponding to any given value of phase angle may be determined. The corresponding critical value of applied voltage and current may be calculated by substituting the critical value of λ_c, instead of α_c, in the steady-state equations 5 and 6, respectively. Values of λ_c corresponding to different values of ϕ are plotted in Fig. 8. The calculated curve is the boundary between stable and unstable modes of operation. For values of circuit parameters inside the region bounded by this curve and the X-axis, the circuit exhibits a hysteresis effect, while outside this region the behavior of the circuit is described by a single-valued function and the circuit is stable. From Fig. 8, it may be seen that no hysteresis effect exists if the phase angle is less than 32.5 degrees. The critical value of the phase angle $\phi = \tan^{-1} 2/\pi = 32.5$ degrees may be obtained by letting $\lambda_c = 0$ in equation 14.

In spite of the approximation applied, the condition of stability given by equations 13 or 14 is an exact condition because at the point where the circuit becomes just unstable, the subsequent transient starts with a slow change. During this instant, the approximate equation is exact. This may be verified graphically from a comparison of Fig. 8 with the minimum points of Fig. 7(A), deduced on the basis of exact steady-state equations showing that the results obtained from these two figures for the condition of stability are identical. An analytical proof of this may also be obtained from the investigation of the stability of the difference equation. The solution of this equation is of the form:

$$RI_n = D\left[1 - \frac{2K_3 - \pi \tan\phi}{K_3}\right]^n$$

where D is a constant corresponding to the initial conditions. From this solution it may be concluded that the circuit is unstable when the absolute value of the quantity in the bracket exceeds unity. This is true since n takes consecutive integer values, thus causing RI_n to increase indefinitely. This condition is, of course, limited by saturation effects in physical systems. The condition for stability of the difference equation may thus be expressed as

$$\left|1 - \frac{2K_3 - \pi \tan\phi}{K_3}\right| \leq 1$$

At the boundary of the stable region this equation may be written as

$$\left|1 - \frac{2K_3 - \pi \tan\phi}{K_3}\right| = 1$$

From this equation it may be concluded that the stable region has two boundaries defined by the following two equations:

$$+\left[1 - \frac{2K_3 - \pi \tan\phi}{K_3}\right] = 1$$

or

$$\frac{2K_3 - \pi \tan\phi}{K_3} = 0$$

$$-\left[1 - \frac{2K_3 - \pi \tan\phi}{K_3}\right] = 1$$

Fig. 10. Equivalent feedback diagram for the basic ferroresonant circuit of Fig. 1 for the case of rectangular excitation

or

$\phi=0$

The boundary of stability defined by the first equation is the same as equation 13, derived for the differential equation, while the second equation indicates that the system becomes unstable at negative values of phase angle $\phi=\tan^{-1}(1/\omega cR)$, that is, at negative values of frequency which are physically unrealizable. From these results the following conclusions may be made concerning the behavior of the basic series ferroresonant circuit:

1. The circuit is stable for $\phi<\tan^{-1} 2/\pi=32.5$ degrees.
2. For values of $\phi>\tan^{-1} 2/\pi$ the circuit is unstable in some regions of its operation where the output changes in an exponential manner limited by saturation effects. Since the equation involved is of the first order, there is no possibility of sustained oscillation in this ideal circuit.
3. Unstable operation associated with negative phase angles predicted mathematically is physically unrealizable.

Frequency Response

The frequency response of the basic ferroresonant circuit in the stable regions may be obtained by assuming the amplitude of the rectangular applied voltage to be modulated with a low-frequency signal compared with the carrier. Consequently, the resultant variation in the half-cyclic average value of current will be sinusoidal also. This is true for small variations where the behavior of the circuit is described by linear equations. The speed of response may thus be obtained from the frequency-response characteristics expressing the ratio of the output current to the input signal at different signal frequencies, modulating the constant carrier frequency.

The dynamic behavior is given by equation 10 which may be rewritten as

$$K_3\Delta RI_n+[2K_3-\pi\tan\phi]\times\left[RI_n-\frac{2E_{DC}{}^*-4\times10^{-8}\times AB_cN\omega K_2}{2K_3-\pi\tan\phi}\right]-\Delta E_n{}^*-2[E_n{}^*-E_{DC}{}^*]=0 \quad (15)$$

where $E_{DC}{}^*$ is the mean half-cyclic value or initial value of the amplitude of the rectangular applied voltage (carrier). Assuming the carrier amplitude to be modulated with a low-frequency sinusoidal signal of angular frequency ω_m, then $E_n{}^*-E_{DC}{}^*=E_n{}^{*\prime}$ is the sinusoidal variation of the amplitude of the applied voltage from its mean value. Also

$$\left[RI_n-\frac{2E_{DC}-4\times10^{-8}\times AB_cN\omega K_2}{2K_3-\pi\tan\phi}\right]=RI_n{}'$$

is the variation of the half-cyclic average value of RI_n from its mean average value. This is true since it may be shown that the second term in the brackets is the mean average value of RI_n corresponding to $E_{DC}{}^*$.

Making use of these facts and putting $\Delta E_n{}^*=\Delta E_n{}^{*\prime}$ and $\Delta RI_n=RI_n{}'$, equation 16 may be written as

$$K_3\Delta RI_n{}'+[2K_3-\pi\tan\phi]RI_n{}'-\Delta E_n{}^{*\prime}-2E_n{}^{*\prime}=0 \quad (16)$$

This equation relates the sinusoidal variations in the half-cyclic average value of current and voltage from their mean value. Taking the Laplace transform of equation 16 and neglecting the initial conditions gives

$$K_3[\epsilon^{\frac{\pi}{\omega}s}-1]RI'(s)+[2K_3-\pi\tan\phi]RI'(s)-[\epsilon^{\frac{\pi}{\omega}s}-1]E^{*\prime}(s)-2E^{*\prime}(s)=0$$

This equation may be written as

$$\frac{E^{*\prime}(s)}{RI'(s)}=\frac{Z(s)}{R}=\frac{K_3+[K_3-\pi\tan\phi]\epsilon^{-\frac{\pi}{\omega}s}}{\left[1+\epsilon^{-\frac{\pi}{\omega}s}\right]}$$

where ω is the angular frequency of the applied voltage (carrier), and $\epsilon^{-(\pi/\omega)s}$, represents a time shift of half a cycle. The sinusoidal response of the circuit may be obtained by letting $S=j\omega_m$ where ω_m is the angular frequency of the modulating signal. Thus

$$\frac{Z(j\omega_m)}{R}=\frac{K_3+[K_3-\pi\tan\phi]\epsilon^{-j\pi\frac{\omega m}{\omega}}}{\left[1+\epsilon^{-j\pi\frac{\omega m}{\omega}}\right]} \quad (17)$$

where K_3 is given by equation 9.

The average admittance of the circuit to the low-frequency modulating signal $Y(j\omega_m)=1/Z(j\omega_m)$ may be obtained from this equation. Thus at $\phi=0$, $K_3=1$ and $Z(j\omega_m)/R=1$, showing that the average impedance $Z(j\omega_m)$ is equal to R, regardless of the frequency of signal or the mean conduction angle (function of applied voltage as given by equation 15). However, this is not true for the case of capacitive loading where the impedance becomes a function of both frequency and amplitude of forcing function. As an example, for $\phi=30$ degrees the value of the nondimensional admittance $RY(j\omega_m)$ is calculated and the frequency-response characteristics are shown in Fig. 9, which is a plot of the magnitude and phase of $RY(j\omega_m)$ for three different values of mean conduction angle (λ) of 0, 20, and 40 degrees taken as parameters. The corresponding three values of applied voltage may be obtained from Fig. 7(A), and are 0.63×10^{-8}, 0.65×10^{-8}, and 0.675×10^{-8}, respectively.

From these curves it may be concluded that the basic ferroresonant circuit behaves in its stable regions as a low-pass filter whose cutoff frequency at a given phase angle is a function of the amplitude of the applied voltage. For a given phase angle the cutoff frequency increases with an increase in the conduction angle or the amplitude of applied voltage. Thus as the mean applied voltage is increased, causing an increase in the mean conduction angle, the circuit becomes faster. When the frequency of variation approaches that of the carrier frequency the admittance becomes zero. It is important to note that the relations given are only valid for small variations.

Transient Response

The bistable behavior of the basic ferroresonant circuit makes it suitable for a variety of practical applications.[8] In most of these applications the circuit undergoes a transient state from one stable mode to the next. Thus a knowledge of the transient behavior of the circuit is of practical importance. The dynamic equations derived in this paper are believed to contain enough information necessary for the determination of the transient response of the circuit. The author wishes only to outline a procedure for the determination of the transient response in the hope that it may be considered by other investigators for thorough treatment.

The dynamic behavior of the idealized series ferroresonance circuit is described by equation 15. For transients due to step changes in applied voltage, $\Delta E_n{}^*=0$, while $(E_n{}^*-E_{DC})$, is equal to the step change in the value of the applied voltage. Denoting this change in the applied voltage by $E^{*\prime}$, equation 15 may be written as

$$K_3\Delta RI_n+[2K_3-\pi\tan\phi]\times\left[RI_n-\frac{[2E_{DC}-4\times10^{-8}\times AB_cN\omega K_2]}{[2K_3-\pi\tan\phi]}\right]=2E^{*\prime} \quad (18)$$

The quantity in the large bracket represents the change in current from its initial value, that is, the half-cyclic average value of the current before the step change in the applied voltage is made. Denoting the change in current by $I_n{}'$, equation 18 may be written as

$$K_3\Delta RI_n{}'+[2K_3-\pi\tan\phi]I_n{}'=2E^{*\prime} \quad (19)$$

The solution of this equation is the

sum of a steady-state and a transient term which is of the form:

$$I_n' = I_{ss}' + D\left[1 - \frac{[2K_3 - \pi \tan\phi]}{K_3}\right]^n \qquad (20)$$

where

I_n' = the half-cyclic change in the average value of current referred to the initial value before the step change is made
I_{ss}' = the change in the average value of the current referred to the initial value when the transient ceases and steady-state operation is reached
K_3 = defined in equation 9
D = a constant depending on the initial conditions

By substituting the condition $I_n'=0$, at $n=0$, in equation 20, the constant D may be evaluated, and thus the equation for current becomes

$$I_n' = I_{ss}\left[1 - \left(1 - \frac{2K_3 - \pi \tan\phi}{K_3}\right)^n\right] \qquad (21)$$

From this equation, the transient behavior of the circuit may be determined. As an example, let the applied voltage be increased suddenly from its initial value E_1^* to E_2^*. Assuming operation in the stable region, the corresponding change in the half-cyclic average value of current flowing in the circuit undergoes a transient reaching a final steady-state value.

The transient may be calculated as follows:

1. Find the value of I_1 and I_2 corresponding to E_1^* and E_2^* from the steady-state equations 5 and 6, expressed graphically in Fig. 7(B). The difference (I_1-I_2) is equal to I_{ss}.
2. Find the value of α_c corresponding to E_1 from equation 5, expressed graphically in Fig. 7(A). Substituting the value of $\alpha_c=\lambda$ in equation 9, the corresponding value of K_3 may be calculated.
3. Knowing I_{ss} and K_3, the change in current during each half-cycle may be obtained by substituting consecutive integer values of n in equation 21, starting from $n=1$.

The value of K_3, determined in step 2, varies continuously with conduction angle. However, for small changes, K_3 may be taken as a constant without appreciable error. For large changes, this assumption may cause an appreciable error. To avoid this, the method of calculation must be so modified that the transient is divided into several stages according to the degree of accuracy required. The final value of one stage is taken as the initial value of the next stage.

A similar procedure may be used to determine the transition time between stable state, if equation 6 is assumed to be valid. As an example, let the voltage be increased from zero to the critical firing voltage at which the current rises to a fixed value determined by the phase angle as seen from Fig. 7(B). Just before the critical firing voltage is reached, the current is zero. The transient associated with the variation of current from zero to its final value I_{ss} may be determined by assuming this change to take place in several stages as before. The value of α_c corresponding to each stage may be determined from equation 6. By substituting $\alpha_c=\lambda$ in equation 9, the corresponding value of K_3 may be determined. It should be noted that the quantity

$$[1-(2K_3-\pi\tan\phi)/K_3]$$

in equation 21 exceeds unity since the circuit is unstable during the transition. This is different from the previous case for operation in the stable region.

Theory of Ferroresonance

The circuit analyzed is the simplest circuit exhibiting unstable and multivalued behavior. The behavior of the circuit is important from both theoretical and practical considerations and has interested engineers for a long time. In a paper by Suits,[6] and subsequent papers analyzing the same circuit, for the less ideal case of gradually varying inductance, the jump phenomenon occurring in this circuit is attributed to an instantaneous resonance taking place when the nonlinear inductance (variable with the amplitude of the forcing function) reaches such a value as to resonate with the fixing capacitance. This is probably the reason for using the term ferroresonance to refer to the jump phenomenon. This phenomenon still exists, and becomes even more prominent, when the saturation characteristic of the nonlinear reactor becomes sharper as indicated in Fig. 3, where curve *a* corresponds to an ideal magnetization characteristic consisting of regions of zero and infinite inductance as indicated in Fig. 2. Since such a reactor having an instantaneous inductance of either zero or infinity could not resonate at any instant with a finite capacitance, such an explanation of the phenomenon is thus contradicted. Another explanation of the phenomenon is attributed to an average resonance between the nonlinear reactor and the fixed capacitance. This view may be contradicted from an examination of equations 11 and 12, describing the dynamic behavior of the circuit on an average basis. Since these equations are only of the first order, there is no possibility of an average resonance.

An accurate explanation of the ferroresonance phenomena may be based on the following two concepts.

NEGATIVE RESISTANCE

The concept of the negative resistance to explain the unstable behavior of a series ferroresonance circuit has been used in the literature. However, no direct mathematical proof of the existence of a negative resistance has yet been given, except indirectly through resort to graphical plots of equations in which the presence of negative slopes are detected. In this paper this concept is varified mathematically from an investigation of the stability of equations 11 and 12 directly, without the need for graphical plots.

FEEDBACK

The concept of feedback to explain unstable behavior was pointed out by the author in reference 4, where an ideal series ferroresonant circuit was analyzed for the case of sinusoidal applied voltage and the instability was attributed to the charge on the capacitor acting as a voltage source helping the applied voltage to saturate the core. Thus, at the instant when the critical firing voltage is just exceeded, the reactor fires and the capacitor charges. The constant voltage V across the capacitor during presaturation intervals in helping the applied voltage will reduce the presaturation intervals; consequently, the conduction intervals are increased. The increase in conduction angle causes more current to flow which, in turn, raises the presaturation voltage across the capacitor. Such an accumulative action, which may be considered as voltage feedback, was used to explain the reason for instability. However, due to the complexity of equations involved, it was not possible to derive the corresponding feedback loop. The simplicity of equations deduced in this paper on the basis of a rectangular excitation makes such a representation possible. This is indicated by the nonlinear closed-loop diagram of Fig. 10, which corresponds to equations 4 and 5. The nonlinear transfer functions depend on the conduction angle which is considered as the output, while the nondimensional applied voltage $E/AB_cN\omega$, is considered as the input. The feedback quantity is $V/AB_cN\omega$, which is the nondimensional value of the voltage across the capacitor during the nonconduction intervals. At $\phi=0$, the gain of feedback loop

$$[1-\epsilon^{-\tan\phi\alpha_c}]/10^8(\pi-\alpha_c)\alpha_c$$

is zero; that is, there is no feedback. For this case the ratio of input to output is given by

$$\frac{\alpha_c}{E^*/AB_cN\omega}=\frac{10^8}{2}\,[\pi-\alpha_c]\alpha_c$$

This equation may be written as

$$\frac{E^*}{AB_cN\omega}=\frac{2}{10^8}\,\frac{1}{[\pi-\alpha_c]}$$

This is the relationship between the applied voltage and conduction angle for a reactor with pure resistive load and rectangular forcing function. This may be proved by letting $\phi=0$ in equation 5. The addition of capacitance is, in effect, equivalent to the closing of the feedback loop. Thus, as ϕ is increased, the gain of the feedback loop increases. Consequently, $V/AB_cN\omega$, which is the feedback voltage, increases. This voltage which appears across the capacitance during the nonconduction intervals is added to the applied voltage; that is, the feedback is positive.

Appendix. Nomenclature

A = effective core area (measures area × stacking factor of the core material), square centimeters
B_c = critical value of flux density at which the core saturates, gauss
C = load capacitance, farads
E^* = amplitude of a constant rectangular alternating voltage applied to the ferroresonant circuit, volts
E_{DC}^* = mean amplitude or initial amplitude of a rectangular alternating voltage of varying amplitude, volts
$E^{*\prime}$ = variation of the amplitude of a rectangular alternating voltage from the mean average amplitude E_{DC}^* or from a given initial amplitude, volts
E_n^*, E_{n+1}^*, E_{n+2}^* = variation of the amplitude of a rectangular alternating voltage from the mean average amplitude E_{DC}^* or from a given initial amplitude, during n, $n+1$, $n+2$ half-cycle, volts
e = instantaneous value of voltage applied to the ferroresonant circuit, volts
f = frequency of the voltage applied to the ferroresonant circuit, cycles per second
I = half-cyclic average value of current flowing in the ferroresonant circuit, amperes
I_n, I_{n+1}, I_{n+2} = half-cyclic average value of current flowing in the ferroresonant circuit during n, $n+1$, and $n+2$ half-cycle of the applied voltage, amperes
I' = variation of the half-cyclic average value of the current flowing in the ferroresonant circuit from the mean average value or from a given initial value, amperes
I_n', I_{n+1}', I_{n+2}' = variation of the half-cyclic average value of current flowing in the ferroresonant circuit from the mean average value or from a given initial value, during n, $n+1$, $n+2$ half-cycle of the applied voltage, amperes
i = instantaneous value of current flowing in the ferroresonant circuit, amperes
i_n, i_{n+1}, i_{n+2} = instantaneous value of the current flowing in the ferroresonant circuit during n, $n+1$, $n+2$ half-cycle of the applied voltage, amperes
N = number of turns of the reactor of the ferroresonant circuit
Q = constant capacitor charge during nonconduction intervals, coulombs
Q_n, Q_{n+1}, Q_{n+2} = constant charge across the capacitor during the nonconduction intervals of n, $n+1$, $n+2$ half-cycle of the applied voltage, coulombs
q = instantaneous value of capacitor charge, coulombs
q_n, q_{n+1}, q_{n+2} = instantaneous value of capacitor charge during n, $n+1$, $n+2$ half-cycle of the applied voltage, coulombs
R_w = resistance of the reactor winding of the ferroresonant circuit, ohms
R_L = load resistance of the ferroresonant circuit, ohms
R = effective resistance of the basic ferroresonant circuit, $R=R_w+R_L$, ohms
V = constant capacitor voltage during nonconduction intervals
V_n, V_{n+1}, V_{n+2} = constant voltage across the capacitor during the nonconduction intervals of n, $n+1$, $n+2$ half-cycle of the applied voltage
v = instantaneous capacitor voltage
α_c = conduction angle for half a cycle of the alternating voltage applied to the ferroresonant circuit during which conduction is maintained at steady-state operation (defined in Fig. 5), degrees or radians
$\alpha_{c(n)}$, $\alpha_{c(n+1)}$, $\alpha_{c(n+2)}$ = conduction angle for the n, $n+1$, $n+2$ half-cycle of an a-c rectangular voltage applied to the ferroresonant circuit during which conduction is maintained for transient operation (defined in Fig. 5), degrees or radians
β = instantaneous value of flux density, gauss
λ = steady-state operation or mean conduction angle α_c of the ferroresonant circuit about which transient variation is assumed to take place, degrees or radians
τ = time of duration of half a cycle of the applied voltage, seconds
ϕ = phase angle of the basic ferroresonant circuit, $\phi=\tan^{-1}(1/\omega CR)$, degrees or radians
Φ = total flux
ω = angular frequency of the rectangular applied voltage to the basic ferroresonant circuit, radians per second

Discussion

R. H. Dennard (International Business Machines Corporation, Yorktown Heights, N. Y.): As Mr. Salihi points out, the conditions he assumes for his analysis should be considered as a limiting case of a general problem. His use of the word "idealized" should not be interpreted to imply any inaccuracy in the analysis which is perfectly valid under certain conditions. Perhaps those conditions should be outlined more clearly. The assumption of zero inductance for the saturated reactor is valid when the product R^2C is sufficiently large as compared with the actual differential inductance for the saturated condition. Under this condition the second-order differential equation for the interval of saturation gives effectively the same solution as the assumed first-order equation. The assumption of zero magnetizing current for the unsaturated reactor is valid when the capacitance is large enough so that it does not discharge appreciably due to the flow of magnetizing current. In addition, the circuit resistance must, of course, be small enough to have negligible voltage drop during the unsaturated interval. An analysis for the case in which the saturated inductance and the magnetizing current are significant factors has been given in the recent literature.[1–3] The mathematical relationships become somewhat more complicated, particularly for the case of sinusoidal applied voltage, but a physical understanding of the circuit behavior is still possible.

Mr. Salihi shows for the case under consideration that points of instability deduced graphically from minimum points on steady-state curves coincide with the points obtained from a mathematical investigation of the dynamic equations, claiming that the former verifies the latter. From this, one might tend to conclude that stability could always be determined by examining the slope of plots of average current versus applied voltage. That this is not valid is shown by the following example.

Evans[1] notes a case in which circuit operation with symmetrical waveforms is superseded by an unsymmetrical operation as the applied voltage is increased. Subsequent literature[2] shows that there is no negative slope in the current-voltage relationship at the point of transition, but an investigation using difference equations verifies the experimental evidence that the symmetrical type of operation becomes unstable at that point.

Gordon R. Slemon (University of Toronto, Toronto, Ont., Canada): I would like to commend Mr. Salihi for pointing out the error in applying the concept of resonance to this type of behavior. Resonance is normally associated with the cyclical transfer of energy between two energy-storage elements. In an ideal switching core there is no energy storage. Thus "ferroresonance consists of a cyclical energy transfer between a source and a capacitive element."

I would question the term "negative resistance" which the author has used. This term also arises from a doubtful analogy with the behavior of linear circuits. While there is a negative damping term in the expression for average voltage (equation 12), the fact that the average voltage is not in equilibrium does not imply the property of negative resistance.

There are other stable modes of operation of this simple circuit normally known as the subharmonic modes. I would appreciate Mr. Salihi's comments on the possibility of applying his difference equation methods to determine the regions of stability of these modes.

H. C. Bourne for Jalal T. Salihi: Dr. Salihi is now in Iraq, address unknown, and unable to write a closure to these discussions. However, I am sure that he appreciates the accurate and pertinent comments by Drs. Dennard and Slemon.

A Small High-Speed Transistor and Ferrite-Core Memory System

Synopsis: Memory for computer-type systems has received extensive study and design effort in the past few years. This effort has been directed mainly at producing faster, larger, and less expensive systems in the thousand- to mega-bit sizes.

This paper describes the design and operation of a 400-bit memory for use in a time-division electronic switching system.

THE design objective of our exploratory development project was to construct a 400-bit memory system to be used in a time-division switching system where the number of circuits controlled required 20 bits to be read out of the memory simultaneously. Our principal objective was to obtain as short a read-write time as possible under the following operating conditions:

1. Temperature. Since this memory was to be a part of a small system, used in a variety of locations, temperature control was not practical. Operation over an equipment temperature range of 30 to 140 F (degrees Fahrenheit) was required.

2. Simplicity and, consequently, cost. In a small memory system the access circuitry accounts for the largest part of the cost. Therefore, simplicity in these circuits was desirable.

3. Solid-state devices. For system size and reliability it was decided that only solid-state components: transistors, diodes, and ferrite memory elements, would be used.

Choice of Memory Element

Besides the ferrite core, there are a number of memory devices, such as the twistor, which are in various stages of research or development which offer promise of high speeds. However, for this system it was decided to use the ferrite core because of its present wide acceptance as a reliable device. Of the many commercially available cores with like characteristics and switching times in the 2-μsec (microsecond) range the General Ceramics Corporation *S4-F394* core was chosen.

General Systems Block Diagram

A block diagram of the over-all system is shown in Fig. 1. The information in each row of the core array is read and written back in time sequence. The read pulse from the horizontal drive circuit reads a row of cores. The signals from the 20 cores are examined by readout detectors which discriminate between a *1* and a *0*. Immediately following, a write pulse is delivered to the same row. Prior to the write pulse the system has received information as to whether the same or dif-

ferent information is to be written back into the memory. The write-erase logic then causes the appropriate vertical-drive circuit to produce write pulses. The coincidence of the horizontal and vertical pulses causes the selected cores to switch, thus writing the information. During the next time slot the adjacent row of cores, i.e., the next word, is subjected to the same operation. This process of reading and rewriting each word (or writing a new word) continues in a sequential fashion until all 20 words have been processed. The cycle is then repeated. The sequential operation of the memory is controlled by the binary counter which delivers 20 binary words to the horizontal drive and then recycles. The horizontal-drive circuitry acts as a stepping switch, sequentially selecting one out of the 20 rows in the memory.

The read-write operation for each word requires 5 μsec as shown in Fig. 2. This 5-μsec time slot is divided into the read and write phase by means of timing pulses from an external clock. The cycle time for processing all 20 words is 100 μsec.

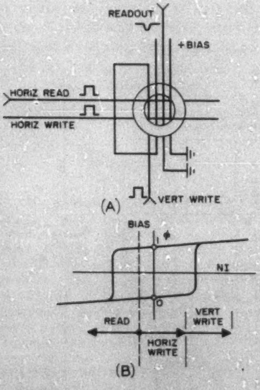

Fig. 4. Memory core connections

Memory Core

The memory-core characteristics place requirements on the access circuitry as well as determine, to a large degree, the systems operating margins. Twenty-five *S4* cores were measured and the resulting data are shown in Fig. 3. These data represent the limiting characteristics. For example, the switching-time curves show the slowest core-switching time for each of the conditions of temperature and drive. The output voltage represents the lowest output voltage for a *1* from any of the 25 cores. The walkdown (W_d) curve represents the highest read voltage from any core after a series of half-write pulses.

The W_d curves as plotted were obtained by using half the pulse current of that reported on the abscissa. Thus W_d at say 800 ma (milliamperes), is not with a disturbing current of 800 ma but of 400 ma. This is similar to actual system operation.

From Fig. 3 the unbiased operating limits can be determined. The drive-current limits are determined by three points:

1. The maximum amplitude of a series of half-write pulses at 140 F which will not cause switching of an unselected core. This current is found to be 400 ma.
2. The minimum amplitude of a full-write pulse, which will just switch the core at 30 F, is 660 ma.
3. The minimum amplitude of read pulse which will provide a satisfactory output signal, as determined from the curves, is 780 ma.

With no bias the operating points are then: read, minimum 780 ma; and one-half write, minimum 330 ma, maximum 400 ma.

Biased operation of the memory offers several advantages. When coincidence current operation is used only for writing, bias in the read direction offers the following advantages: greater variation in the half-write current, and reduction in read drive required.

Setting the bias at 300 ma the pulse current amplitudes are as follows: minimum amplitude of read, 480 ma; and one-half write, 480 ma to 700 ma.

Memory-Array Wiring

D-c bias and current pulses are applied to the memory core as determined by the wiring for the array which is shown in Fig. 4(A). Two horizontal wires are provided; one for the read-drive pulse and the other for the horizontal half write. Four vertical wires are provided; one for bias, one for the readout signal, and two for a double-turn vertical half-write pulse. A hysteresis loop of a core is shown in Fig. 4(B). The bias is in the read direction such that nominal-read, horizontal-write, and vertical-write drives are approximately equal amplitude.

Transistors

Two basic types of transistors are used throughout the memory system. One is a low-power n-p-n diffused silicon unit and the other a medium-power germanium-

alloy junction transistor. The germanium transistors are available in both n-p-n and p-n-p types. Table I lists some of their important characteristics. Three of the characteristics: high-current β, frequency cutoff, and power-handling capabilities, determine to a large extent the over-all systems design and performance. The number of stages necessary for a desired drive current depends on β, of course. The upper limit on the speed at which the access circuitry can be expected to perform depends on frequency cutoff and power-handling capabilities. These are not much out of line with the core performance for the design speed.

The silicon transistor is used wherever circuit design permits, and eventually it is expected that silicon will be used throughout. The vertical circuits make use of both types of transistors while the horizontal circuits are made up entirely of the germanium units.

Horizontal Drive and Binary Counter

Two basic building blocks are used to make up the horizontal-drive circuits. A 5-stage binary counter cycling from *0* to *19* establishes the means of sequential access to the 20 rows of the memory. Transistor-diode logic is then employed to instrument a binary to 1-out-of-20 translator. Distributed among the 20 rows are a total of 40 high-current memory pulses, 20 read pulses and 20 half-write pulses. The 5-stage binary counter's normal cycle of 32 is shortened to 20 by a reset circuit, or, more exactly, an advance circuit. A block diagram of the counter is shown in Fig. 5(A). The binary-counter stages are of special design to provide a good output waveform. A circuit diagram is shown in Fig. 5(B). Diodes connected between the transistor's collector and the cross-coupling capacitor provide isolation which permits an output waveform determined largely by the transistor characteristics and not by other circuit elements. Also, diodes have been connected between base and collector terminals of the transistors to limit the degree to which high-β units will go into saturation. Rise and fall times of the counter stages average about 0.1 μsec and 0.7 μsec, respectively. The longest advance time, when all stages are switching, is approximately 1 μsec. Since the transistors employed in the counter are of the medium-power variety, they are capable of 200-ma output-pulse current which minimizes the number of subsequent amplifiers.

The horizontal-drive circuits are shown in block form in Fig. 6. The first two binary counter stages operate in conjunction with a binary to 1-out-of-4 translator to operate transistor switches on one side of the memory. On the other side of the memory the five transistor switches are operated from the remaining three binary counter stages and a 1-out-of-5 translator. Thus, the 1-out-of-20 selection is accomplished in matrix form with two translations: 1-out-of-4 and 1-out-of-5; these are combined as shown in Fig. 7. Relative timing is also shown in the figure. Two translations of 1-out-of-4 are used: one is combined with the clock-read pulses and the other is combined with the write pulses.

A rather high component efficiency is achieved by this circuit arrangement. A total of 37 transistors, including those in

the binary counter, provide the 40 horizontal read and write pulses.

A typical pulse-current path is shown in Fig. 8. Transistor *Q1* amplifies the clock pulse and drives four gate circuits similar to that connected to the input of *Q2*. The horizontal wire through the memory is shown in *RL*. With a positive-going pulse applied to one side of the memory wire an appropriate negative-going pulse is applied to the other by a circuit such as *Q3* and *Q4*. Transistors *Q1*, *Q2*, and *Q3* are p-n-p types and *Q4* is an n-p-n type. The binary counter and *X* pulse circuits operate between ground and the positive battery while the *Y* pulse circuits operate between ground and the negative battery. Stage *Q3* provides the inversion and voltage shift necessary to connect the diode logic from the binary stages to the n-p-n transistor *Q4*.

The power dissipation and, consequently, heating, among transistors is quite evenly distributed. The duty cycle for stages such as *Q2* is approximately one-eighth and for *Q4* it is approximately one-sixth. The collector voltage of the units is kept low during periods of high currents which keeps the collector dissipation to a minimum.

Operation of the memory depends on constant-current pulses, particularly in the write interval when the coincidence of horizontal and vertical pulses is required. The required current regulation is obtained from a voltage source and suitable dropping resistor. The variation in potential drops across transistors and diodes accounts for a large percentage of the existing current variation.

Readout Detector

During the read interval, the switched cores produce an output voltage and the nonswitched cores, a shuttle or noise voltage. These waveforms are shown in Fig. 2(B). The voltage amplitude of a *0* is made up of crosstalk as well as the core shuttle voltage. The readout detector must distinguish the wanted signal from the noise and it must reshape the wanted signal. To provide sufficient delay from the read to the write interval the detector output is stretched as shown in Fig. 2(D). This stretching is necessary for rewriting the information in the memory.

The readout detector diagram is shown in Fig. 9. It is a blocking oscillator circuit with collector-to-base feedback. Since the minimum output from the memory for a *1* is 100 mv (millivolts) and the maximum noise for a *0* can be as high as 50 mv during the read interval, the detector is designed to have a threshold of 60 to 90 mv. The input transformer provides a better impedance match between the memory and the blocking oscillator. The transistor is normally biased in the cutoff condition, and when the signal from the memory exceeds its threshold, an output is produced. The output-pulse width depends largely on the value of the inductance of the feedback transformer, the β of the transistor, and the circuit resistances.

In addition to the noise produced by the shuttling of the cores during the read interval, there is also a large noise caused by the coupling from the vertical-write wires. The noise from the vertical-write pulse is in the form of spikes, both positive and negative. The detector circuit does not respond to positive signals but the negative spikes

are in the same direction as the desired signal and about twice as large in magnitude. The negative spike occurs at the trailing edge of the write pulse just ahead of the read output. To guard against the noise, a 1-μsec interval is provided between read-write cycles and the memory output is strobed during the readout interval. Whether a *1* is present or not will be determined when the enabling gate in the detector circuit is operated. The memory-strobe pulse is shown in Fig. 2(C). Thus, the blocking oscillator detects the wanted signal during the read period and is disabled and insensitive to the noise signal at other times.

A second, and important, function of the detector is to produce sufficient delay in its output such that it overlaps the write interval and information can be recirculated. This delay is obtained by extending the detector-pulse width beyond the read period as shown in Fig. 2(D). To make sure of readout pulse stretching, the blocking oscillator is designed to have its natural-pulse width greater than the clock-pulse width and the clock pulse is then used to turn the blocking oscillator off.

Write and Erase Logic Gates

Writing new information and erasing the old is carried out by the write and erase logic gates. The circuit is shown in Fig. 10. The gates are the connecting links between the readout detector and the vertical-drive circuit. When a write pulse appears at the input of the write logic gate, an output is produced by the vertical-drive circuit. The coincidence of the vertical drive and the horizontal drive writes the information into the memory. When the information is read, it is also written back immediately if there is no erase pulse present. The write logic gate has two inputs, one is the output of the erase gate and the other is an external write pulse; the presence of either input will produce an output from the write gate.

Similarly, the erase gate also has two inputs. One is the output from the readout detector circuit, and the other is an external-erase pulse. The presence of an erase pulse will inhibit any output from the erase gate. On the other hand, the absence of the erase pulse in conjunction with a readout-detector output will produce an output from the erase gate. The erase-gate output is applied to the write gate and is transmitted to the vertical circuit.

Vertical Drive

The vertical-drive circuit provides a pulse of half the ampere turns required to switch a core in the memory. The current pulse must be coincident with the horizontal-write current. This is assured by letting a clock pulse determine the timing. The circuit is shown in Fig. 11. The first stage is similar to the readout-detector circuit in that it uses a blocking oscillator. The output from the logic gate begins during the read interval and lasts into the write interval. However, the blocking oscillator is kept cut off by the negative potential applied during the absence of the vertical-gating pulse. During the vertical-gating pulse, which is positive, the gating diode is cut off. An output from the logic gate is then allowed to trigger the blocking oscillator. The transistor will stay in the ON condition

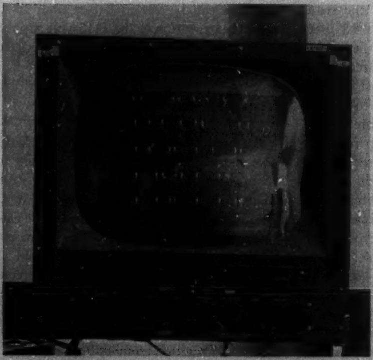

Fig. 14 (left). Visual display of memory contents

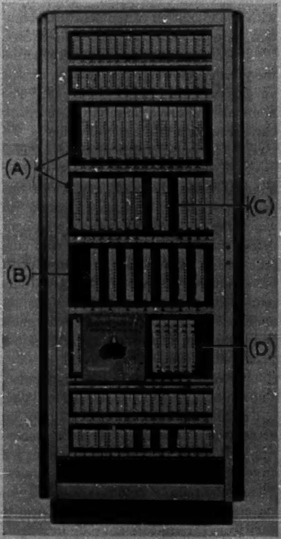

Fig. 15 (right). Memory system

A—Detectors and vertical drive
B—Horizontal read-write
C—Memory
D—Clock

until the gating pulse returns to the negative potential. Thus, in a manner similar to the readout detector, the vertical-output-pulse width in controlled by the gating pulse.

The second vertical-write stage is simply a transistor switch that provides 270 ma of current for driving the memory. The inductance in base circuit helps to turn the transistor ON and OFF rapidly and the rise and fall time of 0.2 μsec are obtained. Stretching of the pulse due to storage time is minimized by the large initial reverse currents provided by the inductor.

Over-all Operating Characteristics

1. Limiting conditions. Limiting conditions associated with reading and writing determine the range of successful memory operation. To have some measure of tolerances of the system, limiting pulse position, width, and amplitude were determined. Since the clock was designed with sufficient flexibility so that the timing and pulse width could be adjusted, easy testing of the memory was possible. The following items were investigated and the results will be discussed: (*a*). minimum horizontal read-pulse width, (*b*). minimum readout detector strobing-pulse width, (*c*). minimum coincidence between horizontal and vertical write pulse, (*d*). minimum read-write time, (*e*). maximum supply-voltage variation, and (*f*). high- and low-temperature operation. These tests, with the exception of temperature operation, were performed at room temperature.

2. Read pulse. Photographs of actual waveforms showing the timing of the various pulses are shown in Fig. 12. The nominal read-drive pulse is 600-ma peak current with a rise and fall time of 0.4 μsec. The pulse width at the base is 2 μsec. Keeping the other pulses at their nominal value, the read-pulse width was decreased. The limiting condition in which the readout detector can no longer detect the signal was when the read current looked like one-half sine wave with base width of 1.2 μsec and the peak current of 500 ma as shown in Fig. 13(A). It appeared that a 600-ma 2-μsec read pulse had sufficient margin to guard against circuit variations.

3. Readout-detector strobing pulse. The strobe pulse samples the memory output during the read interval. It can be made as small as 0.3 μsec in width occurring at the peak of the memory output for any one particular core in the memory. The strobe pulse is common to all detector circuits. Since the memory outputs vary from core to core not only in magnitude but also in waveshape, the strobe pulse must be at least 1 μsec wide in order to sample all the memory outputs.

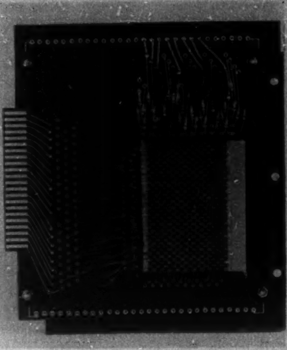

Fig. 16. Core memory array

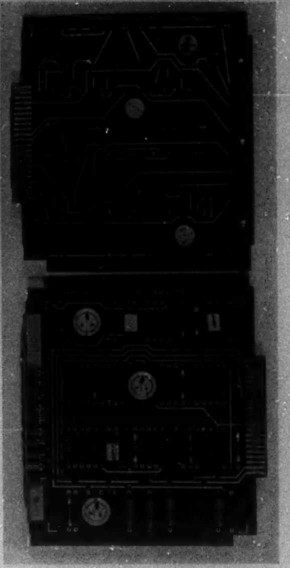

Fig. 17 (right). Vertical circuit component and wiring card

4. Coincidence of horizontal- and vertical-write currents. The results show that the coincidence between horizontal- and vertical-write-current pulses is not as critical as was expected. Their nominal pulse width, across the base, is 2.6 μsec as shown in Figs. 12(B) and (C). The vertical pulse was then set 0.7 μsec earlier and the horizontal pulse 0.7 μsec later than the nominal timing, and the memory performed satisfactorily. With coincidence of both vertical- and horizontal-write pulses the limiting-pulse width was 1.2 μsec as shown in Figs. 13(B) and (C). Beyond this, the memory can no longer recirculate its information.

5. Read-write time. The information just discussed indicates that as far as the memory element is concerned the read-write time can be decreased to 2.2 μsec. However, the outputs from the access circuitry vary from circuit to circuit such that 3 μsec is about the shortest possible read-write time that appears to be obtainable at room temperature. The present system was speeded up reducing the time slot from 5 μsec to 4 μsec to provide an indication of the margin. Time constants in the binary counters were chosen on the basis of 5-μsec time slot so that speeding up the clock beyond a 4-μsec interval was not possible. However, the operating with a 4-μsec time slot verifies the expected margin in the system.

6. Voltage tolerance. Large variation in supply voltage is a good measure of margin in the system. Seven different supply voltages are used in the drive circuits. Each voltage can be varied better than ±10%. The system also performed satisfactorily when all the supply voltages were set 10% higher and 10% lower than their nominal values, which represented their worst combinations.

7. Temperature performance. The memory system consisting of the horizontal-access circuits, the core array, and vertical-access circuits was tested at two temperatures, 30 F and 140 F. The system performed satisfactorily at these temperatures. In addition all the supply voltages can be varied better than 10% with the exception of the −12-volt supply at 30 F. It can only be varied between −11.2 volts and $>|-15 \text{ volts}|$.

Visual-Display Unit

To facilitate testing and also to check the operation of the memory system a monitoring device was constructed and placed in operation with the memory. The unit provides a visual display of the information circulating in the memory system. The bits are plotted on *X* and *Y* co-ordinates on a cathode-ray tube screen in direct correspondence with the core locations. Fig. 14 shows 40 bits distributed throughout 5 time slots as is obtained in an actual memory application.

Conclusions

The 400-bit memory system as installed in a practical application is shown in Fig. 15.

The wired-memory array as it is assembled on a printed-wire board is shown in Fig. 16.

The vertical circuits are arranged with a readout detector, write-erase logic and a vertical-write stage all on one printed board shown in Fig. 17. Twenty such vertical units are used in the system as described.

A high-speed ferrite-core memory system has been designed to provide reliable operation with voltage tolerances of ±10% over a temperature range of 30 to 140 F. A life test is presently being conducted on the system, and at the time of writing, it has been operating successfully without any component failures for more than 3,600 hours. The high degree of reliability has more than met the expected design objective.

Status of Sampled-Data Systems

E. I. JURY
MEMBER AIEE

Synopsis: This paper briefly describes in general terms procedures for analysis and methods of synthesis of sampled-data systems and indicates present areas of research and some of the important problems to be tackled in this field.

In particular, the following items are discussed:

1. Methods of analysis of linear sampled systems including the z-transform, frequency response, impulsive response, and difference equation methods.
2. Procedures for design of sampled-data systems or continuous-control systems employing digital computers. Both time and frequency-domain methods are described.
3. Types of physical implementation of discrete and continuous compensation networks.
4. Sampled-data systems with finite pulse width and pulse-modulated feedback systems and methods for their analyses.
5. Experimental study of a simulated system on a specially built computer.

This paper concludes by describing the present research activities in this field, enumerating some of the problems to be tackled, and suggesting areas for future research in this increasingly important field.

WITH THE complexities that have arisen in the area of automatic radar-tracking systems and with the advent of the use of digital computers in control systems, a considerable amount of activity has arisen in the field of sampled-data systems in recent years. In the course of investigating these systems several analytical techniques for analysis and design have been developed. The application of these techniques to fields other than sampled data is becoming increasingly important. For example, many economic systems, such as inventory control and production control, can be handled as sampled-data systems and hence the aforementioned analysis and design techniques can be applied to these systems. Furthermore, the purposeful introduction of sampling in systems to gain advantage in cost and weight of equipment is drawing considerable attention in industry.

The author wishes in this short paper to indicate some of the progress made in this field and some of the difficult problems yet to be investigated. For brevity, however, the author has found it necessary to concentrate on one aspect of linear sampled-data systems, and thus mentions only methods of analysis, methods of design, implementation of physical components, and finally, progress made in the pulse-modulated feedback systems. Many areas of research and progress have not been extensively discussed in this paper, such as statistical design, time-varying systems, nonlinear sampled-data systems, and variable sampling-rate systems which constitute much of the present activity in this field.

Applications of the techniques of sampled data to other fields, such as network and circuit theory, design of digital computers, numerical analysis, approximation problems to economic and biological systems, magnetic pulse-modulating systems, telemetry systems, information theory, and simulation of systems, constitutes a major area of progress made in this field, and should not be overlooked and, indeed, deserves much more investigation.

For further references on this subject, it is strongly recommended that the reader consult the two complete bibliographies published recently.[1,2]

Methods of Analysis

Sampled-data systems can be analyzed for stability, and their response to specific aperiodic inputs may be studied using any of the following methods: difference equation method, impulsive response method, frequency response method, or the z-transform method. These methods are discussed in detail in the literature and although each has its advantages and disadvantages, it appears from the trend of recent publications that the z-transform method is more promising.

DIFFERENCE EQUATION AND STATE VARIABLE METHODS

Sampled-data systems can be analyzed for stability and their response at sampling instants may be determined by sets of difference equations with constant coefficients.[3] For obtaining the total response, these difference equation coefficients become periodic functions. For sampled-data systems with periodically time-varying sampling rates, these equations become linear difference with periodic coefficients. Operational solutions of such equations are discussed in the literature.[4]

The state variable method[5] is based on the concept of introducing a set of numbers (called state variables) which contain all the past information of the system and from which one can evaluate the future behavior of the system for any input. By using vector notations for the state variable one can obtain the stability conditions and the output response of the sampled-data systems in terms of matrices.

IMPULSIVE RESPONSE METHOD

This method actually is a step-by-step method of analysis of sampled-data systems.[6] It has the advantage that the total response can be obtained, but suffers from computational labor and loss of insight to the behavior of the more complicated systems. It is based on the assumption that the finite pulses which excite the

system are approximated by impulses or delta functions.

Frequency Response and Signal Flow Methods

This method employs the conventional s-plane techniques.[7] However, since the exact description of sampled-data systems involves mixed transfer functions in ϵ^{Ts} and s, approximation techniques are necessary for this approach. The approximation involves the reduction of the polynomial of ϵ^{Ts} into a rational function of s and by doing so, the conventional techniques developed for continuous systems can be applied to sampled-data systems.

The signal flow method is a technique based on replacing the sampler by a signal source[8] to obtain input-output relationships for sampled-data systems. This technique has been extended towards obtaining a general input-output relationship for multisampled-loop sampled-data systems.[9]

z-Transform Method

This method[10,11] with its extension, the modified z-transform,[12–15] offers an exact method for analyzing single and multirate,[16] and periodically time-varying sampling rate,[17,18] sampled-data systems. It has the advantage that the output can be expressed in a closed form Stability studies are readily effected with this approach. The z-transform method is essentially one that transforms the difference equations into algebraic equations in terms of (ϵ^{Ts}) or (z). This method has a limitation in that it is based on the approximation of finite pulses by impulses. The extension of this method into finite pulsed systems is referred to as the p-transform[19] method which will be discussed in the section on sampled-data systems with finite pulse width.

Mathematical Equivalent of Sampled-Data System

Actual sampled-data systems operate with information of finite pulse width, with these finite pulses being fed into a linear system as shown in Fig. 1. The mathematical description of the sampler using the z-transform method is based on approximating the finite pulses by impulses whose areas are equal to the input amplitude at the sampling instants. This is only valid if the gain of the original system is multiplied by h. Furthermore, this approximation is valid only if h is small compared to the dominant time constant of the system, usually between 1/5 to 1/10. The equivalent mathematical model of Fig. 1 is shown in Fig. 2.

The two systems have almost identical outputs on the condition that: 1. $KG(s)$ has a continuous impulse response, and 2. the pulse width h is small compared with the dominant time constant of $KG(s)$. Experimental results indicating the effect of varying the pulse width for one and two time-constant sampled-data systems are introduced in the experimental study section.

In most papers on sampled data, the authors have been concerned with sampled data as such, as shown in Fig. 3. However, the experimentalist must recognize that this system can be closely approximated by the physically realizable system shown in Fig. 4, in which case a division by h is necessary. Thus, the preceding discussion shows that division or multiplication by h depends on the kind of analogy desired.

In most sampled-data systems, a sort of hold-circuit is used which converts the very short pulses (impulses) into pulses usually of constant amplitude for the total sampling period. In the cases where the hold-circuit is considered "ideal" the z-transform method is used as an exact description of the physical sampled-data system.

Furthermore, if rectangular pulses with finite width are used, then it can be shown that when the pulse width becomes small the z-transform is obtained provided the gain of the system is multiplied by the pulse width, and then when the pulse width approaches the sampling period (staircase shape) the gain of the system is unchanged. This method has been successfully applied by Zypkin.[15]

Synthesis of Sampled-Data Control Systems

In general, synthesis procedures can, on the whole, be divided into two categories:

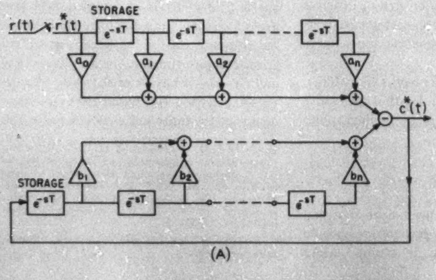

Fig. 7. Discrete compensator

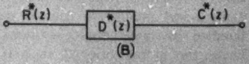
A—Programing
B—Block diagram



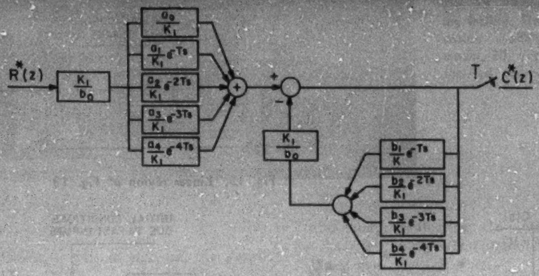


Fig. 8. Delay line of discrete compensators

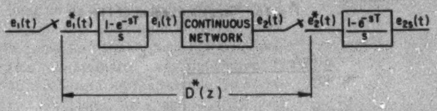

Fig. 9. Pulsed R-C network of discrete compensators

1. Synthesis with continuous compensators such as linear lumped-parameter networks.

2. Synthesis with discrete compensators, single or multirate, such as digital computers, delay lines, and pulsed networks.

As can be seen from the nature of classifications 1 and 2, synthesis procedures are somewhat different in each case.

In discussing the continuous network compensation method, it will be assumed for simplicity that series compensation, as shown in Fig. 5, is the desired form; however, minor loop compensation could be advantageously used depending on the system requirements.

The methods used for determining the transfer function $G_c(s)$ in terms of poles and zeros in the s-plane are the following:

Frequency response methods. These methods in turn could be subdivided into approximate and exact methods. The approximate methods are mainly Linvill's procedures[7] of Nyquist locus shaping in the $\Sigma KG(s)$ plane and Sklansky's z–s approximations.[30] The exact methods[18] are based on loci-shaping in the $KG^*(z)$ plane which shows the effect of $KG(s)$ poles and zeros on the sampled-data transfer function.

The frequency response methods, similar to the continuous case, are employed to yield a satisfactory value for frequency overshoots and bandwidths, which in turn influence the transient and steady-state behavior of the system.

Time-Domain methods. These methods are based on shaping the transfer function in the z-plane to yield a satisfactory response to aperiodic inputs or to certain error functions. From the over-all transfer function one can determine the z-transform of the compensating element either approximately or exactly depending on the rigid requirements imposed. Several methods[21] are proposed, mainly approximate, but they yield a realizable transfer function of the continuous compensator depending on the response requirements imposed.

The use of discrete compensators as shown in Fig. 6 simplifies the methods of synthesis considerably in view of freeing the compensator transfer function from the plant transfer function. Thus, the techniques developed for such procedures are tackled in the $z=\epsilon^{Ts}$ plane.

Similar to the continuous network synthesis both frequency and time-domain procedures are employed.

Frequency methods. These are divided into two categories: 1. shaping of the Nyquist diagram[32] in the KG^*z plane; and 2. shaping of the Bode diagram through use of the bilinear transformation:[33]

$$z=\frac{w+1}{w-1} \tag{1}$$

The frequency methods as proposed are exact and yield satisfactory results; however, frequency shaping mainly improves the response at the sampling instants. The modified z-transform can be readily employed in the frequency domain, wherein a certain measure of ripple can be estimated.

Time-domain methods. There are several methods proposed which are outlined in the following.

1. The time-domain synthesis method based on the forcing of the roots of the characteristic equation of the system to be at the origin in the z-plane[11,34] or at a particular parameter α between zero and unity, known as the staleness factor.[35]

2. The method of Bergen and Ragazzini[36] in designing the discrete compensator to yield a certain ratio of finite polynomials in Z which represents the transfer function in the z-plane.

3. Methods based on the modified z-transform to insure certain continuous responses, either dead beat or otherwise.[31,34,37]

4. Methods based on minimizing the total-square error or other error criteria.[28]

5. Root-locus method, based on relating the effect of pole and zero locations of the discrete compensator to the total response.[29,30]

This discrete compensator method, either in the frequency domain or in time-domain, can also be applied where digital computers are used in continuous systems, in which case T, the sampling period, could be changed.

It may be noted here that the use of digital elements in control systems greatly enhances the flexibility of design for the desired system output.

Physical Implementation of Compensators

The synthesis methods described earlier yield the transfer function required for effective compensation. Depending on the design method, either discrete compensator or continuous compensator transfer functions are obtained. The former is a rational function in z and the latter is rational in s. Since physical realization for continuous compensators are extensively covered in network theory

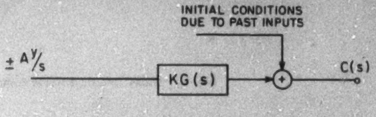

Fig. 16. Saturating region of Fig. 13

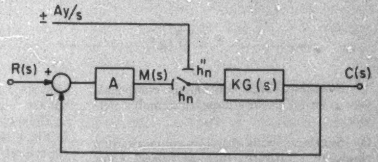

Fig. 17. Finite-pulsed feedback system of Fig. 13

their discussion is not elaborated on in this summary.

Discrete compensators can be physically realized through several methods, namely, programing, delay elements, pulsed *R-C* networks, and computer operational-instruction methods.

PROGRAMING METHOD[31]

With the growing field of digital computers and the development of various components in this area, the control engineer has the particular advantage of the use of such computers in the realization of discrete compensators. There are mainly three methods of programing: direct, cascade, and parallel, as well as cascade-paralleled programing. A typical diagram of a direct programing unit is shown in Figs. 7(A) and (B).

The choice of the method of programing depends on the number of storage registers, the computing time required, and the value of accumulation of round-off errors. Much research is directed toward construction of special computers for control systems.

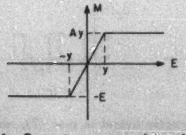

Fig. 14. Saturation type of nonlinearity

DELAY ELEMENTS METHOD[24]

This method indicates that the discrete transfer function where the numerator and denominator are rational polynomials in *z*, with the denominator of equal or higher order than the numerator, can be realized with the use of pure delay elements, voltage dividers, two algebraic summing devices, and two amplifiers. A typical configuration for such a realization is shown in Fig. 8. Methods of realizing pure delay elements are discussed in the literature.

PULSED R-C NETWORKS PROCEDURE[32]

This method utilizes *R-C* networks where the output is sampled in synchronism with its sampled input, as shown in Fig. 9. This performance is similar to that of digital computers, but with a considerable reduction in cost. However, this reduction is paid for with lack of flexibility. This procedure offers alternatives for realization; namely, cascade, feedback, and parallel or combinations of all of them.

OPERATIONAL-INSTRUCTION METHOD[11,25]

The realization of the discrete compensator using the pulsed *R-C* network requires in most cases a sampler and a zero-order hold in its output. This operational method removes this restriction by using a feedback realization procedure as shown in Fig. 10. This method can also be used for closely simulating the discrete compensator on an analog computer.

Sampled-Data Systems with Finite Pulse Width[10]

In the analysis of sampled data as discussed previously it is assumed that the sampler acts as an impulse modulator which is followed by a hold circuit before the information is fed into the plant. Based on this assumption the *z*-transform and the modified *z*-transform are readily applicable and have been successfully used.

In the situation where the pulses are of finite duration of comparable value with the system time constants, the *z*-transform does not yield the correct behavior for such systems. In such cases, a new form of Laplace transform called the *p*-transform could be used.

Consider an input to a sampler as shown in Fig. 11(A), the sampled output can be represented by Fig. 11(B), assuming a uniform pulse width *h* and fixed sampling period. Essentially, the sampler acts as a pulse modulator which can be mathematically described as:

Fig. 18. Computing facility, Donner analog computer model 30, and associated equipment

$$r_p(t)=r(t)u_p(t) \qquad (2)$$

where $u_p(t)$ is a unit pulse function shown in Fig. 11(C).

Taking the Laplace transform of equation 2 and effecting the complex integration in the v-plane yields for the transform of the output.[13] (The v-plane is a complex variable plane in which equation 3 is evaluated using the contour Γ. In this integration the variable s in $R(s)=r(t)$ is replaced by v, and in $U_p(t)$ it is replaced by $s-v$. For a complete discussion on the evaluation of the integrals in equations 3 and 7, the reader is referred to section 9.1, pp. 313–317 of reference 35.)

$$R_p(s)=\mathcal{L}[r_p(t)]=\frac{1}{2\pi j}\int_\Gamma R(v)\times \frac{1-\epsilon^{-h(s-v)}}{(s-v)[1-\epsilon^{-T(s-v)}]} \qquad (3)$$

where $R_p(s)$ is called the p-transform of $R(s)$ or $r(t)$ and denoted by:

$$R_p(s)=P[R(s)]$$

Evaluating the integral in the left half-plane enclosing only the poles of $R(v)$, $R_p(s)$ becomes:[13]

$$R_p(s)=\sum_{\substack{\text{roots of}\\ B(v)}} \text{Residue of} \left[\frac{A(v)}{B(v)}\frac{1-\epsilon^{-h(s-v)}}{(s-v)(1-\epsilon^{-T(s-v)})}\right] \qquad (4)$$

where

$$R(s)=\frac{A(s)}{B(s)} \qquad (5)$$

Equation 4 indicates that the p-transform of $R(s)$ is composed of rational functions of ϵ^{-hs}, ϵ^{-Ts}, and s. Once the transform of the sampler output is found, the usual Laplace transform procedure can be used to find the transform output $C(s)$.

To obtain the time output the inverse p-transform is effected which is based on the inverse modified z-transform procedure to give:

$$c(t)=P^{-1}[C(s)]=Z_m^{-1}[C^*(z,m)] \qquad (6)$$

where $C^*(z,m)$ is the modified z-transform of $C(s)$.

Alternately, evaluating the integral for $R_p(s)$ in the right half-plane of the v-plane[13] gives the following:

$$R_p(s)=\sum_{\substack{k=-\infty\\ k\neq 0}}^{k=\infty} R(s-jk\omega_r)\times \frac{1-\epsilon^{-jhk\omega_r}}{k}+R(s)\frac{h\omega_r}{2\pi} \qquad (7)$$

where

$$\omega_r=\frac{2\pi}{T}$$

Equation 7 yields for the limiting cases:

$$h=T,\ R_p(s)=R(s) \qquad (8)$$

and when $h=0$ and the pulse function approaches a unit impulse, $R_p(s)$ becomes:

$$R_p(s)=R^*(s)=\frac{1}{T}\sum_{k=-\infty}^{k=\infty} R(s+jk\omega_r) \qquad (9)$$

The form of $R_p(s)$ given in equation 7 can be used for approximate analysis of finite-pulsed sampled data in the frequency domain.

Approximation methods for finite-pulsed sampled data based on flat-top pulses has been used by Zypkin. Also for these approximations the modified z-transform can be applied as also discussed in detail by Zypkin.[15]

Finite-Pulsed Feedback Systems[33]

Extension of the techniques developed in connection with the p-transform, for exact analysis of feedback systems taking into consideration the actual pulse shape, can be easily applied. The mathematical details are straightforward and discussed by Farmanfarma;[33] however, the principle of the analysis is based on representing a finite-pulse feedback system, shown in Fig. 12(A), by its equivalent model shown in Fig. 12(B). Stability studies can be made, and the actual response can be easily calculated.

Application of Finite-Pulsed Systems Theory to Nonlinear Systems

The theory developed in connection with finite-pulsed feedback systems can be advantageously applied to nonlinear

B—Continuous impulse response; errors small for sufficiently small h

feedback systems. This is due to the equivalence of such systems as shown in the following.

Consider the feedback system shown in Fig. 13 with a saturating-type nonlinearity indicated in Fig. 14.

The characteristics of this nonlinearity are:

$$M = A\,E \text{ for } -Y<E<Y$$
$$M = A\,Y \text{ for } \begin{matrix} E>Y \\ E<-Y \end{matrix} \qquad (10)$$

Such a system has two operating states: 1. when $-Y<E<Y$, the system will operate in the linear region; and 2. when $\begin{matrix} E>Y, \\ E<-Y \end{matrix}$ the system will operate in the saturated region.

The equivalent system of Fig. 13 in the linear and saturated regions are shown in Figs. 15 and 16.

The two states may be represented by the equivalent pulsed feedback system given in Fig. 17. In Fig. 17, h_n' and h_n'' are the durations for which the system remains in the linear and saturated states respectively. The switching from one state to another is achieved in zero time by assumption.

Such a system may be analyzed by the p-transform procedure.[33] In this method both the transient and steady state is obtained.

If the following steady-state condition is satisfied,

$$h_n' = h_{n+1}' = h_{n+2}'$$
$$h_n'' = h_{n+1}'' = h_{n+2}'' \qquad (11)$$

then the system can be considered to be composed of two periodic pulsed feedback systems for which the analysis techniques could be much simplified.

Pulse-Modulated Feedback Systems[34]

The effect of varying the pulse width as a function of the error is a useful means in compensating a continuous or pulsed system. Theoretically, this effect can be studied by a step-by-step procedure. This procedure yields information on the transient response for the first few sampling intervals.

Experimentally, variable pulse-width systems have been investigated in detail and typical useful results stabilizing a continuous system are indicated in the following section on experimental investigation. Further, theoretical and experimental investigations are indeed warranted and recent advances made in the theory of nonlinear difference equations and sampled-data systems can be advantageously applied to the study of pulse-width modulated systems.

Experimental Investigation of Sampled-Data Systems

1. those results which are concerned with the checking of the theory and the effect of the simplifying assumptions made in the analysis; and 2. those results concerning the behavior of sampled-data systems under certain conditions such as variable pulse width.

These experimental results are only typical experiments made of sampled-data systems and by no means constitute an exhaustive study. These experiments were performed at the University of California in Berkeley on a specially built analog computer with special adjustments for sampling, holding, and other facilities for variable pulse width and/or sampling rate. This computer is shown in Fig. 18.

In the first category, Fig. 19 shows the actual response of a single integrator and two-time-constant system (continuous impulsive response) for values of pulse width h. These experimental curves can be compared with the theoretically computed curves [shown in Figs. 20(A) and (B)] based on the assumption of replacing the finite pulses by impulses and hence the use of the z-transform and the modified z-transform.

In the synthesis part and especially in the time-domain synthesis of sampled data using continuous networks, two typical figures are indicated.

Fig. 21 indicates the form of the plant forcing function $e'(n,m)T$ produced by the fourth-order network shown in Fig. 22. This plant-forcing function can be changed to achieve different responses depending on the complexity of the designed continuous network.

For the discrete compensator method of synthesis, Fig. 23 indicates the staircase step-shape input to the plant following the hold circuit of the discrete compensator.

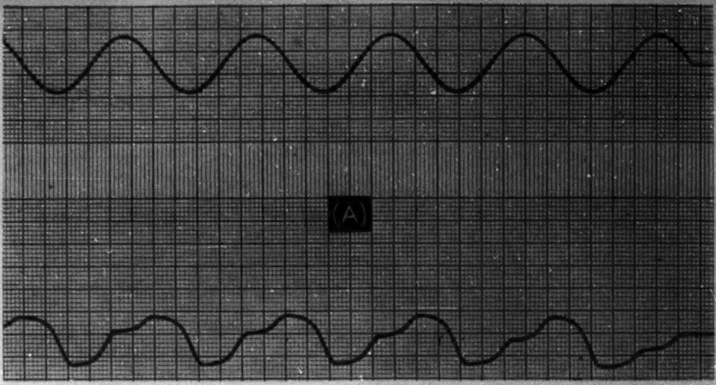
For the synthesis procedure based on the finite-pulsed theory developed for constant pulse width and sampling rate, Fig. 24(A) indicates the step response of a second-order pulsed-feedback system to be compared with the theoretically computed response of Fig. 24(B). Similar comparison for a sinusoidal input are indicated in Figs. 25(A) and (B). It is of interest to note that the response is not sinusoidal as in the cases of sampled-data systems (with almost zero pulse width) and continuous feedback systems.

Among the experimental results of the second category, Fig. 26 indicates the step response of the continuous system and pulse-modulated system. It is noticed that in both cases the pulse-modulated system has a stabilizing effect for it reduces the oscillations. Thus this system can be used as a compensating procedure for a continuous or sampled system provided the pulse width can be varied. Extension of this experimental study for higher-order systems both linear and nonlinear is undoubtedly of importance.

Conclusions

From this summary of some of the progress made in the field of sampled-data control systems, it appears that the linear theory is well organized and integrated. All the information related to linear systems is readily obtainable through any of the several methods of analysis and design mentioned in this progress note.[84] Other features of progress in this field have not been indicated because of limitations in space. Some of the problems which need more investigation in the coming years and which are presently undergoing extensive research are classified in the following three categories:

1. Nonlinear sampled-data control systems. This includes methods of analysis, design, and implementation of nonlinear digital controllers. Research on nonlinear difference equations and difference differential equations is necessarily warranted. The describing function method and the phase plane have been applied with a certain degree



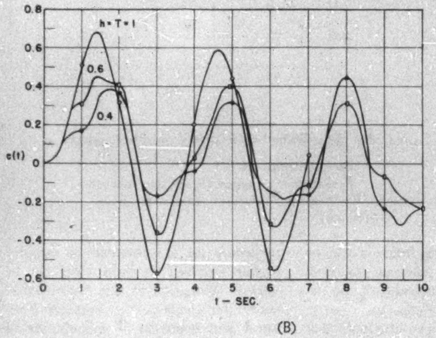


Fig. 25. Second-order system

A—Sinusoidal response
B—Response of system to sinusoidal input

$$R(s)=\frac{2}{s^2+4}$$

of success, but much ought to be done in the general case of nonlinear sampled-data systems.

2. Statistical theory of sampled-data systems. Extension of the Wiener Theory to sampled data has been successfully applied and the use of digital-filter theory in analysis and synthesis needs more research.

3. Adaptive sampled-data control systems. This category includes time-varying sampled-data systems which include varying sampling rate and pulse width or both, also the time-varying digital compensator element to adapt its operation to wide varieties of operating conditions and predicted signals operating in the system. Information theory fields can indeed be applied and extended to perfect the operation of sampled-data systems.

It is hoped that the material of this short discussion will summarize one aspect of the progress made in particular in linear sampled-data feedback systems, with much to be reported on the progress in other facets of this increasingly important field.

Nomenclature in Sampled-Data Field

$KG(s)$ = system-transfer function
s = complex variable of the Laplace transform
z = complex variable of the z-transform (equal to ϵ^{Ts})
w = complex variable in the ω-plane
$\sqrt{\;\;}$ = dummy complex variable
α = staleness factor always between zero and unity
k and n = positive integer
m = continuous variable always $0 \leq m \leq 1$
t = continuous variable, time
ω_r = sampling frequency
h = pulse width
T = period of sampler
$U_p(t)$ = unit pulse function
$r_p(t)$ = sampler output with a finite pulse width
$r^*(t)$ = sampler output with zero pulse width
$R_p(s)$ = Laplace transform of $r_p(t)$
$R^*(s)$ = Laplace transform of $r^*(t)$
$R(s)$ = Laplace transform of $r(t)$
$D^*(z)$ = discrete compensator transfer function
$C^*(z)$ = z-transform of $C(s)$
$C^*(z,m)$ = modified z-transform of $C(s)$
$C_n(s)$ = Laplace transform of the component of the output due to the $(n+1)$th input pulse
$P[\;]$ = p-transform of $[\;]$
$P^{-1}[\;]$ = inverse p-transform of $[\;]$
$z_m^{-1}[\;]$ = inverse modified z-transform of $[\;]$

Considerations Pertaining to the Design of an Electronic Telephone Switching System

B. BRIGHTMAN
MEMBER AIEE

M. P. TUBINIS
NONMEMBER AIEE

THE U. S. Army Signal Corps required a basic telephone switching system which could fulfill the functions of a local central office and provide the basis for a long distance (LD) switching center. In addition, a complete switching network was required, built up of a series of local and LD switchboards.

Due to the tactical character of this network it was required that each office be self-contained and fully transportable either by air or ground. Therefore, weight and size was of the utmost importance. At the same time, however, in order to provide maximum service under emergency tactical conditions the LD central offices were to provide nonblocking facilities. The trunk capacity of each LD office was specified at 160 trunks and 80 links. The local central office, however, was not required to be of a nonblocking type, but did require a relatively high grade of service comparable to a commercial system. Two-hundred-line 80-trunk 60-link circuits were specified for this board. The conflict of requirements here, that is, weight and size versus line, trunk, and link capacity, brought forward the request for an all-electronic system utilizing solid-state circuitry to the maximum extent.

To provide for ease of maintenance, standardization of circuitry in the two types of switchboards was essential. This principle, therefore, underlined the basis for the design of the switchboards.

Skeleton models were built and performed satisfactorily. The first two fully equipped service test models have been produced and are now undergoing production tests.

Nomenclature

TDM = time-division multiplex
SD = seize detector
LC = link circuit
CC = control connector
SSD = seize-signal detector
RA = register allotter

Paper 59-182, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted November 24, 1958; made available for printing April 8, 1959.

B. Brightman and M. P. Tubinis are with the Stromberg-Carlson Company, Rochester, N. Y.

The authors gratefully acknowledge assistance provided by members of the Switching Branch, Data Processing Division, Communications Department of the U. S. Armed Services Research and Development Laboratories, particularly G. Bartle and T. Pfeiffer. Acknowledgments are also extended to the numerous engineers of the Telecommunication Division of Stromberg-Carlson, in particular to S. Weiner, J. G. Pearce, G. O. K. Schneider, and T. Frankel for the contributions made in solving the many problems that existed.

MSD =multifrequency signal detector

Choice of Cross Pointing

A summary of various types of speech cross pointing soon showed that in order to meet the space and weight requirements full utilization of the high-speed characteristics of transistors would be required. For example, a space-division method of providing a speech connection in a balanced nonblocking system would require a cross point per line or trunk per connection to every other line or trunk in the board. For a 160-trunk board this would require (160^2-160) 2 to give 50,880 transistors. However, by utilizing a time-division system the number of transistors required could be reduced, depending upon the trunking configuration, to 4,480 transistors to provide exactly the same facilities. The overwhelming space and weight advantage clearly indicated that our design should be based on a time-division system. After a feasibility study, our design of the complete system was started, and the entire project was split into three main fields of endeavor. These were:

1. Design of a TDM speech path.
2. Design of signaling equipment (such as voice-frequency receivers).
3. Design of an over-all switching system based on items *1* and *2*.

Separate papers[1] are being presented on items *1* and *2* and will not, therefore, be discussed at this time, except as will be necessary to an understanding of this paper.

Trunking

The first tentative system design was based on the following premises.

To meet the nonblocking requirements a link circuit to connect a calling line to a called line would have to be provided on the basis of 1/2 (total line and trunk capacity) of the board. Provision of this very large number of links could be achieved by two methods. One method was to assign a fixed time position per link which required that a line or trunk circuit had to be capable of selecting any one of the total time positions or slots available in order to be able to set up a speech connection. The other method was to allot a fixed time slot to a line circuit and make each link circuit capable of switching to any one of these allotted time slots. This latter method was finally adopted after consideration of the fact that it was obviously desirable to minimize the amount of equipment on a line-circuit basis. It was decided, therefore, to make the link circuit the variable factor as regards time-slot storage and also for it to provide access to supervisory tones such as ring tone, etc.

Before any calculations could be made regarding equipment required, it was obviously essential to know the total number of time slots that could be used within a given frame period, in order to reconstruct the original information after it had been sampled. It is common knowledge concerning time-division multiplexing that the information sampling rate should be at least equal to two times the maximum frequency being transmitted.

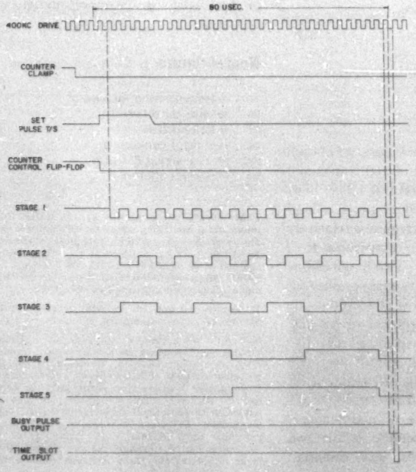

Fig. 1. Timing diagram of time-slot storage counter

At this point it is well to stop to consider the specifications relating to the transmission characteristics of the system, as the choosing of a suitable frame time, sampling time, guard time, etc., was based on these specifications. The salient requirements are as follows:

1. The transmission path had to be capable of carrying data information which limited the maximum delay distortion that could be tolerated through each switchboard to 10 μsec (microseconds).
2. Adjacent channel crosstalk had to be greater than 50 db (decibels) below 0 dbm (db referred to 1 milliwatt) reference level.
3. The insertion loss of the board had to be limited to 0 db ± 0.5 db.

Calculations showed that a frame repetition rate of 12.5 kc would enable us to meet the requirement in item *1* with a relatively small amount of phase equalization circuitry.

In order to meet the requirement of item *2* we had to be sure that the time between successive sampling periods was long enough for the energy stored in the highway (due to stray capacity effects) to decay. This could be met by providing a sufficiently long guard time. However, to ensure that this crosstalk limit was met, irrespective of highway loading and length, it was decided to include an artificial discharge circuit to dissipate any signal energy still present after the assigned sampling period.

This left the insertion loss specification mentioned in item *3* as a factor to be considered in deciding what sampling-pulse width would be used. The use of resonant transfer-type time division is dependent upon pulse-width stability to ensure full transference of sampling power. Therefore, any variation in rise or fall times of two connected multiplexed gates would give an equivalent percentage variation in transferred power level. Due to this, the wider the sampling pulse, the smaller the effect of differences between rise times of differing transistors.

With these factors in mind, the selection of sampling, guard, and frame times was made, bearing in mind the effects they would have on the switching and storage circuitry.

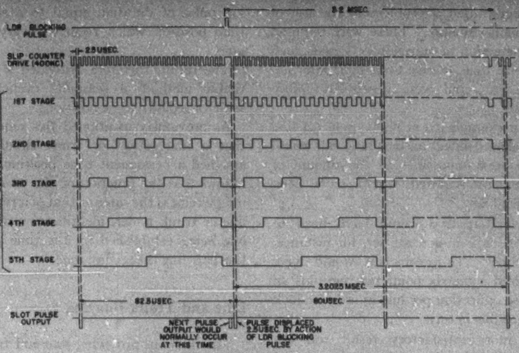

Fig. 2. Timing diagram of slip counter

For simplicity of circuitry and the use of as low a number of components as possible, it was decided that binary storage of time-slot information would be used. A binary number of time slots per frame was therefore desirable. As a result, a frame period made up of 32 time slots was investigated, which, by using a one-to-one ratio of sampling-to-guard time, would provide directly the basic clock frequency of the system. The clock frequency, however, had to be such that transistor characteristics would enable reliable working of the switching circuits, while the sampling time of each time slot had to be sufficiently long to enable the insertion-loss specification to be met. As a result, it was decided that 1.25-μsec sampling and 1.25-μsec spacing between sampling pulses would meet transmission requirements. This gave an over-all pulse cycle of 2.5 μsec per time position or a clock frequency of 400 kc. As already stated, 32 time slots per frame were required; therefore, the frame time was given as (2.5 μsec) 32 which gave 80 μsec per frame or $10^6/80$ which equalled 12.5 kc. With these characteristics specified, work on the transmission and switching circuitry was started.

Storage of Time-Slot Information

The next development stage provided for the manipulation of time-slot intelligence within the switching circuitry. This refers to the manner in which any two terminations could be connected via one of the available number of time periods.

One method, for example, to connect two lines is to allot a common time period to each of the terminations. This, however, requires storage of the time information in each of the two lines.

Two types of storage are available: static and circulating. A look at the static-type memory soon indicated that a large number of components would be required as a separate store per line per time slot would be required together with associated input and output gating. When it is considered that a store such as this would have to be provided per termination, then, for a nonblocking board, a very large number of components would be required. Very rapidly, therefore, the conclusion was reached that a circulating type of memory would be used.

The selection of a transistor counter-type store to provide this function was made, based on the premise that as the system would be of a common control type, fail-safe type of circuitry would be used as far as possible. A transistor-type counter store more nearly approached this requirement. For example, if a failure of the common pulse-drive supply occurred, then each time store in operation at that time would maintain its position with relation to each other store in use; so that when the drive supply was re-established the time relationship between time stores would be maintained, which would not be the case if a delay line had been used. Consideration was also given a slaved multivibrator-type circuit but was discarded for the same reason as for the delay line.

The transistor binary counter that was developed for time memory met the requirements of size, simplicity of operation, and ease of manipulation. The use of a binary counter in this application as opposed to a decimal-type ring counter had several advantages and yet did not have the disadvantage of requiring complicated multiple-output gates in order to extract each count point. The main advantage of using the binary counter was obviously size, as we required at least 32 separate time positions in a frame. With a ring counter-type store, 32 flip-flops would have been required or a 4 by 8 matrix-type count, as against a 5-stage flip-flop binary counter. Frequency breakdown was another desirable feature of the binary counter not given by a ring counter, as only the first stage of the binary is a high-speed count and each subsequent stage is frequency halved. The usual disadvantage of a binary-type store which requires multiple-output gates did not arise, as, in the type of operation in which it was required, we were only interested in obtaining a single output. True, this output had to be capable of producing a pulse related to any of the 32 time positions in the frame but this was obtained by initially triggering the counter at the time interval required so that its output pulse was directly related to the time period of the count initiating pulse; see Fig. 1. For example, if 32 separate counters are considered, each in a static condition, and reset to the same position and each then triggered consecutively by one of the 32 time-position pulses, then at the end of the frame each of the 32 counters would be running but each would be out of step by the count of one compared with the preceding counter. The over-all result therefore, if each of the outputs of the 32 counters were added timewise, would be to reconstruct the originating 32 separate time positions. Each counter therefore would provide an output pulse in phase with the time position of the pulse which initially triggered it.

Basically, therefore, all that is required to connect two lines together out of a multiple via a coincident time position, is a binary counter in each of the two line circuits preset to a fixed position. The trigger input to the two counters would be gated in simultaneously with a pulse whose time position is related to a "free" pulse within the 32 time positions constituting a frame. The two counters in each of the lines would, therefore, each produce a pulse coincident with each other which if applied to a multiplex switch would provide a speech connection between the lines.

Scanning of Voice-Frequency Detector Circuits on a TDM Basis

The various voice-frequency detectors that would be required throughout the system caused a problem in the use of common circuitry. These were required for detection of supervisory signals such as seize tone, release tone, digit information, etc., and were necessarily bulky in size.

For example, to provide an SD per line in order to detect an incoming call would have been impossible, as the amount of equipment required would have been tremendous.

An alternative would have been to provide a common SD per, for instance, 100 lines. However, this would have required a matrix point per line plus an audio connection per line in order to look at each line in turn.

A more satisfactory result was desired, therefore a method was evolved for scanning on a TDM basis so that individual space-division access to each line circuit was not required.

In order to utilize the already existing TDM switches providing speech access from each line to the multiplex highway, it was very quickly realized that if each line circuit was permanently allotted a time position and continuously pulsed, regardless of whether the line was busy or free, then a subscriber requiring a connection would transmit seize tone, which would be gated onto the multiplex highway via the line-circuit multiplex switches. It can be seen, however, that as each line is allotted its own individual time position, no connection between any two lines can be established without going through an intermediate time-coincidence conversion circuit.

Therefore, if a common seize detector was provided which had access to the multiplex highway and also had the facility to look at each time slot in turn for a period depending upon the recognition time of the detector, then it would, in effect, provide facilities to scan each line circuit without requiring any space-division equipment

The solution of this problem produced an economical, simple, and reliable method. All that was basically required was to provide a time-slot storage counter with the ability to, in effect, "slip" a time position after a suitably long period of looking at that time position. This was done by producing a "blanking" pulse, to inhibit the clock-driving pulse of the time-slot store (Fig. 2). The result was that the output of the time store provided a pulse shifted in time for each application of the blanking pulse. For example, it was found that the recognition time of the SD was 3.2 ms (milliseconds), therefore, a count-down counter was designed to provide a blanking pulse of duration equal to a single time position which recurred every 3.2 μsec.

The result, therefore, provided a very simple method of scanning cyclicly a series of separate time positions.

As previously mentioned this required that a line circuit or trunk circuit be assigned a permanent time position. It follows that the function of the SD scanning circuit is the same as that of a typical line or trunk finder, identification of the line being established by the time position carrying the seizure tone.

Line and Trunk Busying

The mode of providing line and trunk busying was the next problem to be tackled. Similar to the trunk and line-finding problem just discussed, a space-division method of providing a static store such as a flip-flop per line was obvious but required a large amount of space-division circuitry and interconnections. An investigation was instigated into methods of providing a circulating memory to indicate busy or free conditions, which would result in a single-wire busy-test facility. For example, if it was possible to indicate on a single wire what time positions were already in use, then it would be a simple matter for the routing circuitry to interrogate this wire to ascertain which time positions were already busy before setting up a required connection.

This gave a simple and economical method of providing busy testing facilities and the circuitry required was already provided. It has already been established that any common circuitry connected to a calling line would be connected via a time position generated by its own time-slot store. Therefore, if the output of this store was connected to a common bus similarly connected to all other circuits that generated a time slot, then any of these circuits generating a time pulse would also feed that pulse onto the common bus. By comparing the presence or absence of this pulse referenced in time with the known time position of a required connection then a line-busy condition would be detected by the presence of the busy pulse inhibiting the connections. The problem here was to ensure that the busy-line pulse was already present before actual testing, as differences in rise times of gating circuitry providing the coincidence checking might result in a faulty test condition. This was overcome by making the busy pulse originated by a time store, equal in width to a full cycle of the main-drive frequency of 400 kc. This provided a busy-pulse width of 2.5 μsec as against the time-slot pulse width of 1.25 μsec, thereby ensuring that a busying pulse would always be present on the busy-test bus before a coincidence check with a time slot was made.

This common bus, therefore, provided two basic functions: 1. It inhibited the common SD from looking at a line once that line was busied. 2. It provided busying intelligence to the line selector to enable that circuit to determine if a terminating connection was already in use.

Speech Cross Pointing Between Two Line Circuits

Since it was established that the line circuits would be assigned permanent separate time positions, the problem of providing a coincidence point for a speech connection was solved by providing an intermediate switching point between any two lines. This is called the link circuit (LC) and has, in effect, two separate time stores. Each time store controls a multiplex switch which allows the calling and terminating time-slot information of the relevent line circuits to be read into the line circuit to provide access to each line. Conversion at this point into audio intelligence was made so that it could be resampled by the time position of the other line, and also to provide an effective connection between the two circuits.

An understanding of this basic thinking behind the system will enable the following system description to be more fully understood.

Systems Operation

To describe the system which has been developed, some preliminary background information will be required. As stated previously, it is a TDM system utilizing 32 time slots of 1.25 μsec duration at a repetition rate of 80 μsec for 12.5 kc. A guard period of 1.25-μsec duration which precedes and/or follows each sample pulse, is used to clamp the previous signal period to reduce crosstalk to the required levels. These pulses are generated by the use of a binary counter driven from a 400-kc oscillator. In the local switchboard 200 lines and 80 trunks have to be provided with individual identities. This is accomplished by assigning 28 pulses to 10 separate paths or highways. These 10 highways are physically separated from each other and can only be switched

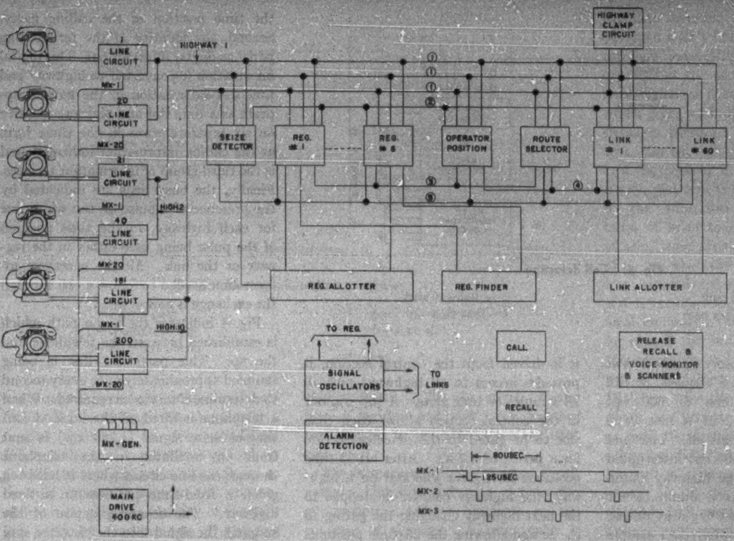

Fig. 3. Block diagram of local switchboard

1—Multiplex highways
2—Calling time slot and highways busses
3—Digit-transfer busses
4—Terminating time slot and highways busses
5—Busy-test busses

at the link circuit which will be described later. Since the 10 highways are isolated, the same pulses are used on each of the 10 highways. That is, pulse *1*, or *MX1*, will drive a send and a receive switch in a line circuit on each of the 10 highways simultaneously. The same is true for *MX2*, etc. In this way, 280 (10×28) individual identities are obtained.

The line circuit mentioned is the circuit at which the audio signal arriving is chopped up and distributed in time on to the highway. At the same time, any signal passing through the exchange in this time period is gated off the highway, converted to audio, and transmitted as an audio signal. All signals arriving and leaving the switchboard are audio signals. Each line circuit is assigned a permanent time slot, i.e., is constantly being sampled by a fixed *MX* pulse, on a given highway. This identity is unique and can be assigned a number which will select this line circuit. The method for selecting this number will be discussed later.

Up to this point, we have covered the subscribers' access to the exchange via line circuits. Now, the question of the amount and type of common equipment in the local switchboard which is used by the subscriber will be discussed (Fig. 3). The first item encountered is the SD which is a single unit consisting of a control connector (CC), seize-signal detector (SSD), and a control unit. These subunits will be covered with more detail when a call is followed through the exchange. The next unit utilized is the register allotter (RA), a single unit, which distributes the call into one of six subscriber registers (SR). Following the registers, is a register finder (RF), another single unit, whose function is to sequence the use of the route selector, which in itself is a single unit. The link allotter (LA), whose function is similar to the RA, distributes the call to any one of 60 links which are the only pieces of equipment remaining in the call during the entire conversation period.

In order to release the equipment a scanner periodically samples each link for release signal. This scanner also searches for recall, and is utilized for voice monitoring in order to release a link if it has been engaged and fails to release for some reason. Further discussion of this point will be carried out later. A ring-trip scanner also samples each link for the purpose of shutting off ringing.

The operator's position has direct access to every link on a common audio path that is controlled by switches. A call and an RCF, each an individual unit, seek out links which have been premarked as operator's calls or recalls, and provide both searching and cueing action for the operator. The operator's keyboard is of the throw-off type which can connect a call in a premarked link, extend a call, or give information after connecting to this link with the operator's key. However, after restoring the key to its normal position, the operator cannot reenter an established call unless a recall condition is placed on this link. A separate service link is provided for extension of calls originated by the operator. Digital information is keyed into a PR which is solely for the use of the operator.

The remaining equipments which make up the electronic section of the switchboard are the pulse and signal generating equipment, highway clamp circuits, routine test circuits, and alarm scanning and detection equipment. The binary counter which generates the *MX* pulses is denoted as the *MX* generator. The 400-kc generator, or what we refer to as the MDR generator, is the master clock which drives the *MX* generator and all other binary counters utilized in the exchange for generating sample pulses for driving audio switches similar to the line circuit. The signal generator and supervisory tone generator provide the audio tones for signaling in the system and any necessary supervisory tone. For signaling, 1,700 cps (cycles per second) is utilized as the seize signal; 1,900, 2,100, 2,300, 2,500, and 2,700 cps, utilized in pairs make up digital signals; 2,900, plus each of the previously mentioned frequen-

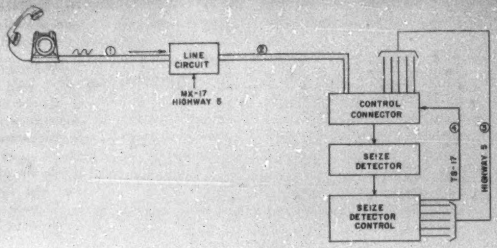

Fig. 4. Call detection

1—Audio path
2—Multiplex path
3—Highway mark
4—Time slot

cies, is used for supervisory signals such as release, recall, interlock request, or call terminated. Ring tone is 600 cps modulated at 20 cps, at a rate of 1 second on and 2 seconds off. Line and trunk busy tone are 600 cps interrupted at different rates. The highway clamp circuit simply acts as a dump circuit which is opened on every highway during the guard period following each sample pulse. Its purpose is to discharge stray capacities which would retain part of the previous conversation sample and allow this to leak into the next sample period. The routine test equipment is provided to allow service personnel to send calls into preselected registers and links for checking their operation. The alarm circuit is divided into two groups. One section is utilized to constantly monitor each highway. A constant tone of 1,000 cps is gated out in time position 32 and is detected by this circuit. If for some reason, this tone should not be detected, an alarm is given indicating a faulty highway. The second section is really a scanner which scans for various alarm conditions throughout the system, and upon finding one, gives a visual and audio indication.

This covers all the equipment other than the charger and batteries in the exchange which provide a 24-volt center-tapped output giving three potentials: plus, minus, and ground.

In tracing a call through the exchange certain preset conditions exist and certain scanning actions are in progress. The RA will have premarked a free register so that the next call coming into the exchange will be handled by this register. In a similar fashion, the LA will search out a free link and also premark this link to handle the next call.

The scanning action which is occurring is being carried out by the SDC. The CC is connected to all highways and since it is driven from the control section, it provides access to all highways and all 28 samples or time slots. A slip counter in the control section allows each time slot to be gated to the detector section for a period of 3.2 ms. After all 32 time positions have been checked on a highway, the highway counter is stepped to the next highway changing the gating to the CC and allowing the 28 time positions on this highway to be checked. This scanning continues until a seize signal (1,700 cps) is detected. At that time, the SSD sends a pulse to the control section which stops the scanning action of the unit and initiates a demand condition on the RA.

A little more information at this point will aid in following the call through the exchange. Three separate bits of information are transferred internally in the exchange. First, the identity of the calling party. This identity is in the form of highway and time-slot information. The highway is transferred by marking two of five leads and the time slot by gating out a negative pulse in the time position of the calling party. Second, the identity of the terminating party as digital information. This digital information is converted to highway and time-slot information in the RS and appears as a time slot and highway identity on six separate wires in the same form as the calling information indicated and is the third group of information accesses. Finally, the busy lines are indicated by the presence of a pulse on ten wires, one for each highway, in the time position of the pulse being used either in the register or the link. All the necessary information needed to follow a call through the exchange is now at hand.

Fig. 4 indicates the audio path which is established between the telephone and the SD. This particular line is being sampled approximately once every second to determine if service is required. When a telephone is lifted off the hook, a continuous seize signal (1,700 cps) is sent from an oscillator in the telephone through the line circuit where it has been given a fixed-time position on a fixed highway. The scanning action of the SD gates the signal into the detector stag where it produces a mark for the control section, stops the scanning action and thus retains the identity of the party originating the call. At this time a demand condition is placed on the RA to transfer the call to one of the registers. At this time, assuming that no other call exists in the exchange, no pulses are present on the busy-test busses. A busy pulse on one of these busses inhibits the SD from sampling this time position. However, the scanner does not advance, skipping a busy pulse in the scanning process.

Fig. 5 indicates the next step in establishing the call. As previously stated, a register is preallotted by the RA which

5—Time slot

has sequentially sampled individual busy-free leads from the registers, stopping on a register indicating a free condition. When a demand condition is placed on the allotter by the SD, a write signal or demand answer is sent to the SDC enabling it to write the identity of the calling party by marking two of the five highway busses between the SD and the register. At some time during this writing period, which would normally persist for 160 μsec, a time slot is transferred to the register which will open a gate allowing the 400-kc MDR pulse to drive a 5-stage binary counter, gating out a time slot to a CC identical to the one used in the SD. Simultaneous with the write signal to the SD, a read signal is sent to the preselected register allowing the identity of the highway to be stored in the static form, and enables the time slot from the SDC to trigger a binary counter for dynamic storage of the time position of this call. The register indicates busy after storing the information, showing this condition on the busy-free lead to the RA. After a write-read time of 160 μsec, the RA samples the busy-free lead from the register to determine if the information has been stored in the register. If, at this time, the register has failed to read this information and has not indicated busy, the allotter alarms this register and steps on to the next register, repeating the read-in process a second time. If a second attempt fails, the demand answer is removed resetting the SD; the call is abandoned, and a major alarm indicated.

Assuming that the register is operating satisfactorily, the information is read from the SD and a busy indication is forwarded to the allotter. The write signal is removed from the SD, resetting the SDC which proceeds to scan the exchange again. The RA steps off the busied register and seeks out another free register to premark it for the next call.

The memory unit in the register, which gates a highway and time slot to the CC, performs several functions in the progress of the call. A busy pulse is gated out of the register on to the busy-test bus associated with this highway in the time position of the calling party. This pulse inhibits the SDC from further sampling of this time position and is utilized by the RS in determining whether a line or trunk is busy or idle. At this time, the register acts as the terminating party (Fig. 6). The act of storing the identity of the calling party triggers the control section of the register. An MSD can be considered as the ear of the register while the control section can be considered as the vocal section. The initial action of the register is to check that the seize signal is true. No voice guard is present in the SD and a fairly wide band is sampled for a seize signal to obtain the high-speed response for the fast scanning action. The MSD is equipped with a full voice guard and narrow band-pass filters (band width ±50 cps around the signal frequency). The seize signal is passed into the detector which gives an indication if a true seize signal is present. If the signal is absent, the call is rejected after 20 ms and the register is reset. If the signal is real, dial tone is sent from the register to the subscriber following a timed burst of seize tone. This initial burst of seize tone preceding the dial tone is of no use when the call is placed directly from the subscriber; however, when the call is coming over a trunk from other local exchanges, this burst is responsible for closing the audio path of the link in the preceding exchange. This function will be explained in more detail later. Dial tone trips the seize tone in the telephone and persists for 10 to 20 seconds, or until the first digit is keyed. If the subscriber fails to key within this period, the call is rejected and the register is reset. A 10- to 20-second interval is allowed for every digit keyed until sufficient information is keyed into the register. When sufficient digital information has been stored, the input to the register is blocked and a demand condition placed on the RF.

Fig. 7 illustrates the next item of control equipments which are utilized in the progress of a call. The RF is brought into action by the demand from a register, and answers the demand by marking a lead to this particular register. This answer allows only the digital information to be read out of the register in 2-out-of-5 form on 15 wires. These wires are common to all registers, and as a result only one register is given access to the RS at any one time. The RF provides this controlling function. The appearance of digital information on the busses between the register and RS

starts the trunk hunting, or selection, of the required line.

At this time, the information present on the ten busy-test busses from the registers and links is utilized in selecting a free trunk or line (Fig. 8). If a trunk is required, the busy-test busses are scanned along with time slots assigned to this trunk group. Any trunk which is busy will inhibit the appearance of a pulse within the RS and will allow the scanning action to continue. As soon as an idle trunk in the group is scanned, a pulse appears which stops the scanning action, and this pulse may be assigned to the call. A secondary busy test is performed at this time to ensure that no call is being terminated or originated externally at this time. This reduces the unguarded time between exchanges to approximately 160 μsec, or the write time between the route selector and link. In the selection of a line circuit for a subscriber, the time slot of the desired party is gated out and compared with the busy test associated with the highway to which this party is connected to determine if this party is free. If this line is found idle, the highway and time slot of this terminating party is applied to another CC identical to that previously mentioned and a seize and release detector is allowed to sample the desired subscribers lines for a period of approximately 75 ms. If either a seize signal or release signal is present, a mark is sent to the control section of the RS and a busy condition is established for the line. In place of the identity of the required party being read out, an artificial time slot and highway is transferred to the link which will allow a busy tone to be returned to the subscriber.

Assume that the line is found idle, in which case, after a prescribed sample period, the line is indicated free and the read-out action occurs. Fig. 9 indicates the elements which enter into this action. Since the identity of the calling party is stored in the register at this time, this information must be read out of the register into the link. The same information busses which were used to transfer the identity between the SD and the register are used between the register and the link. To prevent any information which may be present on these busses between the SD and register from entering a link at this time, an allotter-inhibit signal is sent from the RS erasing any information present. A guard time of at least 160 μsec follows this inhibit signal prior to the read-write mark from the RS to both the register and to all links. The LA, however, has premarked one particular link so that the read mark will only be effective in this link. The control section of the LA also senses this write-read mark and starts a timing cycle, after which a sample pulse is sent to determine if the link has read the information presented. Here again, failure to read the information is assumed as a fault in the link, and the LA steps to the next free link and attempts to engage it. Failure here also triggers a major alarm which is indicated by the control section of the LA.

RS, the write-read mark in the register will allow the identity of the calling party to be transferred from the memory of the register to a similar memory in the link. Simultaneously, on a separate set of information busses, the identity of the terminating party is written from the RS to a second memory unit in the link. The terminating party may be a line, trunk, or busy-tone equipment in the exchange. The storage of both identities is the criterion for indicating a busy link. This is forwarded to the LA on the link-free bus which starts the LA searching for another free link, and resets the answer condition of the RF (Fig. 10). The removal of the answer condition on the register resets the register and removes the digital information from the RS. Removal of the digital information resets the RS erasing the inhibit allotter and write-read mark to the links and registers. At this time the only equipment remaining with the original call is the link. The link at this time is marking two time positions on appropriate busy-test busses corresponding to the calling and terminating party identities and prevents sampling of these by the SD (Fig. 11). Since the position of the two time positions does not coincide in most cases, the multiplex signals are converted to audio in the link circuit. The conversion to audio between two different multiplex pulses will also be used in the operator's connection and detection of supervisory signals by the release, recall, and voice monitoring equipment.

When the two time slots are transferred into the link, a splitting feature prevents the audio path from being completed while a ring signal is sent to the calling party and ring-back tone to the subscriber (Fig. 11). This splitting feature is also utilized by the operator to establish recalls by releasing one or the other party without breaking down the complete connection. A ring-trip scanner samples the audio portion from each link, and is looking for a seize signal from the terminating telephone. When the called party lifts the handset from the telephone, seize signal is sent as though a call was being originated. This signal is detected by the ring-trip scanner which triggers in the link a burst of 600 cps tripping the seize tone in the terminating telephone. At the end of this burst of tone, the splitting feature in the link connects the audio path and conversation can take place between the two subscribers.

Fig. 12 indicates those equipments which are engaged in what you might call a passive roll in the exchange. The release, recall, and voice monitor is periodically gated into the conversation by the scanning action, checking to determine that conversation is in progress and that neither a recall or release signal exists. When either party terminates the call by replacing the receiver, a release signal is sent from the telephone and is detected by the release detector when it samples this link, causing a temporary storage element to be set in the link. This gates out a regenerated release signal in both directions for a period of from 2 to 4 seconds. At the end of this period, the link is reset, erasing the stored identities in the memory sections of the link and producing a free condition. Resetting of the memory

units removes the marked time positions on the busy-test busses and these lines can again be scanned by the SD and appear as idle lines to the RS.

Each call through the exchange is processed in the same manner. The speed of setting up the call is approximately 700 ms excluding the time of dialing. From the time the last digit is sent into the register to the time the call is transferred into the link requires 80± 10 ms. The major portion of this time is spent in the secondary test performed in the RS.

The engineering test models of this system have been successfully demonstrated, and the larger service test models are in the process of being tested.

Mixed Transcendental and Polynomial Transforms

OTTO J. M. SMITH
MEMBER AIEE

THERE ARE a variety of engineering applications in which the dynamics of the equipment being used or designed are expressible by a Laplace transform which contains both polynomial functions of s and exponential functions. In networks and in feedback control systems, transcendental terms in the Laplace transform arise due to diffusion in a transistor, dead time or time of flow of materials in heat exchangers and flow reactors, catalyst flow time in a catalytic cracker, time of transmission of an electromagnetic pulse in radar and telemetering applications, time of transmission of an ultrasonic pulse in sonar, materials transport time in thickness controls for rolling mills, the sampling time in sampled data systems and in digital computer controls, and the carrier period in magnetic-amplifier and thyratron-type controls. This paper will present some of the basic features of the mathematical treatment of mixed transcendental and polynomial transforms. Root locus methods, complex-plane techniques for factoring polynomials, and evaluation of the residues for an inverse transform can all be performed through the use of two complex planes, one for the polynomial representation, and the other for the transcendental terms.

Lumped-Parameter Relationships

The simplest lumped-parameter network is that shown in Fig. 1, consisting of an RC low-pass filter. The transference or the system transform is defined as the Laplace transform of the output function of time divided by the Laplace transform of the input function of time, when all of the energy storage elements have zero energy stored in them at time $t=0$. With this definition, the system transform is identical to the Laplace transform of the impulse response of the network or the Laplace transform of the weighting function of the network. For the circuit in Fig. 1, the weighting function is

$$W(t)=\frac{1}{T}\epsilon^{-t/T} \tag{1}$$

The Laplace transform of this is

$$G(s)=\mathcal{L}W(t)=\frac{1}{1+sT} \tag{2}$$

The sinusoidal response of this network is the value of G when $s=j\omega$. The roots of the transference $G(s)$ for complex values of s are called the zeros of the transference. The roots of the reciprocal of $G(s)$, or the roots of the denominator of $G(s)$, are called the poles of this function. Fig. 1(A) shows the network, Fig. 1(C) the impulse response, and Fig. 1(B) a plot of the single pole of this network in the complex frequency plane. The pole lies on the negative real axis at a value of $-1/T$.

The step response of this system is the integral of the impulse response, or is the inverse Laplace of the system transference divided by s. The response to a unit step is shown in Fig. 1(D). All linear lumped-parameter dynamic systems have system transferences which can be represented by a ratio of polynomials in s. If the numerator is a Hurwitz polynomial the system is called a minimum phase system. If the denominator is a Hurwitz polynomial the system is stable. A basic characteristic of all lumped-parameter systems and of all transferences represented by a ratio of polynomials in s, is that every transient continues to infinite time and approaches its final values asymptotically. Only if the initial stored energies in a system are equal to the final values required by the input transient to the system is the final value realized instantly, and there will be no transient.

Distributed Parameter Components

The characteristics of nonattenuating distortionless transmission lines are shown in Fig. 2. A transmission line with time delay τ_1 will deliver a voltage $f_1(t)$, which is equal to the input of the transmission line $f_0(t)$ delayed in time by the amount τ_1:

$$f_1(t)=f_0(t-\tau_1) \tag{3}$$

The Laplace transform of the output of a transmission line is equal to

$$\mathcal{L}f_1(t)=\epsilon^{-s\tau_1}\mathcal{L}f_0(t) \tag{4}$$

When the input to a transmission line is a unit impulse whose Laplace transform is unity, then the transform of the output of the transmission line is

$$\epsilon^{-s\tau_1}$$

This therefore, is the transference of a nonattenuating distortionless transmission line or, in fact, the transference of any pure dead time. Figs. 2(C) and 2(D) show the delayed impulse outputs of two different transmission lines. If the two transmission lines are cascaded then the output is equal to the convolutions of the weighting functions of each network which are

$$W_1(t)=\delta(t-\tau_1) \tag{5}$$

$$W_2(t)=\delta(t-\tau_2) \tag{6}$$

The convolution of the weighting functions of these two cascaded transmission lines is

$$\begin{aligned}W_1(t)^*W_2(t)&=\delta(t-\tau_1)^*\delta(t-\tau_2) \\ &=(\mathcal{L}^{-1}\epsilon^{-s\tau_1})^*(\mathcal{L}^{-1}\epsilon^{-s\tau_2}) \\ &=\mathcal{L}^{-1}(\epsilon^{-s\tau_1}\epsilon^{-s\tau_2})=\delta(t-\tau_1-\tau_2)\end{aligned} \tag{7}$$

Paper 59-917, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21–26, 1959. Manuscript submitted December 16, 1958; made available for printing May 12, 1959.

Fig. 2 (right). Impulse responses of distortionless transmission lines, pure dead time

As shown in Fig. 2(E), this is a single impulse delayed by the sum of the delay times of the two lines.

Mixed Transcendental and Polynomial Transform

A mixed transcendental and polynomial transform is obtained by cascading a transmission line and a time constant. The Laplace transforms of the individual blocks are shown in Fig. 3. The substitution of the variable $-y$ defined by

$$-y_1=\epsilon^{-s\tau_1} \tag{8}$$

for the variable s will facilitate a variety of manipulations of these transforms. This is a conformal transformation from the complex s plane to the complex y plane. The impulse response of the system shown in Fig. 3 can be obtained either by the inverse Laplace of the product of the system transforms, or by the convolution of the weighting functions of each network. The over-all impulse response is

$$W(t)=\mathcal{L}^{-1}\epsilon^{-s\tau_1}\frac{1}{1+sT} \tag{9A}$$

$$=\delta(t-\tau_1)^*\frac{1}{T}\epsilon^{-t/T},\quad t>0 \tag{9B}$$

$$=\frac{1}{T}\epsilon^{-(t-\tau_1)/T},\qquad t>\tau_1 \tag{9C}$$

Notice that this function is zero up to the time τ_1 and then is a decaying exponential after that time. The waveform of the decaying exponential in Fig. 3 is the same as that shown in Fig. 1.

Infinite Series of Transcendental Terms

The impulse response of a system of transmission lines connected in cascade and in parallel can be only a finite number of impulses. But if the transmission line is connected in feedback, then a train of impulses extending to infinite time can be generated. This is illustrated in Fig. 4. The system consists of unity forward gain with a feedback branch including a pure dead time and the attenuation constant k. Instinctively, one knows that an impulse in will be delivered at the output immediately and that a delayed impulse of magnitude k will appear with negative sign after the time τ, due to the storage of this impulse in the feedback transmission line. The delayed impulse at time τ re-enters the transmission line, this time with a negative sign and, after an additional time τ or total time of 2τ it will pass out of the feedback path with absolute magnitude of k^2 and with a positive polarity with reference to the output. This process is continued and will generate the sequence of impulses shown in Fig. 4. The impulse response of the system can be obtained analytically by writing the inverse Laplace of the system transform which is the forward transference divided by one plus the feedback transference.

$$W(t)=\mathcal{L}^{-1}\frac{1}{1+k\epsilon^{-s\tau}}=\mathcal{L}^{-1}G_i(s) \tag{10}$$

Making the substitution of the variable y defined by equation 8, the impulse response of the system in Fig. 4 would be

$$W(t)=\mathcal{L}^{-1}\frac{1}{1-ky} \tag{11}$$

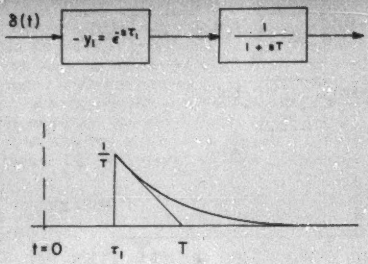
To evaluate the inverse Laplace of a ratio of polynomials in s, one uses the Heaviside partial fractions expansion to obtain a summation of low-order terms, each one of which has a simple inverse transform. In an analogous manner, to obtain the inverse Laplace of a function of y, one must obtain a summation of positive powers of y in some sort of series. The simplest series expansion for equation 11 is that for a reciprocal. It is

$$\frac{1}{1-ky}=1+ky+k^2y^2+k^3y^3+k^4y^4+\ldots \tag{12}$$

Therefore the weighting function of the network is

$$W(t)=\delta(t)-k\delta(t-\tau)+k^2\delta(t-2\tau)-k^3\delta(t-3\tau)+\ldots \tag{13}$$

This is the equation for the alternating chain of impulses shown in Fig. 4. The envelope of this chain is given by



$$\underbrace{\frac{1}{T}\epsilon^{-(t-\tau_1)/T}}_{t>\tau_1} = \delta(t-\tau_1) * \underbrace{\frac{1}{T}\epsilon^{-t/T}}_{t>0} = \mathcal{L}^{-1}\epsilon^{-s\tau_1}\cdot\frac{1}{1+sT}$$

$$\text{Envelope} = \epsilon^{-\frac{t\ln\frac{1}{k}}{\tau}} = k^{t/\tau} \tag{14}$$

If k is less than 1 then the envelope diminishes in amplitude. The s plane has complex pole pairs in the left-half plane. A loop gain greater than 1, however, will cause k to be greater than 1 and the envelope will continuously increase in magnitude in an unstable oscillatory manner. This corresponds to right-side s-plane poles in complex pairs.

If the feedback is positive then k is negative and a substitution in equation 13 will show that the signs of all of the impulses will be positive. The envelope will die down in a monotonic manner if k is less than 1. There is one pole on the negative real s-plane axis, but other poles as well. The envelope will increase in an unstable manner if k is greater than 1.

Fig. 5 shows the representation of the impulse response of dead time in feedback in three different complex-frequency planes. The first is the very familiar s plane. An examination of equation 10 will show that the poles of this function are given at the specific values of s of

$$s = \alpha + j\beta \tag{15}$$

when

$$\epsilon^{-s\tau} = (\epsilon^{-\alpha\tau})(\epsilon^{-j\beta\tau}) = -\frac{1}{k} \tag{16}$$

These poles occur where

$$\alpha\tau = -\ln\frac{1}{k}$$

$$\beta\tau = (2n-1)\pi \tag{17}$$

There is a column containing an infinite number of poles in the s plane, one for each value of n. These are spaced at intervals of $\beta\tau = 2\pi$. The functions plotted in Fig. 4 and Fig. 5 are for the particular case when $k = 0.707$.

Because of this infinite column of poles, the use of root locus methods in the s-plane for designing control systems is difficult. The value of a complex function is given by the distances to all of the zeros and poles,[1] for the usual rational functions.

The distance product is defined as the function of a complex variable s calculated by taking the product of all of the distances from the zeros to the value of the variable s in the s plane, divided by the product of all of the distances from the poles to the same value of the variable s in the s plane. Or, stated another way, the distance product is the continued product of all of the distances to s from every singularity, counting the distances from zeros with positive unity exponents (no change), and counting the distances from the poles with negative unity exponents (reciprocal distances). The distance product cannot be evaluated graphically when there are an infinite number of singularities. For this reason a change of variable into the y or the z plane is desirable. Fig. 5(B) shows a plot of the function $G(z)$ where the variable z is defined as

$$z = \epsilon^{+s\tau} = -\frac{1}{y} \tag{18}$$

The function must be the same, independent of changes of variable.

$$G_4(s) = G_4(y) = G_4(z) \tag{19}$$

In the z plane,

$$G_4(z) = \frac{1}{1+k\epsilon^{-s\tau}} = \frac{z}{z+k} \tag{20A}$$

Using this variable, dead time in feedback has a zero at the origin of the z plane and a pole at $-k$. The z plane is related to the s plane in the following way: the origin of the s plane maps into the point 1, 0 in the z plane. Patterns in the near vicinity of the s plane origin map unchanged into patterns in the near vicinity of (1,0) in the z plane. The $j\omega$ axis of the s plane maps into the unit circle in the z plane. The entire left-half s plane maps into the area enclosed by the unit circle in the z plane. There are an infinite number of superimposed Riemann leaves in the z plane because each horizontal strip of width 2π in the s plane maps into the z plane to cover the area of the entire plane completely.

According to equation 20(A) the function $G_4(z)$ for any point z is equal to the distance from the zero at the origin to that point, divided by the distance from

the pole at $-k$ to the point z. Therefore, the conventional procedure of evaluating functions of a complex variable geometrically in a complex plane by evaluating the distance product works satisfactorily in the z plane for transcendental functions of s representable by a ratio of polynomials in z.

Fig. 5(C) shows the Laplace transform of the impulse response of dead time in feedback plotted in the y plane, where y is defined by equation 8. The origin of the s plane plots into the $(-1,0)$ point in the y plane. In the vicinity of this point the s plane and the y plane are identical. The $j\omega$-axis of the s plane plots into the unit circle in the y plane and the point $j\pi/2$ marked a in the s plane plots into the point $j1$ in the y plane. The entire right half of the s plane is enclosed by the unit circle in the y plane. All singularities outside of the unit circle correspond to stable poles or minimum-phase zeros in the s plane. The y plane has many Riemann leaves, each horizontal strip of vertical width 2π in the s plane plots into a complete coverage of the y plane. One advantage of using the y plane is that the infinite column of poles in the s plane becomes a single pole in the y plane. The function is given by

$$G_4(y)=\frac{1}{1+k\epsilon^{-s\tau}}=\frac{1}{1-ky}=\left(\frac{-1}{k}\right)\frac{1}{\left(y-\frac{1}{k}\right)} \qquad (20B)$$

This has a single pole located at $y=1/k$.

The function $G_4(y)$ can be evaluated geometrically in the y plane by first factoring out the constant $-1/k$ as shown in equation 20(B). The remaining factors of y have a distance product equal to the product of the distances from all of the zeros to the point y divided by the product of the distances from all the poles to the point y. Again this function of a complex variable can be evaluated geometrically.

When there are no zeros, use unity for the "distance to the zero." It is apparent that, to perform this calculation, one may choose whichever plane results in the simplest computation. The s plane is ruled out because of the infinite column of poles. In this particular example the y plane is most convenient because it has a single pole. However, the z plane is not much more difficult to use, because it has only one pole and one zero.

Fig. 5(A) has an infinite column of minimum-phase zeros which lie at negative real infinity at the far left of the s plane. If the output of the circuit in Fig. 4 had been taken from the output of the transmission line, then the first pulse of the pulse train in Fig. 4 would have occurred at time τ. This would have been a nonminimum phase system, and the infinite column of zeros for Fig. 5(A) would have been at the far right edge of the s plane. The z plane would not have had a zero at the origin, and the y plane would have had a zero at the origin.

Polynomial of Transcendental Terms

Two transmission lines in parallel, or a transmission line in parallel with a constant transference, will have a finite number of impulses in the impulse response.

An infinite train of pulses in the time domain must be represented by poles in the frequency domain. If the train is composed of impulses there will be an infinite number of s-plane poles, or at least one z-plane or y-plane pole. This is analogous to the time domain responses shown in Fig. 1 which approach a final value asymptotically at infinite time, and therefore must be represented by a pole, in this case, in the s plane.

If the time domain response stops in finite time, then the Laplace transform does not have any poles in the finite s plane. It also does not have any poles in the finite y plane, nor can a pole lie within the unit circle which would represent an unstable system. The transform can have poles in the finite z plane however, because poles at the origin of the z plane are necessary to balance all of the zeros which appear in the finite z plane.

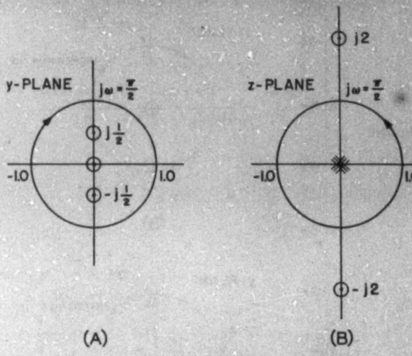

Fig. 7 (left). Transmission lines in parallel

Fig. 8 (above). Roots of transcendental transforms for transmission lines in parallel

Fig. 6 shows a transmission line added to unity. In this case the gain coefficient of the transmission line k has been selected as less than unity for purposes of illustration. Fig. 6(B) shows the impulse response consisting of two impulses only. The Laplace transform of the impulse response of this system is given by

$$G_5 = \mathfrak{L}[\delta(t) + k\delta(t-\tau)]$$
$$= 1 + kz^{-1} = \frac{z+k}{z} \qquad (21)$$

This function has one pole and one zero in the z plane as shown in Fig. 6(C). The pole is at the origin. The zero lies within the unit circle if k is less than 1. This corresponds to a minimum-phase system. If k is greater than 1, the second impulse is larger than the first impulse, and the zero of the transference lies outside the unit circle. This corresponds to a non-minimum phase system. The z-plane zero is plotted in the s plane in Fig. 6(D). It becomes an infinite column of zeros at $(\alpha\tau = -ln\ 1/k)$, with vertical co-ordinates of the zeros being the values of $\beta\tau$ given in equation 17. If $k > 1$ then the real co-ordinate of the column becomes positive and the column of zeros is in the right-half s plane.

G_5 as given in equation 21 can be evaluated for any value of s by finding the corresponding value of z, and then computing the distance product which, in this case, is the distance from the zero to the point z in the z plane divided by the distance from the origin to the point z in the z plane.

A more general case is that shown in Fig. 7, where the system consists of two transmission lines in parallel. The delay time is different in the two transmission lines. A minimum common submultiple of the two delay times is chosen. This value is called τ. The delay time of the first line is $n\tau$ and the delay time of the second line is $m\tau$. Their Laplace transforms are

$$G_n = k_1 \epsilon^{-sn\tau}$$
$$G_m = k_2 \epsilon^{-sm\tau} \qquad (22)$$

The impulse response of these two transmission lines in parallel is given in Fig. 7(B). It is

$$f_6(t) = k_1\delta(t-n\tau) + k_2\delta(t-m\tau)$$
$$= \mathfrak{L}^{-1}(k_1\epsilon^{-n\tau s} + k_2\epsilon^{-m\tau s}) \qquad (23)$$

Fig. 8(A) shows the y-plane plot for the system transference of the two transmission lines in Fig. 7, derived from

$$\mathfrak{L}f_6(t) = k_1(-y)^n + k_2(-y)^m$$
$$\mathfrak{L}f_6(t) = k_1(-y)^n\left[1 + \frac{k_2}{k_1}(-y)^{m-n}\right]$$
$$= k_2(-y)^n\left[\frac{k_1}{k_2} + (-y)^{m-n}\right] \qquad (24)$$

The transference has an nth order zero at the origin of the y plane and a large number of other zeros at the roots of

$$y_0 = -\left(-\frac{k_1}{k_2}\right)^{\frac{1}{m-n}} \qquad (25)$$

The particular case plotted in Fig. 8(A) is for $n=1$, $m=3$, $k_1=1$, and $k_2=4$. For this particular case, the complex zeros are nonminimum phase because $k_2 > k_1$. There are two complex zeros because the difference between m and n is 2. In general the complex zeros will be equiangularly located on a circle corresponding to the roots of a negative real number. The number of complex zeros will be equal to the difference between m and n. There will be, in addition, a high-order zero at the origin of the y plane with an order corresponding to the smaller of the two numbers n or m. The total number of zeros in the y plane is equal to the larger of the two numbers n or m. In a similar manner, the z-plane pattern can be plotted from

$$\mathfrak{L}f_6(t) = \left(\frac{k_1}{z^m}\frac{k_2}{k_1} + z^{m-n}\right) = \frac{k_2}{z^m}\left(1 + \frac{k_1}{k_2}z^{m-n}\right) \qquad (26)$$

This has an m-order pole at the origin of the z plane and it has complex zeros located at the roots of

$$z_0 = \left(-\frac{k_2}{k_1}\right)^{\frac{1}{m-n}} \qquad (27)$$

These complex zeros will be equiangularly spaced on a circle centered at the origin of the z plane. The transference of the circuit in Fig. 7(A) can be evaluated for any complex frequency by determining the corresponding value of y or z for this complex frequency, and determining the distance product in the y or the z plane. It is important that the gain coefficient k_2 or k_1 respectively be multipled by the distance product to obtain the value of the transference.

Mixed Lumped Parameters and Dead Time

The systems shown in Figs. 4 through 8 inclusive are all composed of pure dead time components. Their transferences

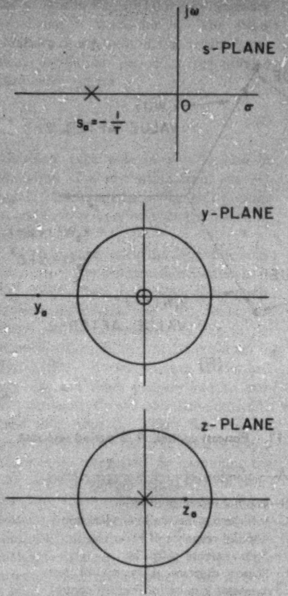

Fig. 9 (left). Simultaneous use of two complex frequency planes for dead time in cascade with single time constant

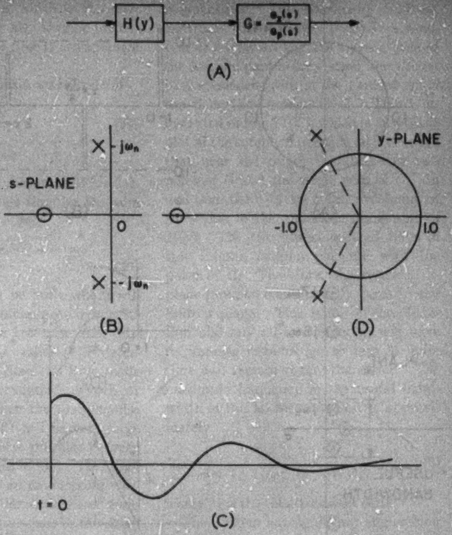

Fig. 10 (right). A—Delay-line compensator for lumped-parameter system; B—G in s plane; C—G plotted in y plane; D—Impulse response of G alone

are polynomials in y or z. The only mixed system which has been discussed so far is that shown in Fig. 3. Its transference is the product of a function of y and a function of s. It is interesting to examine how this function may be expressed graphically. The transference is

$$\frac{\epsilon^{-s\tau_1}}{1+sT} = \frac{-1}{T}\, y\, \frac{1}{s+\frac{1}{T}}$$

$$= \frac{1}{T}\,\frac{1}{z}\,\frac{1}{s+\frac{1}{T}} \tag{28}$$

The equation was arranged so that only positive powers of the variable appeared. To represent this system with a finite number of poles and zeros requires two different complex-frequency planes. One of these must be the s plane and the other can be either the y plane or the z plane. In the s plane there is a single pole at $-1/T$. In the z plane there is a pole at the origin. Fig. 9 shows these two planes and the locations of their singularities. In addition, the location of the pole at s_a is plotted in the z plane at the point

$$z_a = \epsilon^{+s_a\tau} \tag{29}$$

In Fig. 9 the y plane is shown. It has a single zero at the origin. In addition, a point is shown on the y plane corresponding to the location of the pole in the s plane. This point y_a is given by

$$y_a = -\epsilon^{-s_a\tau} \tag{29A}$$

It may seem trivial to evaluate the impulse response of this system from the complex frequency planes shown in Fig. 9. However, for more complex systems, this is an efficient and practical way to obtain the impulse response. The impulse response is the convolution of the chain of impulses generated by the function of y and the summation of exponentials generated by the function of s. In this trivial case, the s plane yields a single term which is

$$\frac{1}{T}\epsilon^{-t/T}$$

Also in this particular case a single zero in y produces the function $-\delta(t-\tau_1)$. The resultant impulse response of the system is therefore

$$W(t) = \left(-\frac{1}{T}\right)\left(-\delta(t-\tau_1)^{*}\epsilon^{-t/T}\right) \tag{30}$$

The convolution of a finite sum of impulses and a continuous function is best evaluated by the application of the superposition theorem. In this particular case, there is only one impulse and the continuous function is only shifted in time as indicated in equation 9(C)

$$W(t) = \frac{1}{T}\epsilon^{-(t-\tau_1)/T} \quad t > \tau_1$$

Posicast Control

There is a form of control called a Posicast system.[1] These systems have a delay-line compensator prior to a lumped-parameter system. For a single impulse into the compensator, it delivers a chain of impulses of finite number and these excite the lumped-parameter system in such a manner that it reaches its final value in finite time and the output of the lumped-parameter system remains constant at its final value thereafter. These are called deadbeat systems by engineers. The engineering features have been described in the literature.[2,3] To get an intuitive feeling for this method of control imagine that the lumped-parameter system has a significant oscillation with small damping. Then each impulse that leaves the delay-line compensator and excites the lumped-parameter system will excite a damped oscillation. The condition for satisfactory deadbeat control is that the sum of the various shrinking phasors representing these damped oscillations should add to zero after the last impulse excitation. The algebraic sum of the areas of the several impulses that entered the lumped-parameter system should be unity to correspond with the unit impulse which enters the delay-line compensator.

Another way of looking at this type of control is to imagine that the delay-line

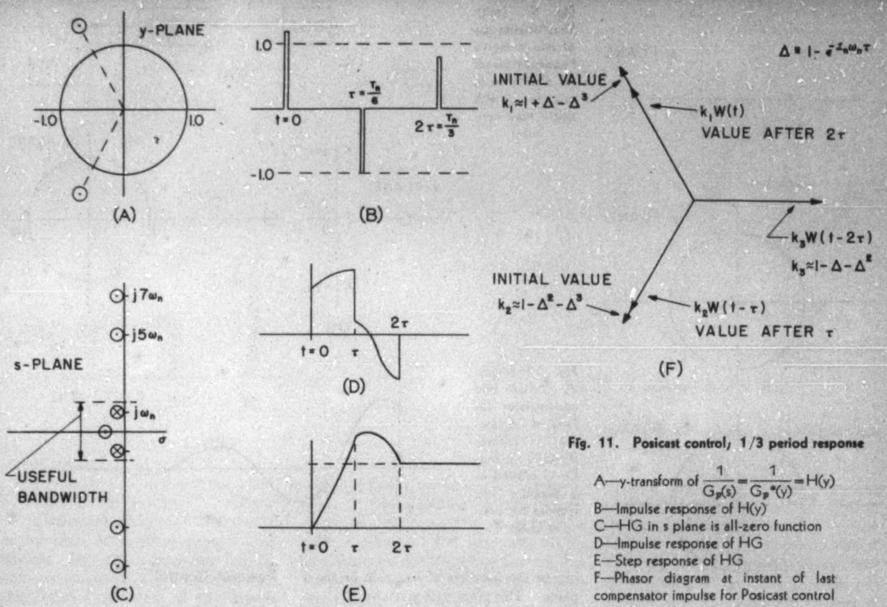

Fig. 11. Posicast control, 1/3 period response

B—Impulse response of H(y)

C—HG in s plane is all-zero function

D—Impulse response of HG

E—Step response of HG

F—Phasor diagram at instant of last compensator impulse for Posicast control

compensator generates a polynomial in y. This polynomial in y has zeros in the complex-frequency plane. The lumped-parameter system however has poles which represent its resonant frequencies and time constants. The correct deadbeat design is one in which, for each pole in the lumped-parameter system there is a coincident zero generated by the delay-line compensator.

Fig. 10 shows an example of this type of system. Fig. 10(A) is the block diagram of the compensator and the oscillatory member. Fig. 10(B) shows the transfer function of the oscillatory member in the s plane. For purposes of example, this is taken to be a pair of resonant poles and a single real zero. Fig. 10(C) shows the impulse response of G alone. It has an initial step because the system has only one more pole than the number of zeros.

The locations of the poles and zeros of G in the s plane can be plotted at the corresponding complex frequencies in the y plane. We will define a new function of y called the y transform of $G(s)$, which is usually written as $G^*(y)$. This new function, $G^*(y)$, has poles and zeros in the y plane at the identical complex frequencies for which there were poles and zeros of G in the s plane. These locations can be found from the plot of G in the y plane. The function $G^*(y)$ is not exactly equal to $G(s)$. If the function $G^*(y)$ is plotted in the s plane, as it can be, then it would consist of an infinite column of poles in the s plane and another infinite column of zeroes. Only the very-low-frequency pair of poles of this column coincide in the s plane with the poles of G and only one of the zeros of the column of $G_z{}^*(y)$ plotted in the s plane coincides with the zero G_z.

To find any y-transform function $F^*(y)$ given the corresponding s-transform $F(s)$, one may substitute for each term in the s transform of the form

$$\frac{s-s_1}{0-s_1}$$

a corresponding term in the y transform equal to

$$\frac{\epsilon^{-s\tau}-\epsilon^{-s_1\tau}}{\epsilon^{0}-\epsilon^{-s_1\tau}}=\frac{-y+y_1}{1+y_1}=\frac{y_1-y}{y_1+1} \tag{31}$$

The original function $G(s)$ is divided into a ratio of polynomials

$$\frac{G_z(s)}{G_p(s)}$$

The poles

$$\frac{1}{G_p(s)}$$

are plotted in the y plane as the y transform

$$\frac{1}{G_p{}^*(y)}$$

For the location of each root of $G_p{}^*(y)$ in the y plane one generates a y-plane zero. The product of all of these zeros is a function $H(y)$ given by

$$H(y)=\frac{1}{G_p{}^*(y)} \tag{32}$$

This is a polynomial in positive powers of y. It has only zeros in the y plane. There are no poles. Each zero of $H(y)$ is coincident with a pole of the function $1/G_p{}^*(y)$, which is the y transform of all of the poles of the lumped-parameter system G. Fig. 11(A) shows the necessary zeros in the y plane corresponding to the system shown in Fig. 10.

The zeros in Fig. 11(A) can be generated with a quadratic in y. The three terms of this quadratic are shown in Fig. 11(B) as a sequence of impulses. The first impulse is slightly greater than 1; the second impulse is approximately equal to 1; and the third impulse is slightly less than 1 for the particular value of τ which has been chosen for the definition of y. In this particular case, in order to plot the s-plane function in Fig. 10(B) into the y plane in Fig. 10(D) it was necessary to choose a value for τ. The value chosen was one sixth of the natural transient oscillation period of the lumped parameter system.

$$\tau = \frac{T_n}{6} = \frac{\pi}{3\omega_n} \tag{33}$$

Therefore each pole in y is located at one sixth of a revolution from the -1 point. Each impulse in Fig. 11(B) occurs at one sixth of a period after the preceding impulse.

Each impulse from the delay-line compensator excites a damped oscillation as in Fig. 10(C), which approaches zero asymptotically for infinite time. The sum of the three oscillatory components due to the three impulses in Fig. 11(B) is shown in Fig. 11(D). At the instant of the last impulse, the three phasors add to zero and consequently the oscillation ceases to exist after time 2τ. That this impulse response is a very desirable mode of operation can be recognized by examining the step response of the system with its compensator, Fig. 11(E). The output of the lumped-parameter system for a unit step into the compensator is given by the integral of the curve in Fig. 11(D). This integral rises monotonically for a time a little greater than τ until it reaches its peak and then it diminishes a small amount until the time 2τ, after which it remains constant thereafter. The reason why the step response of this system shows an overshoot is because of the zero of G in the s plane, due to the transference of the lumped-parameter system. The system response reaches its final value in 1/3 cycle.

The phasor components of the oscillation are shown in Fig. 11(F). The first impulse excites the oscillation $k_1W(t)$ which has a radian frequency ω_n and dimensionless damping ζ_n. A measure of the damping is the per-unit envelope loss in 1/6 cycle,

$$\Delta = 1 - \epsilon^{-\zeta_n\omega_n\tau} \tag{34}$$

The first impulse has a magnitude of

$$k_1 = \frac{1}{(1-\Delta)^2+\Delta} \tag{35}$$

After 2τ, this phasor has an angle of 120 degrees and has shrunk (attenuated) to

$$k_3 = (1-\Delta)^2 k_1 \tag{36}$$

The second impulse excites the oscillation $-k_2W(t-\tau)$, which has an initial magnitude of

$$k_2 = (1-\Delta)k_1 = \frac{1}{(1-\Delta)+\left(\dfrac{\Delta}{1-\Delta}\right)} \tag{37}$$

After τ units of time, which is at $t=2\tau$, this phasor will have also shrunk (attenuated) to k_3. At this time it has an angle of -120 degrees.

The last impulse has a magnitude of

$$k_3 = \frac{1}{1-\dfrac{\Delta}{(1-\Delta)^2}} \tag{38}$$

and excites the phasor $k_3W(t-2\tau)$. Immediately after this impulse the sum of the three phasors is zero.

$$k_1W(t) - k_2W(t-\tau) + k_3W(t-2\tau) = 0 \qquad t > 2\tau \tag{39}$$

Other designs can be built which will cause the system response to reach its final value in more or less time than this. The selection of the value of τ determines the response time. If τ is made very small, as for example, 1/20th or 1/30th of a cycle, then the first impulse required in Fig. 11(B) will be very large and the second impulse will also be very large in a negative direction. This may not be feasible from an engineering view point, because these large values of compensation signal require gain in the delay line compensator and in addition may saturate linear components of the system.

Complex-Zero Generator

The principle of the Posicast control described in Figs. 10 and 11 can be used to test unknown systems. The signal generator for the test delivers two successive step functions, like the integral of two successive impulses. The ratio of amplitudes and the time spacing are adjustable. The signal generator is connected to a system, and the output is observed on an oscilloscope. The amplitude and pulse timing are varied until the oscilloscope shows a deadbeat response.

The signal generator has produced an infinite column of complex zeros in the s plane, and deadbeat response means that two of these zeros are coincident with the two complex poles of the unknown system. The resonant frequency and the damping of the system poles can then be read directly from the dials of the signal generator, which are calibrated in terms of the locations of the complex zeros.

This is analogous to a Q-meter, except that the accuracy is high for low Q's, and diminishes for increasing Q.

All-Zero Functions

It can be proved that deadbeat response can be achieved with any lumped-parameter system preceded by a delay line compensator. The criterion for deadbeat control is that for every pole of the function of s representing the transference of the lumped-parameter system, there must be a coincident zero in the y transform of the delay line compensator. This is illustrated in Fig. 11(C), which is an s-plane plot of the complete function HG. Notice that near the origin there are the two poles of G and the single zero of G. In addition there is an infinite column of zeros due to the quadratic numerator of $H(y)$. The two lowest ordered zeros in this infinite column coincide with the poles of G. Therefore, the resultant s-plane function contains only zeros in the finite s plane. This is an all-zero function and any all-zero function will have its impulse response go to zero in finite time and remain at zero thereafter. The maximum frequency in the useful bandwidth of this all-zero function is approximately

$$f_{\max} = \frac{1}{4\tau} \tag{40}$$

where 2τ is the total transient time.

This system has significant engineering advantages over the usual Chebyshev or Butterworth designs for a uniform gain throughout a bandwidth. In these conventional designs, the useful frequency band is filled with poles which distort the function and produce ripples in both gain and phase. Outside of the useful frequency band the function is quite smooth and well-behaved although near zero in magnitude. In the Posicast design the useful frequency band is devoid of singularities and consequently the function has very uniform and constant gain throughout the bandwidth and it is only in the stop band or at the very high frequencies that there are ripples in the gain function, but these occur at frequencies where the gain is so low that the variations in the gain are negligible.

A generalized Posicast control system has an over-all transfer function given by

$$HG = K\prod_{i=1}^{n}\frac{y-y_i}{s-s_i} \tag{41}$$

The zeros of the lumped-parameter transference have been neglected. Each pole of the lumped-parameter transference has a corresponding zero of the y transform at the same complex frequency. All of the constants have been lumped together in the factor K. The specification that each zero of y coincide with a pole of s is given by

$$y_i = -\epsilon^{-s_i\tau} \tag{42}$$

Making this substitution, the system transference is

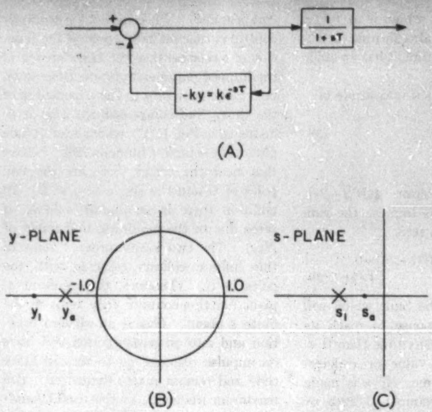

Fig. 12 (left). Simultaneous use of two complex frequency planes for dead time in feedback cascaded with a single time constant

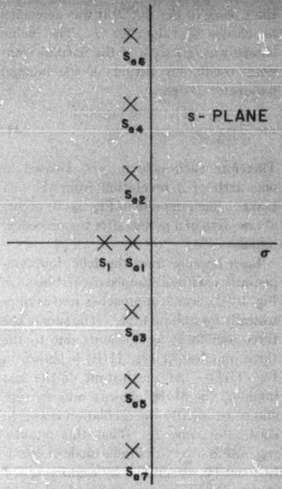

Fig. 13 (right). Poles of partial-fractions expansion of a transform in s and y

$$HG=K\prod_{i=1}^{n}\frac{\epsilon^{-s_i\tau}-\epsilon^{-s\tau}}{s-s_i} \tag{43}$$

It can be shown that the convolution of pulses, each of which lasts only for a finite time, is a resultant pulse which also lasts only for a finite time. To prove that this over-all transference is deadbeat, therefore, we need only prove that each component is deadbeat. By a component is meant a pair consisting of one s-plane pole and its corresponding y-plane zero.

The inverse Laplace of one component of this continued product is given by

$$\begin{aligned}\mathfrak{L}^{-1}C_i&=\mathfrak{L}^{-1}\left(\frac{1}{s-s_i}\right)(\epsilon^{-s_i\tau}-\epsilon^{-s\tau})\\&=\left(\mathfrak{L}^{-1}\frac{1}{s-s_i}\right)^{*}[\mathfrak{L}^{-1}(\epsilon^{-s_i\tau}-\epsilon^{-s\tau})]\end{aligned} \tag{44}$$

The inverse Laplace of the product of two transforms is equal to the convolution of the inverse Laplaces of each transform alone. The first inverse Laplace yields an exponential decay term valid only for positive time. The second inverse Laplace yields the summation of an impulse at zero time and a delayed impulse. The convolution of these two functions is the time domain contribution of this one component pair.

$$\mathfrak{L}^{-1}C_i=\underset{t>0}{\epsilon^{+s_it}}{}^{*}(\epsilon^{-s_i\tau}\delta(t)-\delta(t-\tau)) \tag{45}$$

This contribution is zero for negative time and has the value stated only for positive time. The convolution of the sum of two functions can be written as the sum of the convolutions, and this results in

$$\mathfrak{L}^{-1}C_i=\underset{t>0}{\epsilon^{+s_it}}{}^{*}\epsilon^{-s_i\tau}\delta(t)-\epsilon^{+s_it}{}^{*}\delta(t-\tau) \tag{46}$$

With regard to the first term above, the convolution of a function of time with an impulse at the origin does not change the function of time. Therefore the first convolution is only multiplication, and the function of time still has value only for time greater than zero.

The second term in equation 46, however, is the same as the action of the system shown in Fig. 3 and given by equation 9. It is the convolution of a function of time valid for positive time only with a delayed impulse. The effect of the delayed impulse is to shift the time scale so that the given function of time starts at a later time, and is zero up to this later time and has value only after time τ. Therefore, the sum of the two functions in equation 46 are

$$\mathfrak{L}^{-1}C_i=\underset{t>0}{\epsilon^{+s_i(t-\tau)}}-\underset{t>\tau}{\epsilon^{+s_i(t-\tau)}} \tag{47}$$

The first function starts at time $t=0$ and continues for all time. The second function starts at time $t=\tau$ and continues for all time thereafter. Since the two functions are identical the difference exists only for the time between zero and τ.

$$\mathfrak{L}^{-1}C_i=\epsilon^{+s_i(t-\tau)}\quad 0<t<\tau \tag{48}$$

and the difference is equal to zero for all times that lie outside of this finite span

$$\mathfrak{L}^{-1}C_i=0\quad t<0,\ t>\tau, \tag{49}$$

If there are n different terms in equation 37 then the convolution of the n resultant pulses, each one lasting for time τ, will be a function which lasts for time $n\tau$.

$$\mathfrak{L}^{-1}HG=0\quad t<0,\quad t>n\tau \tag{50}$$

This is the desirable characteristic which Posicast control achieves.

Graphical Residue Evaluation

A system consisting of a delay line compensator with feedback followed by a lumped-parameter system with feedback can have poles both in the y plane and the s plane. To evaluate the characteristics of this kind of system, it is convenient to have rapid graphical methods of determining the frequency response of the system, the root locus in case an additional feedback path is introduced around the cascaded combination and the residues at the poles, so that the impulse and step response may be written down directly from graphical evaluations, rather than from analytical evaluations.

To illustrate these techniques, we will consider the system shown in Fig. 12. This has a delay line in feedback followed by a single-time-constant lumped-parameter system. This has a transfer function given by

$$G_s=\frac{1}{(1+ky)}\frac{1}{(1+sT)}=\frac{1}{Tk\left(y+\frac{1}{k}\right)\left(s+\frac{1}{T}\right)} \tag{51}$$

To distinguish the two kinds of poles and zeros as well as the two kinds of frequency planes, we will call all poles and zeros due to lumped-parameter elements as black ones, and all poles and zeros due to distributed-parameter elements as red ones. We will use subscript numbers for the black poles and subscript letters for the red poles. A single red pole in the y plane plots into an infinite column of red-pole frequencies in the s plane. A black pole in the s plane plots into a single black-pole frequency in the y plane.

The transference of the one black pole and one red pole in equation 51 can be written

$$\frac{G_8}{K}=\frac{1}{(s-s_1)(y-y_a)} \qquad (52)$$

The inverse transform of this is a transient which extends through all time. However, because of the attenuating character of the lumped-parameter filter, the frequency components in this transient have a limited bandwidth. Thus, an acceptable method of writing the transient would be to determine the significant Fourier components and write only these. This means that the single red y-plane pole is replotted as a column of poles in the s plane and the residues are evaluated for only the significant low-frequency poles in this column.

Fig. 12(B) shows the single red y-plane pole at $-y_a$ and Fig. 12(C) shows the single black s-plane pole at $-s_1$. Fig. 13 shows the red poles due to the transmission line plotted in the s plane and marked s_{a1}, s_{a2}, s_{a3}, etc.

The first step in evaluating the inverse transform of G_8 is to expand it in partial fractions corresponding to the terms shown by the poles in Fig. 13. This partial fractions expansion is

$$\frac{G_8}{K}=\frac{R_1}{(s-s_1)}+\frac{R_{a1}}{(s-s_{a1})}+\frac{R_{a2}}{(s-s_{a2})}+\frac{R_{a3}}{(s-s_{a3})}+\dots \qquad (53)$$

This series might not converge, but if the higher frequencies are attenuated, only low-frequency poles need be considered.

The residues are the numerators in this partial-fractions expansion. The residue at the black pole is

$$R_1=\lim_{s\to s_1}\frac{G_8}{K}(s-s_1)=\frac{1}{(y_1-y_a)} \qquad (54)$$

The reciprocal residues at the red poles are

$$R_{an}{}^{-1}=\lim_{s\to s_{an}}\frac{d}{ds}(y-y_a)(s-s_1)$$

$$R_{an}{}^{-1}=\lim_{s\to s_{an}}(y-y_a)+(s-s_1)y(-\tau) \qquad (55)$$

$$R_{an}{}^{-1}=(s_{an}-s_1)y_a(-\tau)$$

In general, the residues at the red poles are

$$R_{an}=\lim_{s\to s_{an}}\frac{G_8(y-y_a)}{Ky_a(-\tau)} \qquad (56)$$

The resultant partial-fractions expansion, which is in a form directly amenable to using inverse Laplace Tables, and in which each term represents a particular frequency in the s plane, is

$$\frac{G_8}{K}=\frac{1}{(y_1-y_a)(s-s_1)}+\frac{1}{(-\tau)}\sum_{n=1}^{\infty}\frac{1}{(s-s_{an})(s_{an}-s_1)y_a} \qquad (57)$$

The residues are the coefficients of the time terms in the inverse Laplace. The magnitudes of these coefficients can be obtained directly from the geometry in Fig. 12. For example, R_1 is the residue of the single s-plane pole due to the lumped-parameter network. If this were completely a lumped-parameter system, then the residue at s_1 would be the value of the function at s_1 with the pole there removed. This is conventionally calculated as the distance product to s_1 from all the other poles and zeros in the system. But as can be seen in Fig. 13, the number of other poles in the s plane is infinite and this distance product would be difficult to evaluate in the s plane. However, equation 54 shows that this distance product can be evaluated directly in the y plane. The residue R_1 for the black pole is equal to the reciprocal of the distance in the y plane from the red pole at y_a to the complex frequency point y_1. This distance is therefore the coefficient of the term

$$\epsilon^{-t/T}$$

in the impulse response of the given system.

The residue at the red pole s_{a1} in the s plane is given by equation 55 or 56. The residue at the red pole frequency s_{a1} in the s plane is equal to the reciprocal of the distance from the black pole s_1 to the location s_{a1} where the residue is to be evaluated, times the distance in the y plane from the origin to the red pole y_a, times $(-\tau)$. This residue is the value of the function G_8/K at the frequency s_{a1}, with the red pole at s_{a1} removed.

There is a calibration constant which has to be included when the residue at a red pole is evaluated in the s plane. This calibration constant is the negative reciprocal of the time base for the y plane, $(-1/\tau)$.

The technique just illustrated can be generalized as follows: A transference which is a product of a ratio of polynomials in s times a ratio of polynomials in y can be expanded in a sum of partial fractions with all of the denominators having units of s. The residue at any given black pole is the distance product from all of the black singularities in the s plane times the distance product from all of the red singularities in the y plane, to the complex frequency of the given black pole. The residue at any given red pole frequency in the s plane is equal to minus $1/\tau$ times the distance product from all of the black singularities, in the s plane, times the distance product from all of the red singularities in the y plane, with an extra pole at the origin of the y plane.

Conclusions

It is hoped that this exposition will have demonstrated the usefulness of a variety of mathematical transformations and techniques. These introductory relationships between frequency domain and time domain representations of transforms which have mixed polynomial and transcendental terms, should be extended to form a complete unified treatise.

An important phase of this work concerns the direct evaluation of residues and root loci in the complex frequency plane, for systems involving feedback around cascaded delay compensators and lumped-parameter elements. Another important field which needs additional work is that involving diffusion processes such as occur in transistors. These transcendental terms have transforms of the form

$$\epsilon^{-\sqrt{s\tau}}$$

Here again a new frequency-domain plane is needed. I hope that these problems will be intriguing to engineers and that they will contribute significantly to our understanding and to the tools available in these fields.

Simulation of Data-Switching Systems on a Digital Computer

F. J. GROSS
MEMBER AIEE

SINCE 1941 automatic data-message-switching systems using teletypewriter techniques have been widely used to transmit messages from each of a multiplicity of sources to destinations in accordance with address codes included in each message.[1] Existing systems have increased in size and complexity along with the business operations which they serve. Future data-message-switching systems show promise of being even larger and more complex, and of operating at much higher speeds.

The performance of such systems is measured by the average annual cost per message for specified requirements of speed-of-message delivery and peak hour capacity under specified conditions of average message length, geographical distribution of sources and destinations, and ratio of annual load to peak-hour load. Maximum performance depends not only on the sound design of the elements of the system, but also upon the skill with which the data system is adapted to the business operations of the user.

Judgment as to the ability of these systems to meet requirements of capacity and speed of delivery involves the laws of statistics and probability that become more difficult to apply as the system becomes more complex.

Simulation of the operation of a data-switching system on a large digital computer is a powerful tool for determining how well it will meet the capacity and speed of service requirements for any specified application. By cut-and-try methods of simulating the operation of various designs and system layouts, one can select the most economical one that will adequately meet the requirements.

Furthermore, if digital computers or other automatic devices are to be directly connected to the data-switching system their operating parameters can be included in the simulation to determine the performance of the proposed composite system.

Equations and graphs based on the theory of probability, such as the telephone trunking formulas, should be used as an aid in selecting the specific system to be simulated, and also in evaluating the results of a simulation. The mathematical relationships are most useful in determining the size of trunk groups and of estimating the number of receivers required at a destination.

Simulation

Simulation is not new. Machines have been built to simulate specific telephone switching systems,[2] and devices such as a-c boards and network analyzers have been used to simulate electric power distribution systems. With the advent of large high-speed digital computers the cost of simulation is greatly reduced. The general principles of performing simulations on computers have been discussed in the literature.[3,4]

In the simulation of the operation of a data-message-switching system the computer calculates the characteristics of each message that would be offered to the system during the peak hour. It also calculates the progress that each message would make through the system and determines the delays it would encounter in waiting for the completion of preceding messages and in waiting for switching operations. Finally, the computer arranges the results in a form convenient for comparison with the results of other simulation runs.

The major steps in the computer program for the simulation are the determinations of the following:

1. Length of each message.
2. Time during the peak hour at which the message is available for transmission (offered time).
3. Originating source at which the message would be offered.
4. Destinations to which the message would be addressed.
5. Machine at the source which would first be available to transmit the message if there is more than one transmitter at the source.
6. Time at which each destination would have assigned an idle receiver.
7. Time at which idle receivers would have been connected and transmission would have started for a message sent simultaneously to several different receivers.
8. End of message time when connections would have been released.
9. Delays met by the message in waiting for other messages which precede it.
10. Delays imposed on the message at different points in the switching process.

PROGRAMMING THE COMPUTER

Because of their high cost and high speed, modern large-scale digital computers are usually operated by a trained staff capable of converting the programmer's instructions into punched cards or magnetic tape, running the problem on the machine, and returning the printed results to the engineer. They have automatic program routines which enable them to accept a program of instructions in the form of simple mnemonic codes each of which refers either to frequently used sequences of machine instructions or to a convenient group of storage registers. The programmer can also use relatively simple format instructions so that the printed results are in a form that is easy to evaluate.

It will be to the advantage of the engineer responsible for the simulation if he either learns to write the mnemonically coded simulation program himself or assigns one of his subordinates to do it. The preparation of the simulation program often leads to a better understanding of the operation of the system and may lead to suggested improvements even before the simulation is run. If it is necessary to employ the aid of a programming specialist, an engineer should work closely with him to insure that this opportunity for better understanding of the operation will not be lost.

To be useful for simulation of a data-switching system the computer should be of a type that can be easily programmed for the following operations by use of mnemonic codes or subroutines:

1. The usual arithmetic processes.
2. Computation of the exponential of a positive or negative argument.
3. Computation of the logarithm of any positive number to the Naperian base.
4. Moving to one of two or three groups of instructions in the simulation program after an arithmetic operation depending on whether the result is positive or negative or zero.
5. Discarding least significant or most significant digits by shifting.
6. Computation of computer-storage ad-

dresses in the computer and insertion of such computed addresses in specified instructions during the computing processes.

Random Numbers

Simulation of a data-switching system requires the frequent use of random numbers. For example, experience with existing teletypewriter data systems teaches us that messages offered to them occur at random times just as they do in telephone systems. Messages are distributed randomly among sources and also among destinations.

Random numbers are listed in tabular form in books by several authors[5,6] and it is possible to reduce them to punched cards or magnetic tape and store them in the computer. A much more convenient source is a series of numbers called pseudo-random numbers that can be calculated as needed by the computer with only three or four instructions and two or three storage registers.[7,8] To form a series of random numbers in a computer, one derives from an available formula, a multiplier, and a multiplicand of several digits each, and stores them in the computer. When the computer forms the product of these two numbers, the product is split and the least significant half can be used.

1. As one of a series of random numbers.
2. To replace the multiplicand before repeating the multiplication to form the next random number in the series.

The multiplicands constitute a series of several million different numbers that are just as useful for simulation as those found in published tables.

In the simulation each random number is used as though the decimal point were to the left, namely as a decimal less than one.

Message Characteristics

The simulation of a data-message-switching system requires that the characteristics of the messages be such that the simulation will represent as closely as possible the operation of the actual system.

MESSAGE LENGTH

Studies of large numbers of messages in teletypewriter systems have taught us that message lengths are distributed exponentially in accordance with the following equation:

$$NP(x)=NK\epsilon^{-cx} \qquad (1)$$

where

N = the total number of messages expected in the simulation
x = the length of each message usually expressed in words
c and K are determined so that the summation of $P(x)$ for all values of x is unity for a specified average message length

In a practical simulation all values of x and $NP(x)$ must be integral numbers. To accomplish this the following equations have been derived from equation 1 in a form convenient for use in programming a digital computer

$$x=\frac{ds+\ln N-\ln NA}{d} \qquad (2)$$

where

$$d=\frac{N\ln N-\ln(N!)}{N(\bar{x}-s)} \qquad (3)$$

and

$$N!\approx\sqrt{2\pi N}\left(\frac{N}{\epsilon}\right)^{N} \qquad (4)$$

$\bar{x}$ = average message length
s = shortest message length
A is varied from one to N, in increments of one, to give the N message lengths required

The values of $\bar{x}$ and s are known constants that depend on the nature of the business operation that originates the message. For example, for domestic air lines x is usually 20 to 30 words or 120 or 180 teletypewriter characters, but for automobile manufacturers the average is usually 50 to 60 words or 300 to 360 characters. In one industrial system the average is several hundred words.

Having assumed an appropriate value of $\bar{x}$, the value N will be found by dividing $\bar{x}$ into the total number of words or characters the system is designed to originate in the simulated time interval which is usually the busy hour.

MULTIPLICITY OF DESTINATIONS

In every data-switching system each message is addressed to at least one destination. However, some business operations require that a certain proportion of messages be sent simultaneously to a multiplicity of destinations. The number of destinations may be two, three, four, or more; up to 200 in some cases.

The system being simulated will have a specified proportion of system load assigned one destination, two destinations, and so on. A suitable device for determining destination multiplicity of a given message consists of several steps:

1. Tabulate the loads, in words, to be delivered in terms of one-destination, 2-destination, 3-destination, etc., multiplicity.
2. Assign a number to the given message by forming a product of a random number and the total system load in words.
3. Subtract successively from this product the one-destination, 2-destination, 3-destination loads until a negative or zero remainder is obtained.
4. Assign to the given message the first multiplicity for which a negative remainder was obtained.

This insures that the more predominant multiplicity will be more frequently chosen by the random process as the message characteristics are developed.

A tally of the load assigned to each multiplicity should be maintained. The computer can be programmed so that if the load assigned to a particular multiplicity is reached or exceeded during the simulation, then either the next higher or lower multiplicity is chosen.

ORIGINS AND DESTINATIONS

For purposes of simulation it is desirable to assign a unique number to each originating point in the simulated system. The use of the system will determine the proportion of the load to be assigned each originating point. Here again, the most suitable device for selecting the point of origin for a message is to develop the product of a random number and the system load, and successively subtract origin loads until the result is zero or negative. That origin is chosen in which the subtraction changed the algebraic sign of the results. Here again a tally of the load assigned each origin should be kept by the computer. As the problem nears completion the program should be such that loaded origins are passed over.

Destinations should be numbered and selected in a manner exactly similar to that for points of origin.

Only one origin will be chosen for each message, but the selection of a destination for a message should be repeated by the computer in accordance with the chosen degree multiplicity of address for that message.

OFFERED TIME

For purposes of simulation, offered time of a message is defined as the time at which the message is available in encoded form at the transmitter source. Experience has shown that messages occur individually and collectively at random during an interval like a busy hour. Two methods are available for determining the offered time of each of the N messages used in the simulation.

In the first method a pseudo-random number is computed for each message.

This number is treated as though the decimal point were at the left so that the random number lies between zero and one. It is multiplied by the simulation interval in seconds, and this product, rounded to the nearest 0.1 or 0.01 second, is used as the offered time of that message. When this method is used the length, origin, and destinations of every message must be calculated and sorted in ascending order of the offered time before the computer can proceed with the simulation.

In the second method the offered time of any message is determined by calculating the elasped time from the offered time of the previous message. To do this a unit time interval is assumed which is short compared to the average interval between offered times. The number of times (M_1) that the elapsed interval between two successive offered times will be less than one unit time interval is given by

$$M_1 = N(1-\epsilon^{-\mu}) \tag{5}$$

where μ is the average number of messages per unit time interval. The number of times, M_T, that are less than T but more than T-1 unit time intervals will occur between offered times is given by

$$M_T = M_1\epsilon^{-T\mu} \tag{6}$$

The computer is programmed to prepare a table of rounded-off values of M_T for various values of T beginning with $T=1$. The computation of the table is stopped when the sum of all values of M_T is equal to N.

Since zero is used as an idle indication it was convenient to assume that the first offered time occurred at the end of the first unit time interval. For each subsequent offered time the computer is programmed to select a random number, multiply it by N, and successively subtract from the product the values of M_T in the table beginning with the table entry for unit time interval. The value of T for which the difference is zero or negative is the one to be used in determining the next offered time. This method provides a random entry into the table. A tally of the use of each value of T should be kept separately from the table and the computer should be programmed to pass over a value of T as the number of times it has been used equals its values of M_T. If the value $T-0.5$ rather than T is added to the previous offered time in computing the next, the last message will occur almost exactly at the end of the simulation time. This is a consequence of integrating equation 7 from $T-1$ to T.

The latter method was developed from the following equation which relates μ, the average messages per unit time interval, to the probability that the next message will be offered to the system T unit time intervals after the last message was offered. It is taken from reference 4.

$$P(T)dT = \mu\epsilon^{-\mu T}dT \tag{7}$$

When the results of the two methods were compared for a specific example, the distribution of messages per subinterval for the second method agreed with the Poisson distribution nearly as well as distribution for the first method.

The first method of computing the offered time has been used on a medium-size computer of 2,000-word internal storage. In this case message characteristics can be punched on cards in one computer run, the cards being passed through an off-line sorter to arrange them in ascending order of offered time and then fed to the computer as needed during the second or simulation run.

The second method has been used on a large computer of 32,000-word storage which was capable of doing the entire problem in one run. This method avoids sorting which would require profligate use of expensive computer time.

Simulation of the System

Having programmed the computer to produce message characteristics in a form suitable for use as inputs to the simulation, consider the systems to be simulated.

Each automatic data-message-switching system comprises one or more of the following major elements: message source, message transmitter, common control, destination, and receivers.

A message source is a point in the system where a data message becomes available for transmission and where it can be held or stored until the switching system is ready to transmit it. Each source is served by one or more transmitters or transmission paths.

The primary function of common control is to sequence the bidding of transmitters for destinations so that one receiver will not be simultaneously connected to two transmitters.

Destinations are points in the system to which data messages are addressed and to which transmitters seek a connection before transmitting the message. Each destination is served by one or more receivers.

In some systems a receiver for one transmission link in the system may serve as a source for another transmission path which will relay the message on toward its destination. To avoid ambiguity, the source where the message first becomes available to the switching system will be referred to as an originating source.

In a real system each of these elements has one of the three following states or conditions:

1. Idle.
2. Busy performing its function with a calculated future completion time.
3. Seized waiting for some switching function to complete or for a busy unit to become available.

In simulation on a digital computer it has been found convenient to use a single storage register to remember the state of each switching element. In each such register the idle condition is represented by zero, the busy condition is represented by the time at which the condition is to end, and the seized condition is represented by a very large constant. If this is done, then proper programming will enable the computer to test the state of the simulated element by testing the contents of the storage register for zero, or by subtracting the contents of the simulation time register from the contents of the state register and testing the result for positive, negative, or zero.

A single storage register is normally sufficient to remember current simulation time during the computer run. At the start of the simulation this register is set to the unit time interval used in the simulation, usually 0.1 or 0.01 second. Although the most obvious manner of conducting the simulation might be to advance the simulation time in small steps and examine all state registers at each step for a change from busy to available, this method is wasteful of computer time. A better method is to program the computer to determine the earliest change of state anywhere in the system and to advance the simulation time register to that time. The computer should be programmed so that after it processes all changes of state occurring at that simulation time it determines the time of the next earliest change of state in the system and advances the simulation time accordingly. In a completely idle system the simulation time is advanced to the offered time of the next earliest message.

For those classes of system elements in which each element has the exclusive use of one or more transmission paths, computer registers are provided for each element to store the addresses of the state registers of the paths used by that element. For example, if some originating sources are served by more than one transmitter than appropriate registers in the computer should be designated for each source

and the addresses of the state registers for the transmitters serving that source should be stored in them. Usually destinations will be provided with similar registers for addresses of state registers for receivers.

In addition to the digital computer storage registers already described, it has been found desirable to provide a large block of registers for the active messages. A message is considered active when its offered time becomes equal to, or less than, the current system simulation time. The messages are sequenced in order of offered time. As a message becomes active it is assigned sufficient registers for the message characteristics previously described, for the address of the state registers of each transmitter and receiver that will be assigned to it, for the time that each transmitter and receiver will become available to the message, and for the times at which transmission starts and ends. In the time-of-availability registers in the message storage block, a zero should indicate that the element is not yet available to the message. The contents of some of these registers are used to calculate message delays.

When the time of the end-of-transmission equals the system simulation time, the computer program should be such that the message is removed from the active storage and the various delays computed and combined with results of previous messages as required by the problem.

Finally, if the common control either sequences or polls transmitters in a particular sequential order then a storage register should be provided to store the identity of the latest transmitter polled. An additional storage register may be needed to remember the simulation time at which the latest transmitter has been polled.

FIRST EXAMPLE

The simulation of a single-line teletypewriter selective calling system is an example of a small system that has been simulated on a moderate-size magnetic-drum digital computer of 2,000 10-digit-word capacity.

The system to be simulated involved half-duplex operation of a single line to which is connected a multiplicity of receiving units and transmitting units. A common control or master control installed at one of the transmitter sites polls the transmitters in a fixed sequence after any station completes its transmission. Polling is continuous when the system is idle. When a transmitter has messages to transmit, it begins transmission only when it is polled by the master control unit. The transmitter is assumed to transmit all messages on hand when polled.

Since only one message could occupy the line at any time and since receivers are connected on the fly in response to address codes, the destination and multiplicity of addresses did not affect the simulation results and were not considered. All other message characteristics were calculated as previously described.

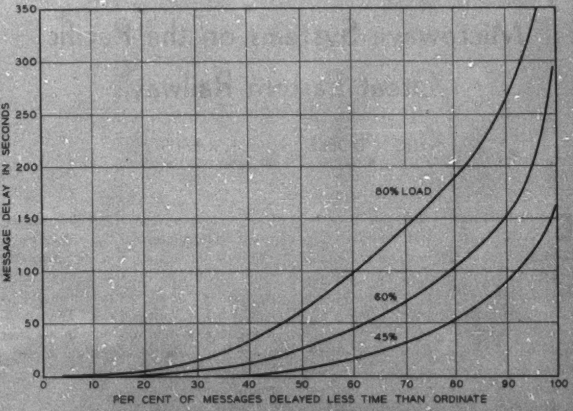

Fig. 3. Cumulative probability of delay from the simulation of a single-line selective-calling system

Transmitter loads were assumed such that their sum did not exceed the desired loading of the line. The load, transmission speed, and average length of message were assumed and this determined the number of messages in the busy hour simulated. Characteristics of every message were computed and punched on cards in one run on the computer. These message cards were sorted in order of offered time on a sorter. A program of instructions conforming to Fig. 1 was prepared and loaded into the computer. During the simulation the message cards were read into the computer under control of the program as illustrated in Fig. 1. Results for each message were punched on cards.

SECOND EXAMPLE

The simulation of a multiline-data-switching system with one switching center is an example of a large system that has been simulated on a high-speed computer with 32,000 words of core storage and on-line tape storage.

From the system to be simulated the transmission speed, average message length, load per source, load per destination, transmitters per source, and receivers per destination were determined. The switching center was assumed ideal with negligible connection time and an infinitely fast sequence circuit in common control.

Offered times were to be computed as needed with 0.1 second minimum between any two. With this ideal arrangement delays would be caused only by messages waiting for previous messages. Results were to be compared later with those of an actual system to see how closely the actual system approached the ideal.

Message lengths were calculated by the computer in accordance with equation 2. With the aid of pseudo-random numbers the lengths were distributed randomly throughout a block of computer storage.

Offered times were computed as needed using the table derived from equation 6 and the other characteristics of the message were computed along with the offered time.

The program of instructions for the system simulation was prepared in conformance with Fig. 2. Computer registers assigned to the sources and destinations contained the addresses of state registers of transmitters and receivers allotted them.

Results

The computer can be programmed to calculate average delays imposed by different parts of the switching systems by summing the delays and dividing by the number of messages. It can be also programmed to maintain appropriate tallies so that cumulative probability curves like those of Fig. 3 can be quickly plotted from printed computer results.

Conclusions

Simulation on a digital computer is a powerful tool for comparing the capacity and speed of delivery of different data-switching systems or of different systems layouts of one type of switching system for given load requirements, before committing money for major design effort or construction.

Simulation of larger systems than those shown can be programmed. Also, more minute details of system operation can be simulated than those described in this paper. However, if the computer storage is exceeded or the computer running time is excessive, then the system simulated is probably too large or it is being simulated in too great detail.

Microwave Systems on the Pacific Great Eastern Railway

R. N. DOBLE
NONMEMBER AIEE

J. E. RAFTIS
ASSOCIATE MEMBER AIEE

EXISTING microwave systems on the Pacific Great Eastern Railway have been depicted on the railway route map. See Fig. 1.

The company provides freight and passenger service over an 800-mile single-track railway system which extends north and south through the interior of the Province of British Columbia in Canada. Its right of way traverses the Coastal, Selkirk, and Rocky Mountain ranges. The company operates its communication facilities for train service and, in addition, leases telephone and telegraph channels to both common carriers and private users. Prior to the installation of microwave radio facilities, communications were provided over open-wire pole lines and via hand-written train orders. That communication system was only in use over about 50% of the present railway route.

Planning

When Pacific Great Eastern contemplated extending its railway lines geographical, operational, and scheduling requirements indicated the installation of comprehensive radio systems.

1. Over most of the planned railway route, terrain was rugged and mountainous: There were areas subject to landslides, there were sections of heavy timber, and there were large stretches of swampy ground. These natural obstacles imposed high initial costs on the construction of a pole line, and subsequently expensive maintenance in its operation. A further consideration was that wire lines might not prove dependable enough for the type of railway service planned.

Paper 59-889, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21–26, 1959. Manuscript submitted March 23, 1959; made available for printing April 24, 1959.

R. N. DOBLE is with the Pacific Great Eastern Railway Company, Vancouver, B. C., Canada. J. E. RAFTIS is with Canadian Motorola Electronics Ltd., Toronto, Ont., Canada.

2. The company wished to modernize its operations to provide communication end-to-end on trains, and from trains in motion to wayside and dispatch stations. These facilities were to be in addition to essential fixed station communications, and could only be set up by using train radio, and by providing vhf (very-high-frequency) radio stations at regular intervals along the right of way. Once the principle of remote radio stations was established it was practical to expand the facilities and choose locations to utilize microwave relay in lieu of pole lines to interconnect dispatchers, wayside operators, and railway termini. Once these microwave relay stations had been developed, it was economical to select an equipment complement to include also a communication system specifically designed to provide lease facilities for operation and maintenance of the Peace River gas pipe line, and lease facilities for other communications users south of Fort St. John. Accordingly, assertation of its rights as a common carrier could be incorporated in the Pacific Great Eastern Railway Company's microwave radio system planning.

3. Construction of the communication facilities had to take place simultaneously with survey of railway right of way and laying of track in the area north of Prince George. While it was possible to build a microwave system completely independent of this major construction project, any pole line work would of necessity have to be delayed until the right of way was cleared and graded. On that schedule the Railway Company could not extend communications to Fort St. John until some time in 1958, and could not provide facilities necessary to the initial operation of the gas pipe line from the Peace River area.

Table I. Traffic Channels

Facility	Fort St. John and Prince George	Prince George and Clinton	Clinton and Vancouver
Voice channels	32	18	60
Remote control channels	2	2	Nil
Teletype channels	20	12	14
Telemetering channels	future requirement		
Vhf radio control channels	9	5	7
Supervisory channels	5	5	5

4. The communication systems were to be operative in the shortest possible time. A system linking Vancouver and Squamish was scheduled for operation in June 1956 with the decision to proceed made early that same year. A system linking Prince George, Fort St. John, and Dawson Creek was scheduled for operation in September 1957 with planning completed in the first quarter of 1956. A system linking Prince George and Clinton was scheduled for operation in September 1957, with construction authorized in the latter part of 1956. A system linking Clinton and Vancouver was scheduled for operation in April 1959 with the decision to proceed made in the second quarter of 1958.

System Description and Facilities

In addition to the links from Fort St. John to Vancouver which have a capacity of 120 channels, the microwave systems include spur links where it was uneconomical to locate main microwave relay stations within easy pole-line access to railway stations. Performance requirements for the systems are stringent to accommodate railway operations without benefit of backup communication services. Major items of electronic equipment comprise a comprehensive and complex system of communications.

1. The longest microwave path on the system is over 60 miles.

2. The shortest microwave path on the system is under 10 miles.

3. The average microwave path on the system is about 25 miles.

All of these distances are measured between active repeater stations. See Fig. 2.

The 800-mile vhf coverage of railway track is accomplished with only 20 drop stations powered with 2-frequency 60-watt transmitters utilizing the same radio sites as main microwave relay stations.

The system linking Vancouver and Squamish spans an air-line distance of 36 miles and comprises four active stations. This system with a capacity of eight channels, was the first trial use of radio by the Railway Company.

The system linking Fort St. John, Dawson Creek, and Prince George spans an air-line distance of 258 miles and comprises 11 active repeater stations and 5 passive repeater stations.

The system linking Prince George and Clinton spans an air-line distance of 222 miles and comprises six active repeater stations and two passive repeater stations.

The system linking Clinton and Vancouver spans an air-line distance of 180 miles, and comprises 11 active repeater stations and 8 passive repeater stations. This system was laid out without employing towers to elevate antennas at microwave relay stations. See Fig. 3.

As authorized for construction, the main microwave links included the traffic channels in Table I.

Electronic Equipment

Microwave r-f (radio-frequency) equipment is of Motorola design and operates in the 6,000-mc (megacycle) frequency band. System requirements pertaining to propagation reliability are met through use of frequency diversity. The r-f baseband has a bandwidth of 1 mc. See Fig. 4.

Voice multiplex equipment is of Philips design and is of the single-sideband type. Two completely independent voice multiplex systems are in use. One system

Fig. 6 (left). Party-line dial panels telegraph loops, vhf drop radio, system interrogation alarm, and microwave for spur link

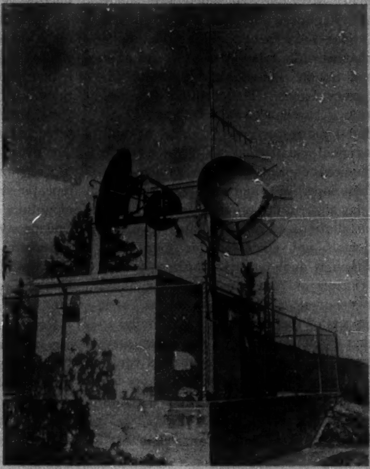

Fig. 7 (right). Microwave antenna systems for both main and spur links at remote site

provides drop and insert circuits at each relay station, and has an ultimate capacity of 16 channels. The other system provides trunk circuits at selected relay stations and has an ultimate capacity of 120 channels. Submultiplex equipment for party-line teletypewriter channels and for alarm, control and telemeter circuits is of Motorola design. This equipment, which is available on a drop and insert basis at each relay station, provides up to 18 channels which can be applied to any carrier derived voice channel. Submultiplex equipment for trunk teletypewriter channels is of Philips design. This equipment which terminates at Fort St. John, Prince George, and Vancouver will provide up to 18 teletypewriter channels over selected carrier derived voice channels. See Fig. 5.

Motorola designed vhf drop radio equipment operates in the 150-mc band. Not all microwave relay stations are equipped with a vhf drop station, as the criteria for selection of suitable vhf sites was complete coverage of the railway right of way with minimum signal overlap between adjacent stations. See Fig. 6.

Auxiliary equipment consists of a Motorola remote supervision and control system working on the interrogation principle, providing five condition reports for each microwave relay station; a Motorola vibracode selective-calling system from Pacific Great Eastern dispatch offices to trains and wayside stations; separate party-line 2-digit dial systems to link wayside stations on the railway and

Fig. 8 (left). View of building and antenna system at Lone Butte

Fig. 9 (right). View of passive repeater site from microwave station at Bowen Island

to link pumping stations on the pipe line. Party-line dial panels were a part of system design for the project.

Spur links comprise Motorola multichannel radio relay systems operating in the 150-mc, 960-mc, and 6,000-mc frequency bands. These equipments provide a basebandwidth of 24 kc, 42 kc, and 1 mc respectively. Single- or dual-terminal installations are dictated by the required dependability in service. Remote supervision and condition reports on relay stations are provided in some of the installations. Frequency diversity operation is not employed on spur links, although dual terminals operate on the principle of "hot standby" to minimize switchover time. Multiplex on spur links is of the short-haul type, similar to that employed for drop and insert service on main links. Submultiplex equipment uses a frequency-shift voice-frequency carrier. See Fig. 7.

Nonelectronic Equipment

Antenna systems at the microwave relay stations usually consist of a tower-mounted reflector and parabolic dish combination, with associated short waveguide runs. Directional antenna arrays are used at vhf drop stations and are located below the reflectors on microwave towers. See Fig. 8.

Passive repeaters comprise both self-supporting and guyed structures. Reflecting surfaces range from 640 square feet to 96 square feet under control of the path lengths and the angle of interception of the microwave beam. As many as three passive reflectors are required to establish the r-f path in several of the microwave hops. See Figs. 9 and 10.

One of the most interesting, and from a technical standpoint one of the most challenging, passive repeater installations is that in the Pine Pass area between stations at Azouzetta Lake and Nelson Creek. Here the microwave beam is actually subjected to a double reversal while passing over the natural obstacle of the Murray mountain range. The passive repeater stations are located on adjacent mountain peaks about a mile apart. One passive repeater looks down at the Azouzetta site from about 1.5 miles away, while the other faces the site on Nelson Creek about 20 miles away. See Fig. 11.

Remote microwave relay stations make use of a variety of a-c power services. Where possible, commercial power is used with stand-by diesel power plants. In some areas twin-diesel engines were installed to provide both main and stand-by service. These installations include a 6,000-gallon storage tank to provide fuel through the long winter period when the station may be inaccessible to heavy vehicles. In other areas the main power is provided by natural gas engine generators, and propane gas storage tanks were installed for stand-by service in the event of a pipe-line failure. See Fig. 12.

Capacity of stand-by power plants ranges from 7.5 to 15 kw. All plants, regardless of fuel type and capacity, were purchased from one supplier to ensure uniformity in system design and interchangeability of parts within practical limits.

Buildings are of concrete block construction with a poured concrete roof, and with projecting supports for mounting parabolic antennas. Size of equipment rooms ranges from 250 square feet to 150 square feet, while size of generator rooms ranges from 150 square feet to 100 square feet. Equipment rooms contain thermostatically controlled electric heating and ventilation, and are designed to accommodate racks up to 9 feet in height, of either the self-supporting or wall-mounted type.

Performance

Each of the three separate sections which, when combined in tandem, make up a continuous radio baseband from Vancouver in the south to Fort St. John in the north, have similar operational requirements.

1. The radio baseband must accommodate 120 voice channels derived by single-side-

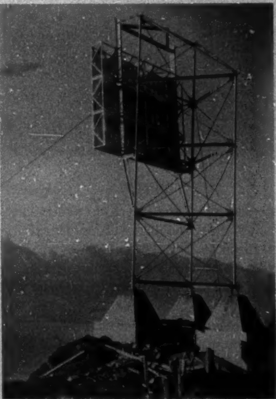

Fig. 10. Passive repeater in Vancouver to Bowen Island path

Vol.
Pt. 1
1959

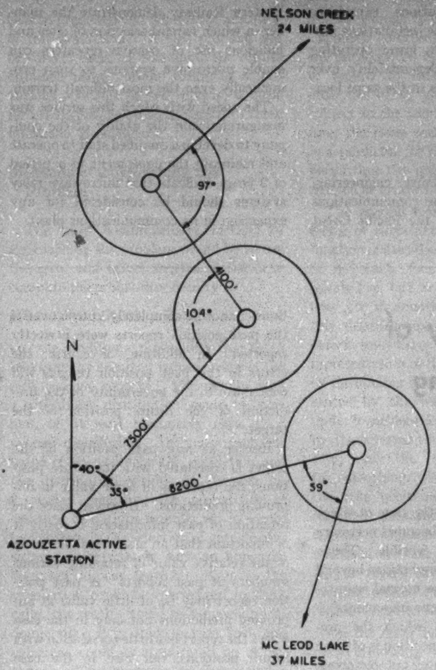

Fig. 11 (left). Microwave paths in the Pine Pass area

Fig. 12 (above). Stand-by engine generator installation at Vancouver

band multiplex equipment conforming to International Telephone Consultative Committee recommendations.

2. Additional channels for Teletype shall be derived by means of submultiplex equipment operating on the frequency shift principle, and conforming to International Telegraph Consultative Committee recommendations.

3. Propagation reliability shall be such that the r-f carrier-to-noise ratio shall exceed 30 db (decibels) for 99.96% of the time averaged over one year.

4. Over any one section, the noise level from all sources on the worst voice channel during periods of normal traffic, shall not exceed 30 dba (decibels adjusted) referred to 0 dbm (decibels referred to 1 milliwatt) transmission level.

Although the microwave baseband will accommodate 240 voice channels, appreciable savings in antenna and passive repeater costs are afforded by designing the system for the transmission performance and channel loading as specified. The average r-f carrier-to-noise ratio per hop is 38 db. This figure in combination with the microwave and multiplex used, has been demonstrated by field test, and has been proved by operating experience to meet the transmission objectives of the company, and to provide an adequate operating margin.

Operation

In 1956, when the Pacific Great Eastern Railway Company decided to begin the construction and operation of these complex microwave communication facilities, its communications staff comprised only one person with a background of knowledge and experience in radio communications.

The company added some eight maintenance technicians and a supervisor during the period to mid-1957, whose responsibilities were to operate and maintain microwave stations spanning over 600 miles of rail line. These persons were given a course of instruction covering all major equipment to be installed. At the end of the course a written examination was given, and the results were used by the chief communications officer at Pacific Great Eastern Railway Company to assist in assigning staff responsibilities. Subsequently the new employees assisted in the check-out of equipment and in system line-up.

The company employed four additional maintenance technicians during 1958 to maintain the 200-mile section south from Clinton. As with their predecessors, these persons were carefully trained prior to and during installations. While the operating group was being built up, the company also expanded its communications engineering and administration group to number six persons, and established a central maintenance depot in Vancouver.

A special control feature with which vhf drop stations are equipped greatly simplifies operational procedure on train-to-dispatcher traffic. All trains in motion are connected to the dispatcher via a party-line telephone circuit. Similarly all wayside stations are connected to the dispatcher via a separate party-line telephone circuit. All transmitters at vhf drop stations are turned off, while all receivers are turned on. When a train originates a call to the dispatch office, the signal is applied to the party line at only one vhf drop station where the vhf transmitter connecting to the train is automatically turned on. The transmitter remains operative for about 10 seconds after completion of the message. The train crew is then immediately advised if the dispatcher is in communication with another train and cannot engage in conversation. Alternately, if the call requires acknowledgment only, this may be given by the dispatcher without the need to select the proper vhf drop station along the route.

All microwave and vhf drop repeaters are equipped with a squelch circuit which prevents noise output from the receiver from loading the microwave baseband in case of path or equipment failure. This device has made significant improvements in the over-all dependability of the communications system in two ways:

1. Without vhf receiver squelch, an entire microwave channel can become saturated by noise in the event of an inconsequential vhf link failure.

2. With microwave receiver squelch, reliable communications can be established on either side of a major system break.

Although the passive repeaters, which are located at altitudes up to 7,000 feet above sea level, are subject to extreme climatic conditions, including winds of hurricane violence and ice deposited by low-level cloud formations, experience has indicated that these installations provide a lower first cost, lower operating cost, and improved dependability over active repeater stations in the same locations.

Conclusions

The successful planning, engineering, and construction of the communications facilities described for the Pacific Great Eastern Railway demonstrate the manner in which careful selection of sites and judicious use of passive repeaters can enable microwave systems to span economically even the most difficult terrain.

The speed with which this service was inaugurated and the ability of the company to develop a qualified staff to operate and maintain the equipment in a period of 2 years, indicate that microwave relay systems should be considered for any expansion in its communications plant.

An Approach to the Study of Automatic Target Tracking

LEONARD PODE
NONMEMBER AIEE

SEVERAL problems encountered in the design of automatic processing systems for data obtained from search radars give rise to a requirement for the prediction of the present or future position of a target on the basis of past position reports. The most obvious of such problems is that of scan-to-scan correlation of target reports. Here the prediction of the present position of the target determines the center of the "gate" in which the target is sought; and the accuracy of this prediction determines the size of the gate. It is important that the prediction be accurate and the gate size reasonably small in order to avoid confusion between neighboring targets. Any scan-to-scan correlation system will break down when the density of targets becomes too great. The accuracy of prediction determines the density at which trouble may be encountered. While it is not expected that target densities will ordinarily attain unmanageable proportions, this situation could easily arise due to enemy action in launching decoys and chaff.

The need to maintain the integrity of target tracks as long as possible in the event that direct sensing of the target position is temporarily lost also makes demands on the accuracy of prediction. Such a situation may arise in the presence of electronic countermeasures or because of other contingencies that may interrupt the normal functioning of the radar system. Of course, when the interruption of target-sensing services is prolonged, past information will become useless and existing tracks would have to be dropped; but it is desirable that the time at which the dropping of targets becomes necessary be extended as far as feasible. Therefore, the extension of predictions beyond what is required for the normal scan-to-scan correlation is of some importance.

Another problem in which the prediction of future target position is of some importance is that of intercept vectoring. Although in this case tactical considerations would enter, predictions formulated without regard to tactical factors, such as will be considered in the present discussion, should be of some interest.

The factors limiting the accuracy with which the future position of the target can be predicted are; first, the maneuverability of the target, and second, the accuracy of past position reports. The possibility of predicting the future position of the target derives from the fact that the target does not have infinite maneuvering capabilities. Its velocity is finite and it has very limited ability to change the magnitude of its velocity. Although it has the capability of orienting its velocity in any direction, the rate at which the direction of velocity can be changed is also limited. Maneuvers are not only limited physically, but also by choice, inasmuch as the target suffers in the attainment of its objective if it is constantly turning. Because the maneuverability of the target is not infinite there will be some correlation between the past positions of the target and its future course. On the other hand, because the target is maneuverable, this correlation will not be perfect so that its future positions cannot be completely known even if the past position reports were perfectly reported. In addition, of course, the errors in the past position reports will contribute to the uncertainty of the prediction of the future position of the target.

Insofar as any past position of the target is correlated with its future positions, the report is of some value in improving predictions. However, since the retention of past information is costly it is important that an assessment be made of the relative value of retaining various numbers of past reports A past position report may be of little value in improving predictions not only in the case where the report has little correlation with future positions, but also in the case where the report is very highly correlated with another report that is retained. Thus, not only the number but the distribution in time of the retained reports is important. The latter circumstance is particularly likely to arise when the system is not synchronous as, for example, when tracking is to be accomplished on the basis of returns from multiple radars operating at different scanning rates.

To facilitate the examination of questions regarding the number and distribution of points to be retained as well as to form a basis for the selection of a prediction method, a solution of the following problem is sought: Given the past position reports $\mathbf{R}_1$, $\mathbf{R}_2$ ..., $\mathbf{R}_n$ at times $t_1, t_2, \ldots, t_n$ respectively, t_1 referring to the most recent report, in consideration of the statistics of the errors associated with these reports and the statistics of target maneuvers, how can the position of the target, $\mathbf{R}_0$, at the future time, t_0,

---

Paper 59-925, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21-26, 1959. Manuscript submitted October 21, 1958; made available for printing May 28, 1959.

LEONARD PODE resides in Sherman Oaks, Calif.

Vol.
Pt. 1
1959

best be predicted and what is the accuracy of this prediction? If this problem can be solved, then, by examining the results obtained using various values of n and various spacings of the reports, a basis for intelligent decisions in regard to these questions is achieved.

Methods of Approaching the Problem

The most comprehensive method of approaching the problem would be to use the error and target motion statistics to compute the probability density

$$p[\mathbf{R}_0(t_0)|\mathbf{R}_1(t_1), \mathbf{R}_2(t_2), \ldots \mathbf{R}_m(t_m)]$$

i.e., the conditional probability that $\mathbf{R}_0(t_0)$ takes on any specified value in view of the past position reports. Presumably such a probability distribution would be normal, or at least reasonably close to a normal distribution; the most probable value of $\mathbf{R}_0$ would be the prediction and the distribution would also furnish information regarding the probability of specified deviations from $\mathbf{R}_0$ which would be valuable in the selection of gate dimensions. Unfortunately such an approach does not appear feasible. Even if the calculation could be carried out analytically, the results would be somewhat academic since it is unlikely that such calculations could be duplicated on a real time basis by a computer of reasonable size.

The compromise that is usually made in such a situation is to use a linear predictor and adjust the constants by the method of least squares. Thus the predicted value of $\mathbf{R}_0$ is taken to be

$$\mathbf{R}_0 \text{ est} = a_1\mathbf{R}_1 + a_2\mathbf{R}_2 + \ldots + a_n\mathbf{R}_n \quad (1)$$

where $a_1, a_2 \ldots, a_n$ are to be adjusted to minimize the expected or average value of $|\mathbf{R}_0 - \mathbf{R}_0 \text{ est}|^2$. The justification for this method of prediction is partly that it can be expected to be accomplished by a realizable computer, partly that it is reasonably amenable to analysis, and that, in addition, though surely not completely general, it is of fairly broad generality. An idea of the generality of the linear predictor can be gained from the consideration that this is the form that would result if the co-ordinates of $\mathbf{R}_1$, $\mathbf{R}_2$ $\ldots$, $\mathbf{R}_n$ are fitted by a linear sum of selected functions of time. These may be a set of polynomials in t, or a set of sinusoids, or any arbitrary set of functions of t.

It is assumed that the target height does not change to any significant extent so that the motion is essentially two-dimensional and that the range of interest is small enough to permit the use of plane Cartesian co-ordinates. Since, for present purposes, no distinction will be made in regard to directions, the two co-ordinates of x_i, y_i of any report $\mathbf{R}_i$ are subject to the same statistics and, therefore, the same coefficients would appear in a predictor for either co-ordinate, thus permitting the predictor equation to be written in vector form as in equation 1.

The encompassing by the linear predictor of curve-fitting with selected time functions raises the question as to whether or not such time functions should be selected or left arbitrary as, in essence, they are in equation 1. The answer to this depends upon whether there is *a priori* knowledge of a time function representation of the motion of the target. Of the number of degrees of freedom represented by the number of past reports under consideration, some are absorbed by the selected time function representation; only the remainder are effective for smoothing. When it is known that the true positions necessarily follow a specified time function form, then the degrees of freedom devoted to this representation are exceedingly well spent, not only in regard to obtaining a good fit to existing points, but more important, in regard to the excellence of extrapolation.

On the other hand when there is no *a priori* knowledge of the functional form of the target trajectory, the time functions must be selected arbitrarily. The number of degrees of freedom that would be devoted to the functional representation would depend upon assumptions made regarding the inherent smoothness, or the spectral characteristics, of the motion of the target and accordingly would vary with the time interval covered by the past reports and the future projections. For time intervals over which relatively smooth behavior of the target trajectory cannot be expected, a relatively large number of degrees of freedom would have to be devoted to the functional representation. In any event, the number of degrees of freedom devoted to the functional representation would be, at least to some extent, a guess. In some cases the penalty for a bad guess could be severe and extrapolations may become rather tenuous. Hence in this case the advantage lies with the linear predictor which, as given in equation 1, does not restrict itself to a specified time function form, but instead allows such forms to develop in accordance with the statistical characteristics of the target's motion, and the errors of past position reports.

Because of the physical limitations on the target's maneuverability, the functional form of the variation of target co-ordinates with time can be specified with confidence when the time interval under consideration is short. Extension of accurate knowledge of the functional form to longer time periods would depend upon assumptions regarding the limitations which the target will choose to impose upon its maneuverability and cannot be projected with great confidence. A study of prediction over time intervals short enough to be treated with functional forms based upon physical limitations would probably be worth some effort. But this question will not be examined here. Present concern will be with predictions over time intervals long enough so that the target has the capability, and presumably, the probability of sufficient maneuvering so that its trajectory cannot be encompassed by simple functional forms. The properties of the predictor given in equation 1 will be examined with this purpose in mind.

It will be noted that in using equation 1 the problem at hand becomes analogous to that of the design of a linear noise filter.

THE NORMAL EQUATIONS

The selection of the coefficients, a_1, a_2, $\ldots$ a_n, to minimize the expected value of

$$(\mathbf{R}_0 - a_1\mathbf{R}_1 - a_2\mathbf{R}_2 \ldots a_n\mathbf{R}_n)(\mathbf{R}_0 - a_1\mathbf{R}_1 - a_2\mathbf{R}_2 \ldots a_n\mathbf{R}_n)$$

leads to the normal equations

$$\begin{pmatrix} \overline{\mathbf{R}_0\mathbf{R}_1} \\ \overline{\mathbf{R}_0\mathbf{R}_2} \\ \cdots \\ \overline{\mathbf{R}_0\mathbf{R}_n} \end{pmatrix} = \begin{pmatrix} \overline{\mathbf{R}_1\mathbf{R}_1} & \overline{\mathbf{R}_1\mathbf{R}_2} & \ldots & \overline{\mathbf{R}_1\mathbf{R}_n} \\ \overline{\mathbf{R}_1\mathbf{R}_2} & \overline{\mathbf{R}_2\mathbf{R}_2} & \ldots & \overline{\mathbf{R}_2\mathbf{R}_n} \\ \cdots & \cdots & & \cdots \\ \overline{\mathbf{R}_1\mathbf{R}_n} & \overline{\mathbf{R}_2\mathbf{R}_n} & \ldots & \overline{\mathbf{R}_n\mathbf{R}_n} \end{pmatrix} \times \begin{pmatrix} a_1 \\ a_2 \\ \cdots \\ a_n \end{pmatrix} \quad (2)$$

where the bar indicates average or expected values. These equations can be obtained by differentiating the average value of this expression with respect to each of the constants, $a_1, a_2, \ldots, a_n$. For a detailed description of the derivation of the normal equations see reference 1. Each target report can be expressed as

$$\mathbf{R}_i = \mathbf{r}_i + \boldsymbol{\epsilon}_i \quad (3)$$

where $\mathbf{r}_i$ is the true target position and $\boldsymbol{\epsilon}_i$ is the measurement error. Since $\mathbf{R}_0$ refers to the true future position for consistency of symbols we may write $\mathbf{R}_0 = \mathbf{r}_0$. It may be assumed that the measurement errors are uncorrelated with each other or the true target positions, so that

$$\overline{\boldsymbol{\epsilon}_i\mathbf{r}_j}=0$$

for all i, j and

$$\overline{\boldsymbol{\epsilon}_i\boldsymbol{\epsilon}_j}=0 \qquad (4)$$

for $i \pm j$.

Actually there would be some correlation in the magnitudes of $\boldsymbol{\epsilon}_i$ and $\mathbf{R}_i$ but if the measurement errors are unbiased there should be no correlation in direction, and this is sufficient for equation 4. The measurement errors may, and probably will be, directionally asymmetrical since errors in azimuth commonly are more significant than errors in range. Even so equation 4 follows when, as is to be hoped, the errors are unbiased. However, inclusion of knowledge of the departure of errors from directional symmetry might be worth considering in a more thorough analysis.

It will be assumed that $\overline{\boldsymbol{\epsilon}_i \cdot \boldsymbol{\epsilon}_i}$ is independent of i; that is to say, the rms measurement error is always the same. Then writing

$$\overline{\boldsymbol{\epsilon}_i\boldsymbol{\epsilon}_i}=\sigma_e^2$$

and using equation 4, the normal equations may be written

$$\begin{pmatrix} \overline{\mathbf{r}_0\mathbf{r}_1} \\ \overline{\mathbf{r}_0\mathbf{r}_2} \\ \cdots \\ \cdots \\ \overline{\mathbf{r}_0\mathbf{r}_n} \end{pmatrix} = \begin{pmatrix} \overline{\mathbf{r}_1\mathbf{r}_1}+\sigma_e^2, & \overline{\mathbf{r}_1\mathbf{r}_2}, & \ldots & \overline{\mathbf{r}_1\mathbf{r}_n} \\ \overline{\mathbf{r}_1\mathbf{r}_2}, & \overline{\mathbf{r}_2\mathbf{r}_2}+\sigma_e^2, & & \\ \cdots & & & \\ \cdots & & & \\ \overline{\mathbf{r}_1\mathbf{r}_n}, & \overline{\mathbf{r}_2\mathbf{r}_n}, & & \overline{\mathbf{r}_n\mathbf{r}_n}+\sigma_e^2 \end{pmatrix} \times \begin{pmatrix} a_1 \\ a_2 \\ \cdot \\ \cdot \\ \cdot \\ a_n \end{pmatrix} \qquad (5)$$

To define the normal equations completely it now remains only to evaluate $\overline{\mathbf{r}_i\mathbf{r}_j}$. Thus one is faced with the task of determining an autocorrelation function for target trajectories.

CONSIDERATIONS IN CALCULATING THE AUTOCORRELATION FUNCTION

The autocorrelation of target positions will depend upon the physical and stochastic properties of target maneuvers. If these are known, or assumed, the autocorrelation may be computed by numerical computation using Monte Carlo methods. However, to avoid the cost and effort required for such machine calculations, an attempt at analytic calculation will be made. As is to be expected for such an attempt, more or less drastic simplifying assumptions will be required.

Whatever method is used, it is important to note some additional factors that will affect the calculation. One such factor is the existence of knowledge regarding the target other than that contained in the past position reports. For example, if the target is identified as an aircraft of a given type, the specification of its maneuvering characteristics can be more restricted than when the identity of the target is not known. It would be manifestly difficult, if not impossible, to work out the autocorrelation functions for all possible, or expected targets. Also, application of such knowledge implies that one autocorrelation function will be used when the target is not identified and another will be employed after the target is identified, thus requiring a considerably more complicated predictor. However, there is one simple target characteristic that can be expected to have a significant effect on the autocorrelation function; specifically, its speed capabilities. This follows from the fact that almost any target that might be considered will be rather limited in its ability to change speed. Hence, a knowledge of the speed characteristics of the target, available from past observations, would play an important part in the calculation of the autocorrelation function.

Of course, some knowledge of the speed of the target is inherent in the existing target reports, but the problem of determining the speed of the target when only the existing reports are available is essentially different from that of determining the target's speed when a fairly accurate estimate is available from past observation. It is, therefore, generally envisioned that tracking procedures would be divided into two phases; the first, wherein a target is initially acquired and an initial estimate of speed is made and the second phase, which may be termed routine tracking, would be applied to targets when a good estimate of the speed already exists. It may be noted in passing that an estimate of target speed at the outset of a track may be very helpful in discarding "false alarms" identified by an unrealistic speed characteristic.

The attempt to calculate the autocorrelation function that will be made herein will be confined to the case of routine tracking. It will be assumed that the target speed is known. The problem will be further idealized by the assumption that the target does not change speed at all.

Another factor that influences the autocorrelation function is the statistics of the distribution in space of target births and deaths. To treat this matter in full detail would require considerable effort. First, there would be the treatment of the range limits of the radar sensing. This would be analogous, in the study of gaseous diffusion, to the effect of an interface between a liquid and its vapor, the interface absorbing molecules and also releasing them. Annihilation statistics would also play a part. Such statistics would be affected by the location of missile batteries and airfields and innumerable other factors.

Even if birth and death statistics could be handled in a reasonable manner, there would remain the problem of reconciling a predictor which always predicts a future position, without regard to life expectancy, with statistics embodying a finite life expectancy. In the present analysis no attempt will be made at treating life expectancy statistics in any detail. The question of life expectancy statistics will arise in connection with the problem of normalizing the observation space. This will be resolved in a somewhat arbitrary manner. However, since birth and death statistics of targets would also be somewhat arbitrary, it is hoped that assumptions made will produce no catastrophic errors.

NORMALIZATION

Consider first the problem of computing the value of $\overline{\mathbf{r}_i\mathbf{r}_1}$. Will this value change with t_i? If statistical properties are to be independent of time, that is to say, if the statistics of target distribution are stationary, then one would expect that this value should not change with time. On the other hand, if target life is taken to be indefinitely long, so that t_i is permitted to increase without limit, then the probability that $\mathbf{r}_i$ will be distant from the center of observations increases. Therefore, taking $\overline{\mathbf{r}_i\mathbf{r}_i}$ to be a finite constant places implicit restrictions on the probability of long target life. This is not of much consequence if the time interval under consideration is so short that the distance the target can move is quite small compared to the assumed constant value of $(\overline{\mathbf{r}_i\mathbf{r}_i})^{1/2}$, but it could lead to difficulties for longer time intervals. Therefore, it may be worthwhile not to restrict the value of $\overline{\mathbf{r}_i\,\mathbf{r}_i}$ to the true dimensions of the target observation space, but to introduce the fiction that the observation space is larger. It would be of interest to examine the case of an indefinitely large observation space. The results then can be expected to conform better with the intuitive conception that the predictor characteristics should be uniform over the observation space. If $\overline{\mathbf{r}_t\mathbf{r}_t}$ were taken to be finite or in particular to be in accord with the dimensions of the observation space, then boundary effects are implied which should be reflected in a difference in predictions for reports that differ only by a translation to or away from the origin.

Accordingly, it will be assumed that $\overline{\mathbf{r}_t\mathbf{r}_t}=r^2$ where r^2 is a constant, independent of t_t, and is eventually to be taken as arbitrarily large.

The assumed invariance of $\overline{\mathbf{r}_t\mathbf{r}_t}$ has some interesting implications. Thus it follows that

$$\overline{\mathbf{r}_j\mathbf{r}_j}-\overline{\mathbf{r}_t\mathbf{r}_t}=\overline{(\mathbf{r}_j+\mathbf{r}_t)(\mathbf{r}_j-\mathbf{r}_t)}$$
$$=\overline{\mathbf{r}_j(\mathbf{r}_j-\mathbf{r}_t)}+\overline{\mathbf{r}_t(\mathbf{r}_j-\mathbf{r}_t)}=0 \quad (6)$$

and hence

$$\overline{\mathbf{r}_j(\mathbf{r}_j-\mathbf{r}_t)}=\mathbf{r}_t\overline{-(\mathbf{r}_j-\mathbf{r}_t)} \quad (7)$$

At first glance this result may seem odd. Consider that $\mathbf{r}_j$ is the more recent target position, then it would seem that $(\mathbf{r}_j-\mathbf{r}_t)$ would be uncorrelated with $\mathbf{r}_t$. In other words, where a target goes would seem to be independent of where it has been. Hence it might be expected that the right-hand side of equation 7 would vanish. But surely both sides do not vanish for then,

$$\overline{(\mathbf{r}_j-\mathbf{r}_t)(\mathbf{r}_j-\mathbf{r}_t)}=\overline{\mathbf{r}_j(\mathbf{r}_j-\mathbf{r}_t)-\mathbf{r}_t(\mathbf{r}_j-\mathbf{r}_t)}$$

would vanish and this clearly is not true. Therefore, it is clear that $\overline{\mathbf{r}_t(\mathbf{r}_j-\mathbf{r}_t)}$ cannot vanish. This may be more readily accepted when it is expressed as follows: When a difference in target positions $(\mathbf{r}_j-\mathbf{r}_t)$ exists, it is more possible that $\mathbf{r}_t$ is in the direction $-(\mathbf{r}_j-\mathbf{r}_t)$ than in the direction of $+(\mathbf{r}_j-\mathbf{r}_t)$. With directions reversed this is also true for $\mathbf{r}_j$ and the assumption of constant $\overline{\mathbf{r}_t\mathbf{r}_t}$ leads to the equality, equation 7, between two nonvanishing quantities.

Since

$$\overline{(\mathbf{r}_j-\mathbf{r}_t)(\mathbf{r}_j-\mathbf{r}_t)}=\overline{\mathbf{r}_j\mathbf{r}_j}+\overline{\mathbf{r}_t\mathbf{r}_t}-2\overline{\mathbf{r}_t\mathbf{r}_j}$$
$$=2r^2-2\overline{\mathbf{r}_t\mathbf{r}_j} \quad (8)$$

the autocorrelation can be obtained from

$$\overline{\mathbf{r}_t\mathbf{r}_j}=r^2-1/2\overline{(\mathbf{r}_j-\mathbf{r}_t)(\mathbf{r}_j-\mathbf{r}_t)} \quad (9)$$

To determine $\overline{\mathbf{r}_t\mathbf{r}_j}$ it remains only to evaluate $\overline{(\mathbf{r}_j-\mathbf{r}_t)(\mathbf{r}_j-\mathbf{r}_t)}$

THE EVALUATION OF $\overline{(\mathbf{r}_j-\mathbf{r}_t\mathbf{r})\;({}_j-\mathbf{r}_t)}$

It may be assumed that the value of $\overline{(\mathbf{r}_j-\mathbf{r}_t)(\mathbf{r}_j-\mathbf{r}_t)}$ is not dependent upon absolute time but is a function only of the time difference $\tau_{jt}=|t_j-t_t|$. The value of this quantity is assumed to be independent of $\mathbf{r}_t$ so that in this calculation, for convenience, one may take $\mathbf{r}_t=0$. The value sought then is the mean-square-distance, $\sigma^2(\tau)$, travelled by a target initially at $\mathbf{r}=0$ in the time $\tau=\tau_{jt}$. Since the direction of the initial velocity is immaterial, it may be chosen arbitrarily, for definiteness, say in the direction of the x-axis. Let θ be the angle between the direction of target's velocity and the x-axis.

Then initially $\theta=0$, and

$$\sigma^2(\tau)=\overline{x^2(\tau)}+\overline{y^2(\tau)}$$
$$=\overline{V^2\int_0^\tau \cos\theta(s)ds\int_0^\tau \cos\theta(r)dr}+$$
$$\overline{V^2\int_0^\tau \sin\theta(s)ds\int_0^\tau \sin\theta(r)dr}$$
$$=V^2\int_0^\tau\int_0^\tau \overline{\cos\,[\theta(s)-\theta(r)]}ds\,dr \quad (10)$$

where on the right-hand side the order of integration and averaging has been interchanged.

Because stationary statistical characteristics are assumed it follows again that $\overline{\cos\,[\theta(s)-\theta(r)]}$ is independent of the absolute value of r and s, but dependent on the value of the time difference $T=|s-r|$ and is assumed independent of the absolute value of $\theta(r)$. The latter assumption implies that the probability of turning is independent of time and past history which may not be strictly true, but is used here as a workable approximation. To assume otherwise would mean that in the tracking process attention should be given to the value of $\dot\theta$ in addition to V, and that some knowledge is available regarding the persistence of $\dot\theta$. The view taken here, that θ might be changed at any time, corresponds to ignoring limitations on $\dot\theta$.

In accordance with the foregoing assumptions, $\overline{\cos\,[\theta(s)-\theta(r)]}$ is taken to be the value of $\overline{\cos\theta(T)}$, for targets for which $\theta(0)=0$. The value of $\overline{\cos\theta(T)}$ can be computed if the probability distribution of $\theta(T)$ is known. To obtain an estimate of this probability distribution, consider the variations of the angle θ in time to be analogous to the one-dimensional random walk problem. Accordingly, the probability density $p[\theta(T)]$ would have the form[2,3]

$$p[\theta(T)]=\frac{1}{(2\pi T)^{1/2}}e^{-\frac{\theta^2}{2\alpha^2T}} \quad (11)$$

In the treatment of gaseous diffusion by the random-walk analogy, it is found that the quantity α^2 is approximately given by the product of the mean free path, the mean speed and a proportionality constant that is close to unity. Analogously, in the case of equation 11, α^2 would be expected to be given approximately by the product of the mean θ excursions between $\dot\theta$ changes, say $\overline{|\theta|}$, and the mean value of $\overline{|\dot\theta|}$. Thus

$$\alpha^2=\overline{|\theta|}\,\overline{|\dot\theta|} \quad (12)$$

As is characteristic of normal distributions, equation 11 cannot be true literally, since it extends to infinite values of θ in finite time, but if the value of α is taken in recognition of the physical limitations on the target's maneuvering capabilities, then the probability of impossibly large values of θ will be negligible. The physical limitations on $\overline{|\theta|}$ are fairly clear. Since only a finite force is available for turning (or as is said, the target can "pull" only a limited number of g's in a turn, generally 3 or less) $\overline{|\dot\theta|}$ is bounded, and in general

$$|\dot\theta|<\frac{3g}{V} \quad (13)$$

The boundness of $\overline{|\theta|}$ follows from the limitations on $\dot\theta$ and the implicitly finite target life.

It would appear, however, that the value of α, while restricted by physical limitations, would be more directly related to the choice the target makes in regard to maneuvering and evasion tactics. Its purpose in life is not to execute evasion maneuvers but to achieve an objective that becomes more difficult if not impossible if it evades excessively. This means that while it has the capacity to make α fairly large by taking headings at large angles to the direction to the objective, it will accept a smaller value of α so as not to prejudice its ability to accomplish its mission. It appears reasonable to assume that it is unlikely to hold headings much more than 10 degrees removed from its average course, so that one may write

$$\overline{|\theta|}<10° \quad (14)$$

Equations 13 and 14 serve to put a bound on α. Rather than assign a specific value to α for study purposes, one may choose to vary α using it as a parameter to describe the extent to which maneuvering and evasion tactics are expected of targets. In this way the factors in the tracking process that influence ability to follow maneuvers may be assessed. For such a study, it is convenient to have a bound on α so that the study is not extended to unrealistically large values.

Assuming the value of α to be known, or suitably chosen, $\overline{\cos\theta(T)}$ may be computed using equation 11. Thus,

$$\overline{\cos\theta(T)}=\frac{1}{(2\pi T\alpha)^{1/2}}\int_{-\infty}^{\infty}\cos\theta e^{-\frac{\theta^2}{2\alpha^2T}}d\theta$$

$$=e^{-\frac{\alpha^2T}{2}} \tag{15}$$

Hence

$$\overline{\cos\,[\theta(s)-\theta(r)]}=e^{-\frac{1}{2}\alpha^2|s-r|} \tag{16}$$

and from equation 10

$$\sigma^2(\tau)=V^2\int_0^\tau\int_0^\tau e^{-\frac{1}{2}\alpha^2|s-r|}dr\,ds$$

$$=2V^2\int_0^\tau\int_0^s e^{-\frac{1}{2}\alpha^2|s-r|}dr\,ds \tag{17}$$

$$=\frac{4V^2}{\alpha^2}\int_0^\tau e^{-\frac{1}{2}\alpha^2s}\left(e^{\frac{1}{2}\alpha^2s}-1\right)ds$$

$$=\frac{8V^2}{\alpha^4}\left(\frac{\alpha^2\tau}{2}-1+e^{-\frac{\alpha^2}{2}\tau}\right)$$

Hence

$$\overline{(\mathbf{r}_j-\mathbf{r}_i)(\mathbf{r}_j-\mathbf{r}_i)}=\sigma^2(\tau_{ij})=\frac{8V^2}{\alpha^4}f\left(\frac{\alpha^2}{2}\tau_{ij}\right) \tag{18}$$

where $f(x)=(x-1+e^{-x})$ and as previously mentioned $\tau_{ij}=|\tau_i-\tau_j|$.

As would be expected, the function $f(x)$ is monotonically increasing. Its first and second derivatives are always positive for $x>0$. When $x\to0$, $f(x)\to x^2/2$ so that

$$\overline{(\mathbf{r}_j-\mathbf{r}_i)(\mathbf{r}_j-\mathbf{r}_i)}=V^2\tau_{ij}{}^2 \tag{19}$$

This corresponds to the case of a nonmaneuvering target, where $\alpha\to0$. The same result applies when the time interval covered is extremely short in which case the target does not have time to maneuver.

Calculation of the Coefficients and the Standard Error of Estimate

The completion of the solution is now more or less straightforward. Using equations 9 and 18, the autocorrelation is given by

$$\overline{\mathbf{r}_i\mathbf{r}_j}=r^2-\frac{4V^2}{\alpha^4}f\left(\frac{\alpha^2\tau_{ij}}{2}\right) \tag{20}$$

This result may be used in the normal equation 5 and the values of the coefficients a_1, a_2, … a_n, found for cases of interest. That the values of these coefficients will converge as r^2 grows indefinitely large may be seen as follows:

The solution of the normal equations can be expressed as the ratio of two determinants using Cramer's rule. All elements of both determinants are of the form: r^2+c_{ij} where $c_{ij}=\delta_{ij}\sigma^2-1/2\sigma^2\tau_{ij}$ (and δ_{ij} is Kronecker's delta). The determinants can be expanded as a sum of determinants having rows (or columns) whose elements are either c_{ij} or are all equal to r^2. Those determinants having two or more rows (or columns) of r^2 will vanish, hence only determinants having one or no rows (or columns) of r^2 will contribute and the solution for the coefficients can be put in the form

$$a_i=\frac{\ell_ir^2+m_i}{n_ir^2+\sigma_i} \tag{21}$$

Where ℓ_i, m_i, n_i and σ_i are independent of r^2 and in general finite. As r^2 becomes large the coefficients approach the values

$$a_i\to\frac{\ell_i}{n_i}\left[1+\left(\frac{m_i}{\ell_i}-\frac{\sigma_i}{n_i}\right)\frac{1}{r^2}\right]$$

$$=p_i+q_i\frac{1}{r^2}\to p_i \tag{22}$$

where

$$p_i=\frac{\ell_i}{n_i}$$

and

$$q_i=\frac{\ell_i}{n_i}\left(\frac{m_i}{\ell_i}-\frac{\sigma_i}{n_i}\right)$$

For present purposes the values $a_i=p_i$ may be used for the linear predictor.

Once the coefficients are known the standard error of estimate say, δ, maybe computed as follows:

$$\delta^2=\overline{(\mathbf{R}_0-a_1\mathbf{R}_1-a_2\mathbf{R}_2-\ldots-a_n\mathbf{R}_n)(\mathbf{R}_0-a_1\mathbf{R}_1-a_2\mathbf{R}_2-\ldots-a_n\mathbf{R}_n)} \tag{23}$$

and noting that the coefficients satisfy equation 2.

$$\delta^2=\overline{\mathbf{R}_0\mathbf{R}_0}-a_1\overline{\mathbf{R}_0\mathbf{R}_1}-a_2\overline{\mathbf{R}_0\mathbf{R}_2}-\ldots-a_n\overline{\mathbf{R}_0\mathbf{R}_n}$$

$$=\overline{\mathbf{R}_0\mathbf{R}_0}-\sum_{i=1}^n a_i\overline{\mathbf{R}_0\mathbf{R}_i} \tag{24}$$

whereupon using equations 3, 4, 9, and 18

$$\delta^2=r^2+\sigma_e{}^2-\sum_{i=1}^n a_i\overline{\mathbf{r}_0\mathbf{r}_i}$$

$$\delta^2=\left(1-\sum_{i=1}^n a_i\right)r^2+\sigma_e{}^2+$$

$$\frac{4V^2}{\alpha^4}\sum_{i=1}^n a_i\left(\frac{\alpha^2\tau_{0i}}{2}-1+e^{-\frac{\alpha^2}{2}\tau_{0i}}\right) \tag{25}$$

Since the coefficients minimize δ^2 under the condition that r^2 is indefinitely large it is clear that the a_i must converge to values such that

$$\sum_{i=1}^n a_i=\sum_{i=1}^n p_i=1 \tag{26}$$

This relationship confirms the uniformity of the predictor in regard to the observation space, since it implies that the predicted position translates with any translation of the past position reports. (Insensitivity to the rotation of the past position reports follows from the use of the same linear predictor for the x and y co-ordinates.)

Using equations 22 and 26 the expression for δ^2 becomes, for indefinitely large r^2

$$\delta^2=\sum_{i=1}^n q_i+\sigma_e{}^2+\frac{4V^2}{\alpha^4}\sum_{i=1}^n a_i\times$$

$$\left(\frac{\alpha^2\tau_{0i}}{2}+e^{-\frac{\alpha^2}{2}\tau_{0i}}\right) \tag{27}$$

APPLICATIONS

The foregoing analysis can be applied to general exploratory studies as well as to cases of special interest. A general study could be executed most readily for the case where the reports and the prediction are evenly spaced in time. Then the parameters that enter the problem are:

Δt = the time interval between reports
α = the maneuverability parameter
V = the target velocity
σ_e = the rms measurement error
n = the number of past position reports that are retained

The coefficients of the predictor are nondimensional. The only other significant result, the standard error of estimate can be put in nondimensional form by expressing it as a fraction of σ_e, $V\Delta t$, or V/α^2. The nondimensional results can only be functions of the nondimensional parameters that can be formed from those just listed. Only three independent parameters can be formed: These may be chosen in a variety of ways. For example, the choice might be:

$$\frac{\alpha^2\Delta t}{2},\ \frac{4V^2}{\alpha^4\sigma_e},\ n$$

Where the predicted position does not conform to the even time spacing then an additional nondimensional parameter will be required. This may be chosen to be the ratio of the projection of time into the future to the time interval between past reports.

When only three or four nondimensional parameters are involved a rather complete study would appear to be feasible. For the case of arbitrarily spaced reports the number of parameters becomes excessive if more than a few past reports are considered. Also the implimentation of a predictor incorporating the results for this situation would be more difficult. However, the calculation of some representative cases may be effective in demonstrating how a proposed predictor departs from what could be obtained, ideally, and for guiding the design of a suitable predictor.

The selection of gate sizes would be predicated upon the value expected for the standard error of estimate, and upon the probability of "escape" that is deemed to be tolerable. An estimate of the probability of escape would be computed upon the basis of an assumed normal probability distribution for the deviation from the prediction. However, it should be kept in mind that such calculations of escape probability do not include the effect of departures of target's motion from the idealized characteristics. The most important factors in this connection are the assumed two-dimensional motion and the constancy of V. Minor variations in V and moderate changes in altitude should work no hardship, and probably, if desired, modifications could be introduced to encompass these. However the possibility remains of drastic departures from the idealized characteristics. Thus when an airplane executes an acrobatic maneuver such as a loop, its track would probably be interrupted. Likewise, a tracking system such as described herein could not be expected to cope with the maneuvers of a heliocopter.

In designing a tracking system, it must be recognized that the probability of escape will not be reduced to zero; at least not with any simple mechanization. A reasonable approach is first to seek to reduce escape probabilities to small values as simply and conveniently as possible. The basic portion of the tracking system should therefore be designed to accommodate the usual or most commonly expected target characteristics. If proceeding in this way the number of fugitives can be kept small, then it may be feasible to institute more elaborate search methods to recapture lost targets should this be needed and/or desired.

Global Public Telephone Service—1958

D. D. DONALD
MEMBER AIEE

T. A. CHANDLER
NONMEMBER AIEE

AT the Symposium on Global Communications in Washington, D. C., in June of 1954, Mr. Donald of the American Telephone and Telegraph Company presented a paper discussing the global public telephone service as provided by that company. It is proposed here to review some aspects of public telephone service in the light of the important developments that have taken place since then.

Overseas Message Telephone Growth

Overseas public telephone service between the United States and other areas in the world has continued to grow since 1953, not only in the number of areas reached, which has increased more than 20%, but also in the number of overseas public telephone messages which are handled. The volume of messages has increased approximately 87% over the number handled in 1953 as can be seen from Fig. 1 which shows the total overseas public messages between the United States mainland and other areas by years. It will be noted that the placing in service of the transatlantic telephone cable system between the United States and Great Britain in September 1956 contributed very substantially in the growth of traffic experienced. As a matter of interest, one year after the transatlantic cable system was in service the volume of messages with Great Britain had increased approximately 90%, with substantial increases also being experienced with those countries on the European continent which are served by direct circuits in this cable system. Another point of interest is that after the cable system had been in operation, it was noted that the average length of conversations between the United States and Great Britain had increased approximately 20% and a similar but somewhat smaller increase was experienced between the United States and countries in Europe which are served by the cable.

The first telephone cable system across the Atlantic Ocean was followed by a similar system between Seattle, Wash., and Ketchikan, Alaska, which was placed in service in December 1956. Again, a marked increase in the volume of traffic occurred with the result that one year later it had increased approximately 30%. A third underseas telephone cable system was placed in service in October 1957 between the mainland of the United States and Hawaii. As in the two previous cable systems, this sytem also shows a substantial increase in the volume of telephone traffic handled. A comparison of the traffic volume for several months prior to the introduction of service over this cable system and the same period one year later shows an increase in the order of 50%.

Fig. 2 shows the various overseas points which are connected with the Bell System to furnish public telephone service. The dots indicate points served by direct circuits or links and the circles are points served by switched circuits; for example, service with the Canary Islands is furnished via Madrid. It can be seen that there are relatively few areas in the world with which service is not available.

Fig. 2. Overseas points of communication and cable routes

Underseas Public Telephone Cable Systems

The underseas telephone cable systems between the United States mainland and Great Britain, Alaska, and Hawaii respectively, are indicated by the solid lines in Fig. 2. The dashed lines on this figure show systems planned to the European continent and to Puerto Rico. The basic design of these systems is the same in that a pair of cables is used, one in each direction of transmission, each is designed to provide 36 voice channels of normal bandwidth, uses flexible repeaters built into the cable, and is powered from the cable terminal stations.

The transatlantic cable system terminals are at White Plains, N.Y., Montreal, Que., Canada, and London, England, with the terminals of the deep-sea cable portion located only at Clarenville, Newfoundland, and Oban, Scotland. This system is a joint project of the General Post Office in England, the Canadian Overseas Telecommunication Corporation, and the American Telephone and Telegraph Company. Of the 36 voice channels in the system $29^1/_2$ are allocated for United States traffic and $6^1/_2$ for Canadian traffic.

From the deep-sea cable terminal at Clarenville, the United States channels are extended to White Plains, by means of a submarine cable system between Clarenville and Sydney Mines, Nova Scotia; by a *TD-2* microwave-radio relay system from the latter point to Portland, Maine; and by cable-carrier groups to White Plains. The Canadian channels branch off at Spruce Lake, a station on the *TD-2* route in Canada, and are extended to Montreal on facilities comparable to those in the United States. In the United States group, a number of the circuits are extended from London to points on the European continent for service with those countries. As the channels in this system are loaded to capacity, discussions are under way between the partners in this project toward increasing the number of voice channels to handle the continuing growth in traffic.

The underseas portion of the Alaska system extends from Port Angeles, Wash., to Ketchikan, Alaska, with an extension at the United States end to Seattle, where it connects with the domestic long-distance network. At Ketchikan, the 36 voice channels connect to facilities of the Alaska Communications System to furnish telephone service to various points throughout Alaska. Between Ketchikan and Skagway in Alaska, service is furnished over Alaska Communications System facilities consisting of a single underseas cable using land-based repeaters.

The underseas telephone cable system with Hawaii is a joint project of the American Telephone and Telegraph Company and the Hawaiian Telephone Company. The deep-sea cable terminals are located at Point Arena, Calif., and Hanauma Bay on the island of Oahu, with the system terminals at Oakland and Sacramento, Calif., and Honolulu. The deep-sea portion of this system is the longest of the three in operation, extending approximately 2,540 miles with 57 cable repeaters in each direction. With the commencement of service over this cable system, overseas dialing was inaugurated simultaneously. On the United States mainland any long-distance operator with access to the dialing network can dial a call to any number in Hawaii connected to the dialing network in that area and similarly, in the opposite direction from Hawaii to the United States mainland. As the channels in this cable are equipped for dialing and a number of the radio circuits between Oakland and Honolulu are also maintained in operation, it was necessary to equip the radio circuits for dial operation as is discussed later in this paper.

These cable systems provide high-quality telephone circuits which meet the same transmission requirements as domestic circuits of comparable lengths. These circuits are free from fading and have a low noise level which is not subject to fluctuations due to radio propagation variations. The transmission-frequency characteristics are stable as contrasted with the variations encountered in high-frequency radio circuits resulting from selective fading. They are free from the usual propagation outages on radio that result from magnetic storms and sudden ionospheric disturbances particularly on the North Atlantic and Alaska routes.

With the success of the three undersea telephone cable systems already in operation it became evident that additional cable systems would be required wherever they were needed to handle large volumes of traffic and could be justified from an economic viewpoint. Plans have been made and construction has commenced on a second underseas telephone cable system across the Atlantic Ocean between the United States and the continent of Europe which is planned for service in late 1959. Partners in this project are the Government Administrations of France and Germany, together with the American Telephone and Telegraph Company. The deep-sea cable terminals for this system will be at Clarenville, Newfoundland, and Penmarch, France. Another system is planned between the United States mainland and Puerto Rico for service in early 1960. This will be a joint project of the American Telephone and Telegraph Company and the Radio Corporation of Puerto Rico, a subsidiary of the International Telephone and Telegraph Corporation. The cable terminals of this system will be at West Palm Beach, Fla., and San Juan, Puerto Rico. The basic design of these two systems will be the same as the three already in service.

As satisfactory results were obtained with traffic operator dialing on the circuits in the Hawaiian cable system, plans have been made to introduce dialing on the Alaska circuits early in 1959. It is planned to introduce dialing on the Puerto Rico circuits when that underseas cable system is placed in service.

Over-the-Horizon Radio

The development of over-the-horizon or tropospheric-scatter radio techniques for multichannel telephone systems has been a significant development in the last few years. This technique permits the establishment of radio links of 200 miles or longer depending on the number of voice channels desired, using radio frequencies in the uhf (ultrahigh-frequency) range. Such systems, when carefully engineered, are capable of providing highly reliable service for a group of telephone circuits up to about 200 in number. Relatively high-power transmitters and large antennas are required for the longer distances and larger numbers of circuits.

The great advantages of this technique lie in the high reliability of the circuits as compared to circuits using high-frequency radio techniques, especially in regions of the world subject to great ionospheric propagation instability. The quality of the circuits provided compares very favorably with those provided by line-of-sight microwave techniques or by cable facilities. Operating as they do in the uhf part of the frequency spectrum such systems avoid additional crowding of the frequency range 2–7 mc (megacycles) required for the 200-mile distance range when using ionospheric-reflection radio techniques. Frequencies in this latter range would not be available in many parts of the world to provide telephone circuits in the quantities that are possible by over-the-horizon systems.

From an economic standpoint the over-the-horizon system is usually somewhat less costly than a deep-sea repeatered submarine cable especially when the number of telephone circuits approach the maximum which the system is ca-

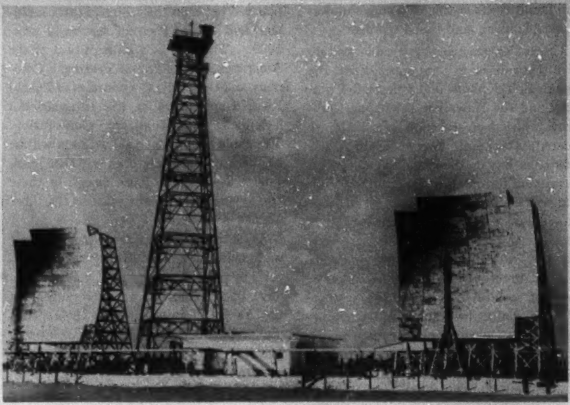

Fig. 3. Florida City Station with 60-foot antennas and microwave tower

pable of handling. For small numbers of circuits, radio using the ionospheric-reflection techniques is far less expensive but does not approach over-the-horizon techniques in quality and reliability. Where line-of-sight radio systems using intermediate repeaters are readily installed and maintained, it appears that such systems will usually be less costly.

An important radio link of this type has been provided between Florida City, Fla., and Guanabo, Cuba, by the American Telephone and Telegraph Company on the Florida end and the Radio Corporation of Cuba, a subsidiary of the International Telephone and Telegraph Corporation, on the Cuban end. This system has been described at other meetings and it is proposed here to only note its general features.

This system employs 10-kw transmitters and 60-foot parabolic reflector antennas. Two channels are provided for full protection of service. Each channel employs space diversity reception and diversity combining of the two channels is also provided. At the United States end a 2-link *TD-2* microwave system connects to Miami and at the Cuban end a similar single link connects to Havana. Fig. 3 shows a general view of the Florida City Station indicating the 60-foot parabolas and the *TD-2* tower. Fig. 4 shows the route layout of the system. This figure also shows the proposed system to Nassau, Bahamas, which is planned for service by the end of 1959. Whereas the Cuban system operates in the 700–900-mc band, it is proposed to operate the Nassau system in the 2,000–2,200-mc band. Thirty-foot parabolic antennas are being employed in the latter system.

The Cuban system at present is providing 36 telephone circuits of the same general grade of quality and reliability as are provided by the cable circuits on the route to Cuba. It is capable of an ultimate capacity in excess of 100 circuits when growth requires this number. Video service is also being provided over this system on an occasional basis, as required, making use of the second radio channel which is provided for protection. Because of selective fading, video service is not entirely comparable to that provided over line-of-sight microwave systems, but monochrome signals acceptable for broadcasting are being received over the system with a high degree of reliability.

Other systems employing over-the-horizon techniques have been provided elsewhere in the world. The most extensive of these used for public telephone service is the Alaska Communication System project called White Alice. This is a joint military and public telephone service system. Other systems used for public telephone service have been installed in Canada, the Caribbean area, and in the European area.

High-Frequency Radio

High-frequency radio continues to provide the facilities for most of the transoceanic links in the world telephone network. Although the use of cables on major traffic routes and over-the-horizon links, in a few cases where they are feasible, will continue to increase, it appears that high-frequency ionospheric-reflection techniques will continue to play a major role in the international public telephone service for many years to come. They are necessary to serve many places where cable is not feasible and over-the-horizon radio techniques are not applicable. They are required to parallel cable routes to provide protection and dispersion of facilities. These radio facilities also provide direct connection between countries where the cable routes traverse intermediate countries. It is urgently desirable that these facilities be improved in quality and reliability. A number of trends are evident in this direction.

The use of single-sideband techniques continues to expand and provides an improvement in service both in signal-to-noise ratio for equivalent power output and a quality improvement. The most important advantage of this technique

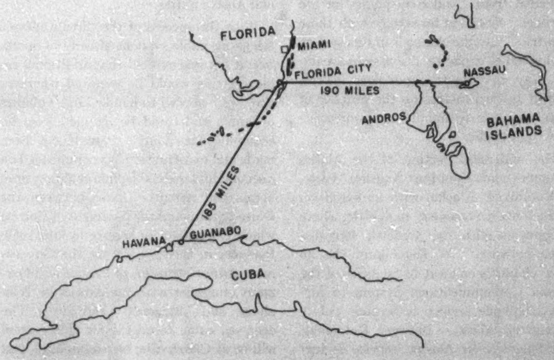

Fig. 4. Over-the-horizon system routes at Florida City

is, however, the conservation in spectrum occupancy which it provides. The overseas public radiotelephone circuits terminating in the United States are approximately 95% on a single-sideband basis now and this percentage is increasing steadily.

There is also a trend toward the use of higher power on transoceanic circuits. In this connection the American Telephone and Telegraph Company has recently placed in service ten newly designed 30-kw power amplifiers. The provision of additional amplifiers is planned for services where a significant improvement in service continuity can be obtained.

This is a single-stage amplifier designed by the Westinghouse Electric Corporation to Bell System specifications. It operates in the frequency range 4 to 26.5 mc, utilizing two Machlett type *6423* air-cooled vacuum tubes connected in parallel and operated in a grounded grid circuit. A peak envelope power of 30 kw is provided into a balanced load of from 200 to 900 ohms resistance when driven by an exciter capable of an output of 2.5-kw peak envelope power. The amplifier output pi-network is somewhat unique in that there are no roller or sliding contacts, the tuning being accomplished by means of fixed coils and variable vacuum capacity, the required combination being switched in by means of vacuum relays.

A servosystem is incorporated in the amplifier and is arranged for interconnection with the servosystem of the Western Electric Company *LD-T2* transmitter used as a driver in such a way that any one of ten preset frequencies may be selected by pushbutton control either at the equipment or, with suitable circuits, from a remote point. Fig. 5 gives a view of part of the transmitter room at the Lawrenceville, New Jersey, station showing these amplifiers with the *LD-T2* driver units.

Fig. 5. Amplifiers at the Lawrenceville, N. J., transmitting station

These are being used on the European paths which approach the Auroral Zone and are most in need of improvement. Most of the European countries where these circuits terminate have also installed equipment of comparable power output.

High-Frequency Radio Spectrum

With the increasing number of fixed radio services operating in the high-frequency range it has been necessary to take advantage of all available techniques to obtain improved utilization of the spectrum and conserve the available frequency space. Typical of such measures is the extensive use which has been made for many years of the single-sideband method of operation and the use of multiplex systems for both telephony and telegraphy.

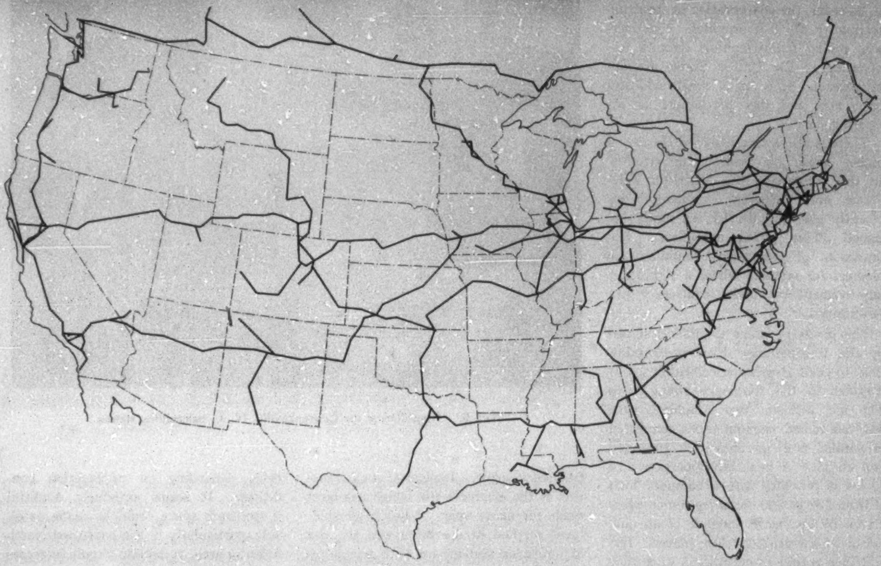
In the paper referred to in the opening paragraph, the results of an analysis showing the number of radio-frequency assignments in the ranges 7,300 to 8,195 kc and 14,350 to 14,990 kc were given. A recent analysis of the same frequency ranges has been made and it shows that there had been an increase of approximately 35% in the number of stations which have registered for operation in these bands. On the average, there are more than 13 stations registered for every kilocycle in the 7,300–8,195-kc range and more than two stations for every kilocycle in the 14,350–14,990-kc range. Considering that each telephone circuit requires a minimum of 3 kc of spectrum space, it can be seen that the likelihood of finding additional frequencies which are clear of interference to provide service expansion is extremely difficult in most parts of the world.

As the overseas public telephone service is continuing to grow, the provision of additional telephone circuits by high-frequency radio using the most efficient multichannel single-sideband techniques would require the continuous use of 108 kc of spectrum space in each direction of transmission to furnish 36 circuits, or the basic capacity of one underseas cable system. This would, depending on the route, require assignments totaling 216 kc in each of four or five different frequency ranges, each being used part-time, depending on propagation conditions. It seems extremely doubtful if spectrum space could be made available, particularly in the congested North Atlantic area, to handle circuit increases of this magnitude.

Line-of-Sight Microwave Radio-Relay Systems

Another significant development in recent years has been the rapid expansion in the use of line-of-sight microwave radio-relay systems in the public telephone networks. This has been particularly true in the United States and Canada and there is considerable use of these systems in Europe and other parts of the world.

Fig. 6 indicates the major microwave radio-relay routes of the Bell System and connecting carriers used for public telephone service in the United States and Canada. It will be noted that the systems extend from coast-to-coast and from Canada to Southern United States. Most of these routes employ the Western Electric *TD-2* radio system. Many sections have been developed to the full capacity of six channels in each direction for telephone and television purposes. The individual radio channels used for telephony are generally developed for about 600 telephone circuits. In deriving the telephone circuits a frequency-division single-sideband carrier technique is used employing the same carrier systems as are used on coaxial cables. The combined carrier signal is transmitted over the radio system by frequency modulation.



OCTOBER 1, 1958

Fig. 6. Broad-band microwave radio-relay system

Vol.
Pt. 1
1959

In the United States a large part of the new long-distance telephone facilities provided in recent years have employed microwave facilities. Experience indicates that this is a highly reliable and economical method of handling telephone service as well as the network television service.

Overseas Dialing

The growth in traffic in the overseas service has made it desirable to consider improved methods of handling calls. Experience in the United States and other countries indicates that calls can be more speedily and accurately established by properly engineered dialing systems. Rapid strides have been made in the United States in applying dial signaling systems to the long-distance network. It was only natural that as the business to Hawaii grew that consideration should be given to extending this method to that part of the United States.

The transmission of dial signaling information and supervisory signals over the underseas telephone cables presents no new problems. The same general methods as are used throughout the United States long-distance network can be employed with appropriate terminal facilities to integrate them with the local dial facilities.

The transmission of signaling information with adequate reliability is a problem on high-frequency radio circuits. It is well known that on high-frequency radio circuits using ionospheric reflections, any single frequency signal is subject to more or less continuous variations in received level due to multipath fading. In telegraph systems these are largely overcome by diversity and frequency shift methods.

The requirements of a dial signaling system for high-frequency radiotelephone circuits are that the signaling tones must be contained within the normal bandwidth of the telephone circuit to conserve the use of the frequency spectrum, the tones must not be transmitted continuously so that the radio transmitter will not be loaded excessively, and the required signals must be received with adequate reliability during all radio propagation conditions during which the telephone circuit is suitable for conversation by the telephone-using public.

A signaling system meeting these requirements has been developed and is being used successfully on the radiotelephone circuits to Hawaii. This sends tones at 800 and 1,900 cycles which are within the telephone band during intervals when signals are required. Tones are sent in duplicate, spaced 1,100 cycles apart to provide frequency diversity, and dial pulses are sent by frequency shift where the frequency of both tones are shifted 200 cycles upward in frequency.

This method is applicable to any high-frequency radiotelephone route where dial signaling is desired. There are a number of problems in introducing dial signaling to foreign countries. When these are resolved it is expected that dial signaling will be expanded. Early applications are expected to be on routes having combined cable and radio facilities. On such routes it is felt that the radio facilities normally used should be equipped for dialing as well as the cable circuits.

Summary and Conclusions

It has been shown that there has been a remarkable growth in transoceanic telephone communications in recent years. This has been stimulated particularly by the provision of underseas telephone cable circuits which provide service in quantity and quality far surpassing what has heretofore been available.

In contrast to the trend toward using

cable in long transoceanic circuits, for which radio has in the past been the means of telephone communication, there is an opposite trend toward using radio for domestic networks and the rather short links to near-by islands. The expanding use of line-of-sight and over-the-horizon radio systems is clearly evident. These systems provide circuits in quality and quantity comparable to what can be provided by wire methods.

High-frequency ionospheric reflection radio continues to be a major method of transoceanic communications. The extension of single-sideband techniques to those cases where this method was not already used and the provision of higher power is improving these communications.

As the major telephone networks are brought closer together by these new facilities, a need exists for improved operating methods including dial signaling. Means have been developed to apply these methods to high-frequency radiotelephone circuits in spite of the transmission difficulties due to multipath fading.

In conclusion, the continuation of present trends seems a certainty. Expansion in the domestic telephone network by means of microwave radio will continue. Additional over-the-horizon radio systems and underseas telephone cable systems for public telephone service will be provided as the circumstances warrant.

The provision of high-grade telephone circuits by underseas cables requires large investments. To help offset the costs of such facilities, means are being developed to use existing cables more efficiently. For example, a system called TASI (Time Assignment Speech Interpolation) is under development in the Bell Telephone Laboratories and seems likely to double the capacity of existing cables. It will do this by taking advantage of the times when people are listening or pausing. The voice channels they leave temporarily unused will be automatically assigned to other talkers; and when a listener starts to talk, he will instantly have the use of a channel which another person has left idle. Wider bandwidth-repeatered underseas cables will also be developed to reduce the cost per circuit where large quantities of circuits are required. The recently announced cable system between the United Kingdom and Canada promises to be a step in this direction, providing 60 circuits with both directions of transmission in the same cable sheath. These developments and others will make for an ever-expanding and more economical Global Public Telephone Communication Network.

Design Parameters for Optimizing the Efficiency of Thermoelectric Generators Utilizing P-Type and N-Type Lead Telluride

R. W. FRITTS
NONMEMBER AIEE

THERMOELECTRIC generators are presently being developed for many uses which range from small flame-operated power supplies for automatic control systems to several kilowatt-size thermopiles for prototype evaluation of marine propulsion systems.[1] This renewal of interest in thermoelectric power generation and thermoelectric heat pumping is based on recent advances in the development of special semiconducting materials which exhibit properties intermediate to metals and semiconductors of the type used in *P-N* junction transistor devices. Often called "semimetals," these thermoelectric materials are prepared from semiconducting crystals which are more heavily doped than transistor devices to provide higher electrical conductivity. Such materials exhibit much lower thermal conductivity than do metals and substantially higher thermal emf (electromotive force).

Thermoelectric generators offer a number of advantages over d-c power sources, such as batteries and rotating machines. They are of simple structure requiring no moving parts; they are silent in operation and capable of virtually endless shelf life when used as emergency stand-by power sources. To what extent thermoelectric generators will replace conventional means for generating electricity will depend largely upon the efficiencies that can be obtained in the semimetal materials now under intensive study in many laboratories.

The basic unit of a thermoelectric generator is a thermocouple comprising a *P*-type element and an *N*-type element placed electrically in series and thermally in parallel as shown in Fig. 1. The *P*-type element conducts electricity through the transport of positive holes end when placed in a temperature gradient exhibits a positive voltage at the cold and with respect to the hot end. The *N*-type element conducts electricity through electron transport and exhibits a negative voltage at the cold end with respect to the hot end. The two voltages add to produce the net emf of the circuit. The metal electrodes serves simply as contact and mounting means and their electrical resistance can be ignored for the purposes of this discussion.

When the Seebeck coefficients of the respective materials, S_p and S_n, measured with respect to a reference metal such as copper, are known, the voltage developed

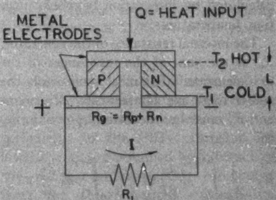


Fig. 1. Basic thermocouple circuit

Paper 59-909, recommended by the AIEE Solid State Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21-26, 1959. Manuscript submitted March 24, 1959; made available for printing April 28, 1959.

R. W. FRITTS is with the Minnesota Mining & Manufacturing Company, St. Paul, Minn.

The author wishes to acknowledge the contributions of R. E. Fredrick, William Huck, and Dr. J. D. Richards to the materials research program and the measurement of transport properties, and the discussions and guidance of Dr. Sebastian Karrer, who is singularly responsible for originating this research and development.

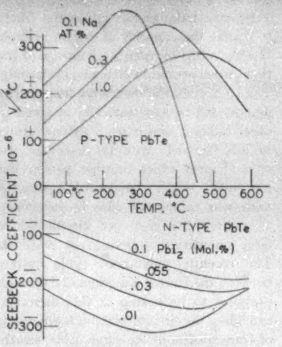

Fig. 2. PbTe Seebeck coefficient versus temperature data

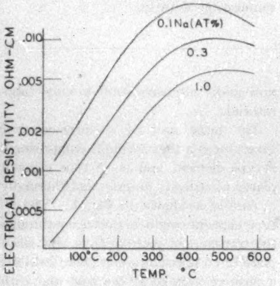

Fig. 3. Resistivity versus temperature for P-type PbTe alloys

in each element is obtained by integrating the Seebeck coefficient with respect to temperature between T_2 and T_1. The open-circuit voltage, termed the Seebeck emf, of the thermocouple is the sum of these two integrals:

$$V=\int_{T_1}^{T_2} S_p dT-\int_{T_1}^{T_2} S_n\, dT$$

In general, the Seebeck coefficients of the semimetals are quite temperature dependent and hence the voltages developed in the thermocouple elements must be calculated by integration between junction temperatures.

The internal resistance of the generator, R_g, is the sum of the resistances of the two elements. For most semimetals the resistivities are temperature dependent and R_g must be calculated by evaluating the integral

$$R_g=\frac{1}{A_p}\int_{T_1}^{T_2}\rho_p\frac{dx}{dT}\,dT+\frac{1}{A_n}\int_{T_1}^{T_2}\rho_n\frac{dx}{dT}\,dT$$

This integral expression for R_g can be evaluated when the resistivity temperature dependence is known and only when the temperature distributions within the semimetals are specified.

The power output of a specific thermocouple can be calculated from the foregoing integral expressions. The heat transferred through the thermocouple elements due to thermal conductivity under open-circuit conditions represents an irreversible loss and must be taken into account in calculating the efficiency of the thermocouple. The thermal conductivity of most semimetals is also temperature dependent and is the major factor controlling the temperature distribution within each element.

Ioffe[2] and others have treated the problem of thermoelectric efficiency thoroughly to find that the maximum efficiency is given by the expression

$$\eta_{\max}=\frac{\Delta T}{T}\,\frac{\sqrt{1+Z\dfrac{(T_2+T_1)}{2}}-1}{\sqrt{1+Z\dfrac{(T_2+T_1)}{2}}+T_1/T_2};$$

$$Z=\frac{(S_p-S_n)^2}{(\sqrt{K_n\rho_n}+\sqrt{K_p\rho_p})^2}$$

where Z is defined as the Figure of Merit and represents the material dependent parameters. S, K, and ρ refer to the Seebeck coefficient, thermal conductivity, and electrical resistivity of the respective elements. Under conditions of maximum efficiency the cross-section ratio for thermocouple elements of the same length is

$$\frac{A_n}{A_p}=\sqrt{\frac{K_p\rho_n}{K_n\rho_p}}$$

The Figure of Merit combines three temperature dependent parameters and hence it also is quite temperature dependent. This temperature dependence of the Figure of Merit must be taken into account if the preceding expression for operating efficiency is to be evaluated with accuracy. Where Z can be plotted against temperature from experimental data, the effective value of Z to be used in the efficiency calculation is the average value of Z obtained from

$$Z_{\text{ave.}}=\frac{1}{\Delta T}\int_{T_1}^{T_2} Z\, dT$$

Where P-type and N-type materials of identical properties are used the Figure of Merit can be reduced to

$$Z=\frac{S^2}{K\rho}$$

where S, K, ρ refer to the properties of either material alone. In the subsequent analysis the Figure of Merit of the

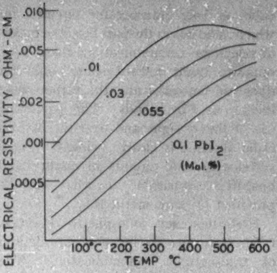

Fig. 4. Resistivity versus temperature for N-type PbTe alloys

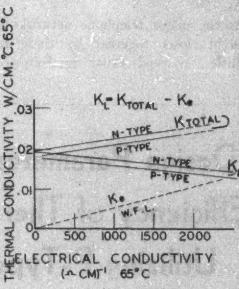

Fig. 5. PbTe thermal conductivity data determined for 65 C

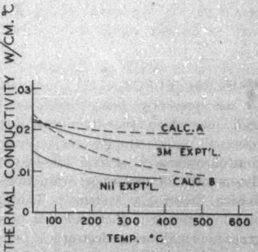

Fig. 6. Experimental and calculated thermal conductivity temperature dependence

N-type element and P-type element will be treated separately for the sake of simplicity and the average value of the two will be used to solve for the efficiency of the combination in a thermocouple.

Examination of the expression for maximum efficiency reveals that a high value of Figure of Merit is required for high efficiency; high hot junction temperatures and large temperature differentials

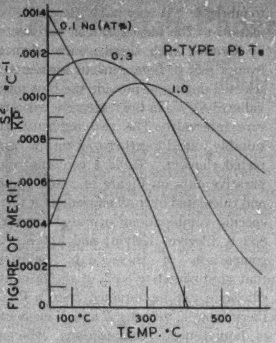

Fig. 7. Figure of Merit versus temperature for P-type PbTe alloys

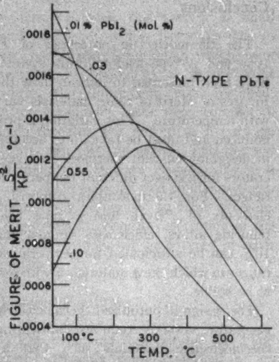

Fig. 8. Figure of Merit versus temperature for N-type PbTe alloys

also increase the efficiency. Hence, for optimum efficiency thermoelectric materials exhibiting high Seebeck coefficient, low electrical resistivity, and low thermal conductivity are desired. Efficiency can be improved by utilizing very stable chemical species for the thermocouple elements so that they may be operated at high hot junction temperatures if high values of $S^2/K\rho$ can be maintained at these high temperatures.

Because of the variation of Z with temperature for most semimetals, there will seldom be a specific homogeneous composition which will exhibit the optimum efficiency over all temperature ranges to be encountered in device design. It is the purpose of the next section to describe the properties of a typical thermoelectric material and present methods for selecting the best compositions for specific thermoelectric generator designs.

Thermoelectric Properties of Lead Telluride Systems

Lead telluride is the first of the new thermoelectric materials to be used extensively in operating thermoelectric generator devices. The successful operation of lead telluride generators at hot junction temperatures of 600 C (degrees centigrade) for several years demonstrates the chemical stability of the binary compound and proves the existence of compatible contacting and mounting schemes.

Lead telluride (PbTe) is a binary compound which melts at 922 C and its chemical binding is largely covalent. The material can be prepared in either *P*-type or *N*-type form and the carrier concentration of either type can be varied over about two orders of magnitude by suitable doping. The system exhibits high carrier mobility for electrons and positive holes, (about 1,800 and 880 cm^2/volt sec respectively at room temperature). Unlike silicon and germanium the mobilities are independent of carrier density up to concentrations of about 10^{19}/cc and the systems are effectively nondegenerate in this same range.

The thermoelectric properties of *P*-type and *N*-type PbTe alloys are shown in Figs. 2–6, plotted for the temperature range over which reproducibility can be achieved for long term service. At the lower temperatures the Seebeck coefficient and resistivity increase with increasing temperature characteristic of an extrinsic semiconductor. At elevated temperatures this trend reverses and further temperature increase induces intrinsic ionization of electrons and holes typical of a pure semiconductor. Impurity doping which increases the density of electrons or holes at all temperatures has a twofold effect on these alloys. Increased doping reduces both the Seebeck coefficient and the resistivity in the extrinsic range. Increased doping also extends to higher temperatures, the point at which the transition from extrinsic to intrinsic behavior occurs. This is most important since the highest values of Figure of Merit are obtained in systems which are primarily extrinsic in nature.

Fig. 5 shows how thermal conductivity is influenced by increased doping which causes a proportional increase in electrical conductivity. The upper curves specify the total thermal conductivity and the lower curves indicate how the lattice conduction is reduced by the addition of the doping agent to the PbTe lattice. This reduction in the lattice conduction is to be expected as the solid solution of the doping agent introduces scattering centers in the periodicity of the PbTe crystal. The lower curves are obtained by subtracting the nondegenerate electric component from the total thermal conductivity. This electronic component is given by the following:

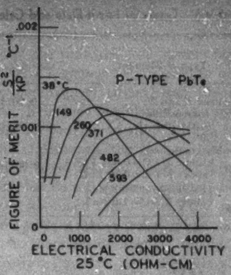

Fig. 9. Figure of Merit isotherms of P-type PbTe alloys plotted against room temperature conductivity

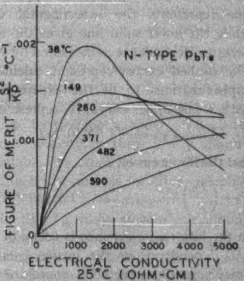

Fig. 10. Figure of Merit isotherms of N-type PbTe alloys plotted against room temperature conductivity

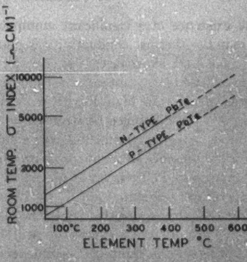

Fig. 11. Room temperature conductivity index to optimum $S^2/K\rho$ versus temperature

Table I. Figure of Merit Data and Calculated Efficiencies of Different PbTe Combinations

Type of Elements	N	P	Average	Calculated Efficiency
Idealized P and N	0.00133 C^{-1}	0.00105	0.00119	11.70%
Single composition N....0.055 PbI_2 P...1.0 Na	0.00115	0.000835	0.000992	10.28%
Doubly segmented N... below 371 C=0.055 PbI_2 above 371 C=0.10 PbI_2	0.00119		0.00109	
P... below 315 C=0.3 Na above 315 C=1.0 Na		0.00100		11.02%

Note: only $T_2=866$ K $T_1=311$ K $S^2/K\rho$ C^{-1}.

$$Ke=2\left(\frac{k}{e}\right)^2\sigma T=1.5\times10^{-8}\sigma T$$

The temperature dependence of thermal conductivity for a single PbTe composition is shown in Fig. 6. The upper solid line represents the experimental data while the lower solid line gives the temperature dependence as measured by Nii.[3] The dashed curves represent calculated approximations to fit the experimental data. The upper curve, A, represents

$$K_T=K_{(\text{lattice } T=65\text{C})}+1.5\times10^{-8}\sigma T$$

and the lower curve, B,

$$K_T=\left(\frac{To}{T}\right)K_{(\text{lattice } T=65\text{C})}+1.5\times10^{-8}\sigma T$$

In the latter case account is taken of the $1/T$ dependence of the lattice conductivity normally expected in crystals of this type. From theory the most realistic expression for thermal conductivity is

$$K_T=\left(\frac{To}{T}\right)K_{(\text{lattice } T=65\text{C})}+1.5\times10^{-8}\sigma T+\text{radiation term}$$

The existence of a significant ambipolar term in the thermal conductivity is questioned as high extrinsic carrier concentrations will tend to suppress the minority carrier density in high Figure of Merit alloys. The difference between curve B and the upper experimental curve suggests the presence of a radiation transfer mechanism in PbTe crystals placed in a temperature gradient.

For the purposes of this paper the first thermal conductivity expression will be used wherein the temperature independent lattice term is taken from the lower curves of Fig. 5. The plots of Fig. 5 are considered to be the most accurate data available on the thermal conductivity of doped PbTe.[4] The resulting error in the calculated Figures of Merit will be conservative and the true materials efficiencies will be somewhat higher than the values to be given here.

The values of $S^2/K\rho$ calculated from the data of Figs. 2 to 6 are plotted in Figs. 7 and 8 as point functions of temperature. For both P-type and N-type systems low concentrations of doping agents, and hence low carrier densities, provide high $S^2/K\rho$ values at low temperatures. High concentrations of doping agents provide high $S^2/K\rho$ values in the higher temperature ranges.

The Figure of Merit isotherms in Figs. 9 and 10 are obtained by cross-plotting the data of Figs. 7 and 8. If in turn the room temperature electrical conductivities corresponding to the $S^2/K\rho$ maxima of Figs. 9 and 10 are plotted against the isotherm temperatures, an index is obtained which specifies how the composition of the thermocouple element must be varied to provide the maximum value of $S^2/K\rho$ at each point in the temperature gradient. Room temperature electrical conductivity is a more convenient measure of the actual electron or hole concentration than would be the concentration of the doping impurity. The reason for this is that any one of several P-type or N-type doping agents may be used to alter the electrical properties in an approximately equivalent manner. Once the desired room temperature conductivity index is specified then the specific concentration of the selected doping agent may be obtained directly from the doping curves.[5]

When thermocouple elements are constructed in this manner against known temperature distributions, the highest mean value of $S^2/K\rho$ is obtained yielding the ultimate materials efficiency possible in combinations of lead telluride. This room temperature conductivity index is given in Fig. 11 for both P-type and N-type lead telluride alloys. The corresponding Figure of Merit variations with temperature of these optimized P-type and N-type thermocouple elements are represented by the envelopes to the curves of Figs. 7 and 8.

Thermocouple elements with the prescribed concentration gradient of doping agent for maximum $S^2/K\rho$ are difficult to fabricate. A reasonably close approximation to the ideal case can be effected by forming each thermocouple element from a pair of homogeneous segments of selected doping to provide the best mean value of $S^2/K\rho$ in the respective temperature intervals. The two segments are suitably joined together to form the completed element. Table I contains comparative data on Figure of Merit values and calculated over-all efficiency for three specific combinations operated between 866 K (degrees Kelvin) and 311 K. A comparison of these data indicates that approximately 85% of the ultimate efficiency can be obtained from a PbTe thermocouple utilizing P and N elements of homogeneous compositions, whereas the use of doubly segmented P and N elements affords about 95% of the ultimate value.

Conclusions

The thermoelectric properties of P-type and N-type lead telluride systems have been presented to indicate how the Figures of Merit of these materials vary with temperature. This variation is pronounced and must be taken into account in designing efficient thermoelectric generators for use over different temperature ranges. For thermocouples comprising elements of P-type and N-type lead telluride alloys, efficiencies approaching 10% can be anticipated for temperature ranges in which these materials are known to be stable.

The design of optimized thermoelectric generator systems requires fabricating thermoelectric materials such that at each point in a thermocouple element the crystal is doped to provide the maximum Figure of Merit for the temperature at that point. While the data presented herein pertain to lead telluride systems, the same analysis can be applied to other thermoelectric materials as well.

The Flagstaff-Phoenix TJ Radio System

JOHN W. HIDY
MEMBER AIEE

THE Bell Telephone Laboratories, Inc., have recently completed the development of a microwave radio system to operate in the 11-kmc (kilomegacycle) band. The system is coded *TJ* and is designed for short-haul and medium-haul systems. One of the first systems was installed between Flagstaff and Phoenix, Ariz. It is hoped that a description of the system may be of interest to other engineers in the communications industry.

This paper will describe the layout and some of the special engineering features of the Flagstaff-Phoenix *TJ* radio relay system. Because this system is small and packaged, it has been possible to use prefabricated buildings which were temporarily located at a central point where the equipment was installed. After equipment tests were completed, each repeater was moved as a package to its permanent location. This method of operation appears economically feasible and it is hoped that similar arrangements may be applied to other projects. The detailed technical description of the *TJ* radio system will be covered in other papers.

Present Facilities

The telephone facilities on the Flagstaff-to-Phoenix route consisted of an open-wire line equipped for various types of carrier. By 1956 these facilities had been developed to nearly their maximum capacity. Studies indicated the requirement for circuits to northern Arizona would necessitate either expansion of the present route or development of a new route. The open-wire line was old and had been constructed with light poles. It would not therefore carry the load of additional crossarms and wire. Since it would not have been economical to rebuild the old line, there remained two alternatives: to construct a new open-wire line arranged for O type carrier, or to develop a radio relay route.

Cost studies indicated that the new open-wire line would cost less initially, but that, for the circuit cross sections greater than about 60 2-way circuits, the radio with L carrier multiplex equipment would be more economical. Since the estimated circuit requirements through the 20-year engineering period were in excess of 400 channels, it was decided to develop a radio relay route.

Radio Systems Considered

The Western Electric Company *TD-2* microwave system operating in the 4-kmc band was available. However, the route which had been selected did not lie along existing wire lines. Since the *TD-2* system assumes that the order wire and control circuits will be routed over wire lines, the system would have required an excessive expenditure for the construction of open-wire circuits. A second radio system to accompany the *TD-2* was considered for the order wire and control circuits, but this also proved too expensive. It was expected that future legs to Prescott and Winslow would be required within the engineering period. The addition of these legs using the *TD-2* system would have necessitated using two frequency-modulation terminals at Mingus Mountain and two at Mount Elden. This would have added appreciably to the cost of the system.

The development of a second Western Electric microwave radio system coded *TJ* and designed to operate in the 11-kmc band was nearing completion. The development schedule indicated that the first bays could be shipped during the fourth quarter in 1957. Since the additional circuits were required for service during the summer of 1958, the *TJ* system was considered a good candidate for the proposed route.

A comparison of the *TD-2* and *TJ* microwave systems indicated that the *TJ* system could be installed more economically and that its capacity would be sufficient for the engineering interval. Two of the principal costs factors favoring the *TJ* system were a built-in order wire and control circuit, and the fact that frequency-modulation terminals would not be required at future branching points. Although the system had not been tried in service, information indicated that its transmission characteristics should approach that of the *TD-2* when used within the design limitations. It was therefore decided to use the *TJ* microwave system for the Flagstaff-Phoenix route.

The TJ Radio System

The *TJ* microwave system is designed to operate in 11-kmc frequency range and is intended to operate over distances up to about 200 miles. The system provides for up to six 2-way radio channels. It is operated with one-for-one frequency diversity to protect against outages caused by multipath fading. This leaves a net capacity of three 2-way channels available to the system. The radio channels are suitable for either telephone or television.

In the *TJ* radio system one antenna is used for both transmitting and receiving in each direction. The frequency interval between the regular and associated diversity channel is 240 mc. Since multipath fading is frequency selective, it is believed that this difference will be sufficient to guard against fades of both channels in a given section at the

Fig. 1. TJ transmitter and receiver bay

Paper 59-943, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21–26, 1959. Manuscript submitted March 23, 1959; made available for printing May 4, 1959.

JOHN W. HIDY is with the Mountain States Telephone and Telegraph Company, Phoenix, Ariz.

A project such as the Flagstaff-Phoenix TJ microwave radio system represents the combined efforts of many more engineers than can be named here. The author wishes to express his appreciation for the counsel and assistance of various members of the operating and engineering department of the American Telephone and Telegraph Company, the Western Electric Company equipment engineering group, the Bell Telephone Laboratories, Inc., and other members of the engineering department of the Mountain States Telephone and Telegraph Company.

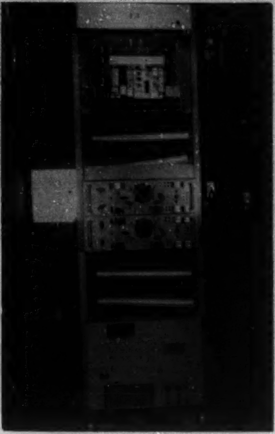

Fig. 2. D-1 alarm and control bay in TJ repeater station

same time. With all six channels in each direction equipped, there will be 80-mc separation between the unmodulated radio frequencies of each channel. Separation of each of the channels at the equipment is accomplished by means of waveguide band-pass filters. Additional segregation between the regular and diversity channels is obtained by means of vertical and horizontal polarization on the radio path. Fig. 1 shows a *TJ* transmitter and receiver bay.

With this arrangement, all transmitters and receivers in one direction are connected to the same antenna. The regular equipment bays and the diversity equipment bays for one direction are grouped and connected to separate waveguides, one for vertically polarized signals and the other for horizontally polarized signals. These waveguides are connected to a polarizer mounted on the rear of the antenna. The two polarizations are fed through a circular feed to the parabolic reflector. Thus, about a 30-db (decibel) discrimination between vertically and horizontally polarized signals may be obtained.

The base-band signals are fed to the regular and the diversity transmitters in parallel. At the receiving end the signals are received by two receivers and the strongest signal is selected by a diversity switch and fed to the next transmitter at a repeater point or to the multiplex equipment at a terminal. The diversity switch is designed to compare the level of the radio signals at the input of the receivers and the level of the 2,600-cycle control tones at the output of the receivers. If the level of the signals at the regular channel drops by a predetermined amount below the level of the signals of the diversity channel, a switch will result. The transfer switch has contacts arranged in a make-before-break sequence.

The design of the *TJ* system is such that the signals are returned to the base-band frequencies at the output of each receiver. This arrangement makes it practicable to apply the order wire, alarm, and control circuits directly to the base band without modulation. This is accomplished at each terminal or repeater by means of low-pass and high-pass filters to separate the voice band from the carrier band.

The order wire circuit is a 4-wire circuit so arranged that transmission is from the control terminal through each repeater to the far terminal and back to the control terminal. Each point is arranged to bridge the receiver on the outward direction of the circuit and the transmitter on the inward direction. Thus, for an attendant to talk to someone farther from the control terminal, he talks over a loop through the control terminal and out toward the remote terminal. The calling is over loud speakers. The order wire and control signals are transmitted over a 2,600-cycle tone using a standard single-frequency signaling unit. A 2,600-cycle slot filter is inserted in the voice path to make space for the signaling frequency. The 2,600-cycle tone is transmitted around the loop and back to the control terminal. Alarms are transmitted inward toward the control terminal by suitable coding applied to the tone. Also, orders are transmitted outward over the signaling tone. Up to 18 alarms may be received from each of seven radio stations. Also, ten orders may be transmitted to each station, five of which are used within the system. Fig. 2 shows a *D-1* alarm and control bay.

The order wire is so arranged that the failure of any station will permit a loop back at the next station toward the control terminal. This permits a check of all the stations between the control terminal and the station in the failure condition. It is therefore possible to locate the failure before a repairman is dispatched to clear the trouble.

Route

The route of the Flagstaff-Phoenix *TJ* radio system extends northward from Phoenix 133 miles. The route and profile are shown in Fig. 3.

The Phoenix terminal is located in the seventh floor penthouse of the Phoenix main building. The radio room is designed to provide the space required for all the terminal equipment which may be required in Phoenix within the next 10 years.

The first two repeater sites were located just off the Black Canyon Highway. The first, Desert Hills, is 26 miles north of Phoenix, just east of the highway. Black Mesa is located about five miles southeast of Sunset Point near where the road reaches the top of Black Canyon. The third site is on Mingus Mountain not far from the old mining town of Jerome. The fourth site is on Mount Elden located about 3.7 miles northeast of Flagstaff. The Flagstaff terminal

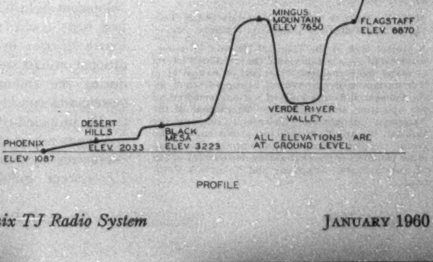

Fig. 3. Route and profile of Flagstaff-Phoenix radio relay route

Vol. Pt. 195

is located in the toll test room of the Flagstaff main building.

The path lengths are as follows:

Location	Miles
Phoenix Main to Desert Hills	25.88
Desert Hills to Black Mesa	21.09
Black Mesa to Mingus Mountain	38.55
Mingus Mountain to Mount Elden	47.84
Mount Elden to Flagstaff Main	3.72

The route extends from an elevation of a little over 1,000 feet to more than 9,000 feet. The extremes of temperature for the various sites range from over 115 F (degrees Fahrenheit) at Phoenix to more than 25 F below zero at Mount Elden.

There is nothing unusual about the first three paths of the route. The Mingus Mountain–Mount Elden path is in excess of 47 miles. However, the profile is such that many times the minimum clearance was obtained. The path from Mount Elden to Flagstaff doubles back on the Mingus Mountain–Mount Elden path with a little more than a 1-degree horizontal angle and about a 6-degree vertical angle. These two paths raised questions regarding rain attenuation and the frequency assignments of the two paths.

Tests made by the Bell Telephone Laboratories, Inc.,[1] indicated that an attenuation loss of about 1.3 to 1.4 db per mile may be expected when it is raining at the rate of one inch per hour. While heavy rains occur along the path, it is expected that they will generally be of a local nature and will not seriously affect the transmission. General rains will usually be of less density and should not cause difficulty even on the long path. At frequencies in the 11-kmc band, no attenuation due to snow or fog has been noted.

In the *TJ* system the frequencies are repeated every second section with protection from overreach interference obtained from cross polarization and zig-zagging. With the Mount Elden–Flagstaff path only slightly over 6 degrees from the Mingus Mountain–Mount Elden path, some concern was felt regarding the normal frequency assignment in the Mount Elden–Flagstaff section. To assure satisfactory operation on the initial installation, frequencies having the widest possible separation were selected for the two paths. It is hoped that experience will indicate that future radio channels may be assigned in their normal order which will make it possible to take additional radio channels into Flagstaff.

Multiplex Equipment

The initial radio channels of this system extend from Flagstaff to Phoenix and are designed for future legs to Prescott and Winslow. The circuit requirements are such that additions in groups of 12 circuits appear feasible. The length of the system together with these circuit requirements made it desirable to use an L-type carrier as the multiplex equipment. This is a single side-band suppressed carrier type of equipment which will load the system least of any of the channelizing equipments available. With the use of the L-type carrier, it is expected that up to 240 telephone circuits may be carried over a single radio channel as compared to 96 if *ON-2* carrier were used.

Towers

The antenna supports used on the Flagstaff-Phoenix route are self-supporting towers designed for the system. The towers at the repeater sites range in height from 60 to 120 feet. Extra height was provided at Mingus Mountain and Mount Elden to assure path clearance for the future Prescott and Winslow legs. The existing tower on the Phoenix main building was used. However, a special attachment was provided for mounting the antenna at the 25-foot point. No tower was required at the Flagstaff main building.

Antennas

The antennas selected for this system were 10-foot parabolic reflectors at all points except Flagstaff and Mount Elden toward Flagstaff. For this section, because it is very short, 5-foot antennas provided sufficient gain. A circular feed to the reflectors is used to accommodate both the vertically and horizontally polarized signals. The signals are fed into separate rectangular wave guides by a polarizer and a transducer mounted in the rear of the antenna. Two waveguides are therefore required for each direction of transmission. The gain of the 10-foot antenna is about 47 db, while that of the 5-foot antenna is 42 db.

The *TJ* radio system was designed for a medium-length light route service. With that objective some short cuts could be made in favor of economy. One of the major economies was obtained through the use of a-c powered equipment. This made the system subject to all of the variations which could occur at the end of long power transmission lines. Since this system was to form the backbone route to Northern Arizona, it would be used for dial, full-period leased wire, Teletype circuits, etc. Transmission of these services makes it imperative that interruptions from all sources be kept at a minimum. Since the power supply to any telephone equipment is one of the possible sources of service interruptions, it became necessary to select a power supply which was both reliable and relatively inexpensive.

Fig. 4. Power plant installed at a repeater station

Three types of emergency power plants were available which might have been used with the *TJ* radio system, as follows:

1. Storage battery plant without an engine stand-by.
2. A standard engine-driven alternator, automatically started.
3. A no-break type of gasoline engine stand-by power plant.

The storage battery stand-by plant would require large motor alternators for converting the d-c power to a-c power to satisfy the requirements of the *TJ* radio system. This not only required more floor space than was available, but with one exception it proved to to be too expensive for this route. The exception was at Phoenix Main, where there was enough capacity available in an existing *L-3* motor alternator set to power the *TJ* terminal.

Standard automatic-start engine alternators were available which might have been used for stand-by power. However, the design of these units permitted a power break of about one minute, which, with the time required for the klystrons to return to the correct frequency, resulted in a break of from 3 to 5 minutes. Since this was to be the main link to Northern Arizona, it was not desirable to expose the system to such interruptions in the power supply.

A no-break type of stand-by power

Fig. 5 (left). Building and power plant foundations ready for building

Fig. 6 (above). TJ repeater buildings on flatcars at Phoenix

plant was available which had been used with considerable success by other utilities near Phoenix. The machine consists of an a-c motor, an alternator, and a heavy flywheel on the same shaft. There is a suitably sized gasoline engine which may be coupled to the flywheel by a friction clutch. When the primary source of power fluctuates beyond predetermined limits, the a-c motor is disconnected from the power source and the clutch is engaged to start the engine. The constants of the machine are such that only a slight dip in the frequency, and no change in the voltage, occur at the instant the engine starts. This type of machine has the further advantage of isolating the equipment from a-c line surges which often occur at the end of a long power line.

The alternators of these sets are self-excited with the field current derived from a separate winding in the stator, which is connected to the field circuit through Magamp-regulated rectifiers. The terminal voltage is regulated by a magnetic amplifier which constantly compares the output voltage to two voltage reference diodes in series.

Tests using an oscilloscope indicate that the output of the alternator is very stable as to voltage and frequency when driven by either the motor or the engine. At the instant of transfer there is a small momentary drop of frequency and no observable change in the alternating voltage. A transient of about $2^1/_2$ volts peak-to-peak is introduced into the -400-volt output of the radio power supply. It may be noted that this figure does not exceed transients introduced by the normal operations of relays associated with the radio equipment. Fig. 4 shows the power plant installed at a repeater station.

Buildings

The *TJ* radio equipment was designed to be installed in small and compact buildings. When the system was being designed, thought was given to a building similar to the freight containers used jointly by the railroads and trucking companies. The building unit was required to be large enough to contain the power plant, the radio, and order wire equipment for a fully developed *TJ* radio route. It was designed to be handled with a moderately sized crane; its dimensions to meet the requirements for transportation on the highway.

Such buildings may be treated independently of the foundation. It was thus possible to pour six concrete piers to serve as a foundation. The piers were located at each corner of the building, and one on each side near the center. An additional pier was poured for an engine foundation. The piers were prepared by the contractor as a part of the work of preparing the tower foundations.

Fig. 5 shows the foundations for building and power plant.

With these thoughts in mind, arrangements were made with a manufacturer of highway freight trailers to construct four units, one for each of the repeater points. The units are $28^1/_2$ feet long and 8 feet wide. A partition is provided to separate the engine room from the equipment room. Each unit is equipped with two outside doors. Figs. 6 through 10 show these buildings in the various stages of the project.

Temporary Location of Buildings

When carrier or long radio systems are installed, a large amount of time is consumed in travel between lodgings and the repeater sites, and from site to site during the initial equipment tests and line-up. The *TJ* equipment and the buildings were of package design. This offered a good opportunity for overcoming some of the difficulties experienced with other systems. The buildings were therefore temporarily located in Phoenix where the equipment was installed and a large portion of the equipment tests made. While the buildings were still temporarily located, the first unit was connected to a temporary antenna, which was directed toward the Phoenix main building. The equipment in adjacent buildings was then connected together by waveguides in which 60-db attenuators had been inserted. This arrangement made it possible to transmit from Phoenix through each repeater station to the center of the Mount Elden equipment and back to Phoenix. It should be noted

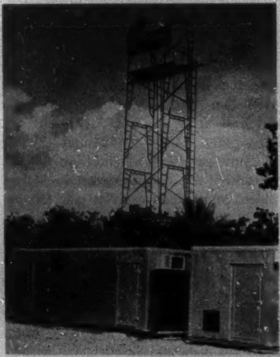

Fig. 7. Temporary antenna and two of the repeater buildings in contractor's yard at Phoenix

Vol.
Pt. 1
195

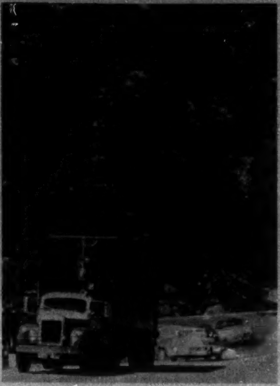

Fig. 8. View showing building fully equipped on truck en route to repeater site

that the circuit had to be looped at the alarm and control bay in the Mount Elden building and could not include the transmitters and receivers looking toward Flagstaff. It was possible to complete all the initial equipment tests at the repeater stations and to simulate transmission tests over all the route except the Mount Elden–Flagstaff section. The loop thus included a total of eight repeater sections.

Discussion of Installation at Central Point

It should be pointed out that the Flagstaff–Phoenix system was one of the early systems to be manufactured. While the prototype system had been given extensive trials and appeared satisfactory, the manufactured product had not been shaken down in the field. The installation of the equipment at a central point made it possible to complete the installation and to make many of the alterations with a minimum effort. In effect this amounted to doing four identical jobs within about 100 yards of each other.

In addition to the equipment installation work by the Western Electric Company, a considerable amount of work was required by an electrical contractor. Here again it was possible to do four identical jobs all in the same area. The result was a uniform installation of both equipment and electrical work.

To maintain the Flagstaff–Phoenix system, as planned, from three points (Flagstaff, Prescott, and Phoenix) it was necessary to train three maintenance groups. Even though this involved paying for maintenance for two groups during the training period in Phoenix, there was enough advantage in working in a central location to offset the additional cost.

Probably the biggest advantage to be gained from installing and testing is the great reduction in travel time to the various sites. It may be noted that work was being done in the buildings from May 19 to October 3, a period of 20 weeks or 98 working days. A conservative estimate of the travel time would be based on an average of two groups of two men each, driving an average of about 50 miles one way per day to reach the buildings, had they been placed initially on the sites. This equates to nearly 20,000 miles of driving and about 1,000 man-hours for travel time alone. In addition, the travel time would have been in excess of the regular working days or the working days would have been effectively shortened, which would have increased the installation interval.

While this system had an abnormally long installation and test-out period, it becomes evident that considerable savings may normally be effected by installing and testing the equipment in a central location.

Conclusions

The conclusions may be summarized as follows:

Installation Interval. By installing the equipment while the buildings were located on the construction lot, full advantage could be taken of the following items:

1. Travel time was reduced.
2. Each work operation was repeated in each repeater after the first.
3. It was unnecessary to pay maintenance for installation crews while working out of town.

While it is difficult to place dollar values on items such as the foregoing, the author estimates that the installation cost did not exceed one half of the cost of installing the equipment at the permanent sites.

Testing Efforts and Cost. The advantages of the centralized testing arrangement had all the advantages listed for installation plus the following:

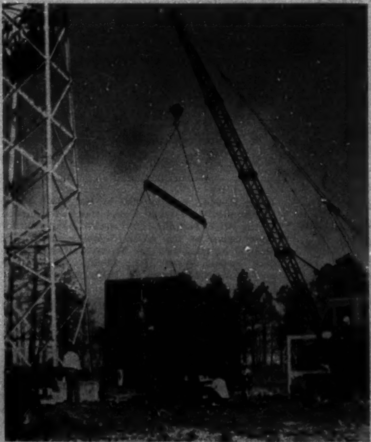

Fig. 9 (left). Building being placed on foundation by crane

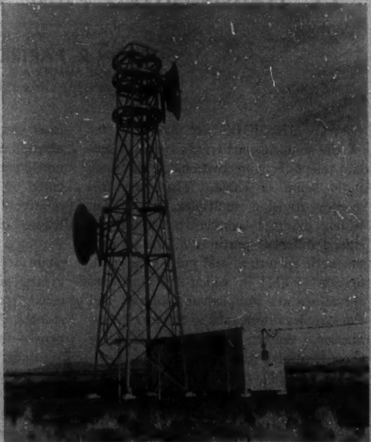

Fig. 10 (right). View of Black Mesa radio repeater station after completion

1. The benefits of a centralized training location.
2. A minimum transportation of testing equipment.
3. Travel time reduced to a minimum.
4. Possibility of obtaining a check of system performance with a minimum of effort.

It is estimated that the cost of the testing of the system did not exceed 75% of the cost of testing the same system, had the repeaters been placed in their permanent location initially. However, it should be recalled that this system was the first to be installed in buildings and then transported to the repeater site where it was retested before service. It is the author's belief that much of the latter testing may be eliminated on future projects, which would improve the 25% saving just noted.

No Trouble from Transportation. No equipment trouble was reported which could be attributed to the transportation to the sites.

No-Break Power Plants. The use of the no-break type of power plant appears to have considerable merit for installations such as the *TJ*. While it is not expected that the reliability will equal that of a storage battery plant, it should be adequate for this system. It is estimated that the interruptions due to loss of power will not exceed one per year for all five plants.

Possibility for Future Development. The method of installation described is, of course, most applicable to light route equipment which may be contained in small, easily transportable buildings. It is believed that the greatest advantage may be obtained by installing and testing the equipment at the factory. This arrangement would permit testing the radio bays and the *D-1* alarm and order wire bays as a system, which would eliminate wiring errors and defective equipment and insure a complete system being shipped. The factory wiring should include wiring for future radio channels.

After the installation and testing are completed, it is believed that the plug-in units should be identified with the associated bays and packed separately for shipment. This would give maximum protection to the equipment and would eliminate any difficulty from the hold-in screws, loosening and permitting the units to fall from the mountings during shipment.

An alternate arrangement of considerable merit would be to prewire the buildings for the electric and communication equipment at the factory where they are assembled. This arrangement has the disadvantage that the testing could not be completed at the factory. The actual installation effort on the job would be very small because of the plug-type connections used between the cable and the equipment. In this case it would probably be more economical to transport the buildings and equipment directly to the sites where the equipment installations would be completed.

Buildings. While the buildings on this project were satisfactory, it has been found that the temperature build-up resulting from the equipment heat is considerably more than was expected. The following suggestions may therefore be helpful on future projects:

1. The ventilation opening in the engine room should be covered with a filter.
2. The radio room of buildings in areas having ambient temperatures reaching 100 F and above should be air conditioned. The reason for this is that the heat dissipated for a fully equipped building would require an excessive volume of air to maintain suitable temperature for personnel and to guarantee save maximum working temperature for the equipment.
3. The radio room of buildings in areas having ambient temperatures ranging below 100 F should be equipped with forced ventilation controlled by a temperature switch. The air intake should be equipped with suitable filters and all openings covered with motor-operated shutters.
4. Changing the lighting from incandescent lighting (initially provided in the project) to fluorescent fixtures is suggested, to alleviate the condition of sharp and dense shadows on both the radio equipment and the test equipment.

A Transistorized Pulse Code Repeater

GORDON R. PARTRIDGE
ASSOCIATE MEMBER AIEE

TWO METHODS are available for the simultaneous transmission of several telephone conversations on the same radio beam or cable. These are frequency division multiplex (FDM) in which different conversations are assigned different portions of the electromagnetic spectrum, and pulse time modulation (PTM) in which different conversations are sampled at intervals and the samples interleaved in time for transmission. Among the methods of pulse time multiplex are pulse position modulation (PPM), pulse width modulation (PWM), pulse amplitude modulation (PAM), and pulse code modulation (PCM). This last method is perhaps the most elegant of all, and the most complicated in terms of the necessary terminal equipment. The advantages procured by this increased complexity are a relatively high immunity to noise in the transmission system and, of special importance in some applications, the possibility of encrypting the signals for greater privacy by means other than the usual "scrambler." Under many circumstances, PCM systems will be less expensive and more reliable than other multiplex methods.

This paper describes an amplifier or "repeater" used for the transmission of PCM on cable. The repeater is one component of a complete communications system developed for the transmission of 24 simultaneous telephone conversations on military spiral-four cable. A brief summary of the system will be helpful in understanding the role of the repeater.

PCM System

TO TIMING AND GATING

Fig. 4. Preamplifier

carrying incoming speech arrive at the coder-decoder assembly from a telephone switchboard. The incoming calls are sampled at a rate of 8,000 times per second, and each amplitude sample is coded by an analog-to-digital converter to a six-digit binary number. The pulse rate leaving the coder is therefore 24 times 8,000 samples per second times six digits per sample, or 1,152,000 bits per second. This frequency is the so-called "baud" rate of the system. If transmission is to be by radio, the output of the coder is connected directly to a radio transmitter. On the other hand, for transmission over cable the binary code is fed next to an assembly consisting of a cable-power supply, order-wire terminal, and fault locator.

The cable-power supply sends direct current down the spiral-four cable to provide power for the repeaters that are spaced at 1-mile intervals.

The order wire enables the wire supervisor to communicate by conventional audio-frequency signals with other attended points in the system by using the phantom circuit of the cable as a 2-wire line.

The fault locator contains equipment for identifying a defective repeater. In the event of a repeater fault, a relay within the dead repeater short-circuits the output of the west-to-east amplifier to the output of the east-to-west amplifier. Suppose, for example, that in a given repeater the west-to-east amplifier is defective. Then test pulses sent from the eastern terminal pass through the good east-to-west amplifier in the defective repeater, and are turned back by the relay to return to the receiving section of the eastern terminal. The test pulses consist of a special pattern, . . .101010*111*01010. . . in which the sequence of three *1*'s is repeated 1,000 times a second. A flip-flop circuit in the terminal is "flipped" when the three *1*'s are sent, and "flopped" when they are received back. Thus the average amount of time the flip-flop is in the flipped condition is a measure of the round-trip time to the faulted repeater. This time is indicated very simply by a D'Arsonval meter in series with the collector lead of one of the flip-flop transistors.

After leaving the power supply, order wire, and fault-locator box, the pulses travel on spiral-four cable to the repeaters. The cable-power supply can power 25 repeaters. If up to 50 are required, the cable system is split in the middle with a power-looping device. This is a transformer assembly that passes the pulse and audio-frequency order-wire signals, but returns the direct current to the power supply from which it originated.

The entire system is fully transistorized, save for a magnetic amplifier in one of the power supplies.

Introduction to the Repeater

Each repeater consists of two amplifier assemblies, plus one power supply, one loading coil, and one fault locator, as shown in Fig. 2. Pulses enter the repeater through the input transformer and pass into the preamplifier. Here they are shaped and amplified sufficiently to operate the timing and gating assembly. After being retimed, the pulses continue to the output circuitry where their widths are standardized and they receive sufficient power gain to continue 1 mile down the cable to the next repeater. The output pulses are approximately 3 volts in amplitude and 0.44 μsec (microsecond) wide. After propagation over 1 mile of cable, the amplitude is reduced about 40 db (decibels), accompanied by serious degradation in the pulse shape because of the rapid increase in cable attenuation with frequency. The attenuation of 1 mile of spiral-four cable as a function of frequency is shown in Fig. 3. The characteristic impedance at the baud frequency is approximately 120 ohms.

Power for the repeaters is obtained from direct current traveling from left to right along the cable in the upper left-hand corner of Fig. 2, passing through the Zener diode, and leaving the repeater along the cable at the upper right-hand corner. The return path for direct current is in the right-to-left direction across the bottom of Fig. 2. The order-wire loading coil is in series with this path. Each repeater takes 67 ma (milliamperes) of current with a drop of 6 volts, or about 400 mw (milliwatts) of power. Audio-frequency order-wire signals follow the same path as the direct current. The relay for looping back pulses during fault locating is also shown in Fig. 2.

Repeater Circuitry

PREAMPLIFIER

The preamplifier consists of five transistors, *Q101* through *Q105*, and their associated components, shown in Fig. 4. The first step in processing the pulses consists of differentiation. This is necessary because spiral-four cable is not polarized. The identity of a given pair of wires is preserved through a reel of cable, but the two wires within a *pair* may be joined to the cable connectors at random. Therefore, the preamplifier

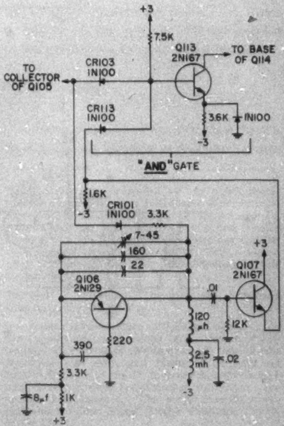

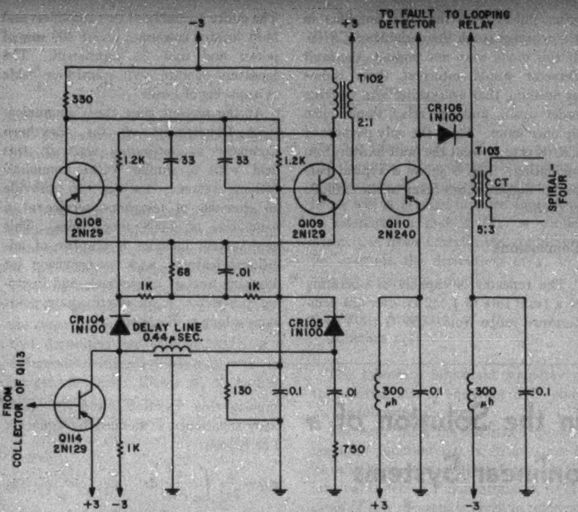

Fig. 7. Output circuitry

must be prepared to handle incoming pulses of either positive or negative polarity. After differentiation, each pulse has a positive and a negative portion. For example, an incoming pulse with a positive-going leading edge will produce a small positive pulse followed by a small negative pulse as a result of differentiating. Another benefit resulting from differentiation is the almost complete elimination of low-frequency components. This is necessary because the low frequencies are attenuated much less than the higher ones. Some patterns, such as ten *1*'s followed by ten *0*'s will have appreciable low-frequency content, and this may saturate the preamplifier if it is not removed. Differentiation is accomplished by the 12 μh (microhenrys) inductor shunted across the secondary of the input transformer.

The load impedances at the collectors of *Q101*, *Q103*, and the interstage coupling network between *Q102*, *Q103* are designed to provide increasing amplification with frequency, compensating more-or-less accurately for the shape of the attenuation curve of the cable. The capacitors between the emitters of *Q101* and *Q103* and ground help to remove high-frequency noise components without appreciably reducing the gain at the 1,152-kc baud frequency. Fig. 5(A) shows the waveform at the input of the repeater, and the amplified signal at the collector of *Q105* is shown in Fig. 5(B). This latter waveform includes a sinusoidal component that feeds through from the timing assembly when no pulses are present.

Timing and Gating

One of the largest problems in a PCM repeater is that of retiming the pulses. A certain amount of crosstalk occurs from pulse to pulse because exponentially-decaying tails are left by pulses passing through a high-pass network. The best remedy would be to direct couple the entire system, from the coder at one end to the decoder at the other. Since this is not practical, the next best thing is to retime the pulses so that the effects of pulse crosstalk (commonly called jitter) are not allowed to accumulate.

Retiming is accomplished by gating a timing pulse through an AND gate. The timing and gating system is shown in Fig. 6. The AND gate consists of diodes *CR103*, *CR113*, and the base-to-emitter diode of *Q113*. The gate is enabled by pulses at the collector of *Q105*, but the actual pulses passing through the gate and eventually appearing at the collector of *Q113* are from the oscillator *Q106*.

Transistor *Q106* and its associated components form a Hartley oscillator operating at the baud frequency of 1,152 kc. The oscillator is synchronized with the pulses by energy passing through diode *CR101* when the anode of this diode is more positive than −3 volts. The sine wave at the collector of *Q106* swings between the levels of −6 and 0 volts. When the waveform is more negative than −3 volts, energy feeds backwards from the oscillator through *CR101* to the collector of *Q105*. This accounts for the sine wave appearing in Fig. 5(B) during times when there are no pulses. The coupling between *Q105* and *Q106* is fairly critical. If it is too tight, any jitter at *Q105* is fed right through the timing system. If it is too loose, the oscillator may fail to keep in synchronism with the baud frequency.

Transistor *Q107* is an emitter follower for decoupling the oscillator from the gate.

Variation of the oscillator's natural frequency with temperature is reduced by the 160 μμf (micromicrofarad) capacitor, which is a temperature-compensating type selected to match the changes of the other circuit components. The over-all frequency change with temperature is about 5 kc, measured with the oscillator in a free-running condition and *CR101* disconnected. This is a small enough variation so that energy from *Q105* can hold the oscillator in synchronism over a temperature range from −55 C (degrees centigrade) to +65 C.

Output Circuits

Retimed pulses from the collector of *Q113* are fed into a grounded emitter amplifier for voltage gain, and thence to a flip-flop where the pulse width is standardized. This assembly is shown in Fig. 7. Transistor *Q109* is normally off and *Q108* is normally on. When a positive pulse from diode *CR104* reaches the base of *Q108*, transistor *Q109* is turned on and energy flows to the base of

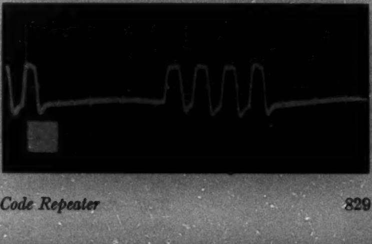

Fig. 8. Output pulses at cathode of CR106. Scale is shown by solid white square: 5.0 volts by 1.0 μsec

the power output stage *Q110* through transformer *T102*. After a delay of 0.44 μsec, the pulse that passes through the delay line turns *Q109* off again. In this manner, the width of the output pulses is standardized.

Transistor *Q110* is connected to its output transformer through a diode *CR106*. This diode is part of the fault-locating system. If pulses appear with reasonable regularity at the anode of *CR106*, a bias is maintained on a transistor in the fault-locating circuit (not shown) that keeps the fault-locator relay in the open-circuited state. Failure of pulses at the anode of *CR106* permits the relay to make contact. When this happens, pulses from the good amplifier in the repeater reach the cathode of *CR106*. If this diode were not present, the fault detector would interpret these pulses as meaning that everything is in working order again, and the relay would open up once more. Thus, the only purpose of *CR106* is to prevent the fault locator from oscillating. Fig. 8 shows a typical pattern of output pulses taken at the cathode of *CR106*.

Conclusions

The repeater is capable of operating at a baud rate of 1,152 kc over the temperature range from −55 C to +65 C. The entire assembly of two amplifiers and fault locator consumes about 400 mw of power and uses 26 transistors. The repeaters operate with spiral-four cable at a spacing of 1 mile.

At the present time the Communications Department of the Raytheon Company is continuing work in this field with a similar PCM communications system designed to provide 96 channels of telephone service at a baud rate of 4.608 megacycles. This new system includes a number of additional features, such as provision for dropping one set of channels and inserting a new set at an intermediate point along a long-haul system.

Recurrence Relations in the Solution of a Certain Class of Nonlinear Systems

ALFRED A. WOLF
MEMBER AIEE

THIS PAPER (a modified version of the material in an unpublished paper of the same name by the author presented at the AIEE 1957 Summer General Meeting) introduces aspects of a generalized mathematical theory for the analysis of a certain class of nonlinear systems. (Since the original presentation of this paper other work has appeared,[1-6] which enlarges on the comments made here and extends the present work.) It is shown that under a very broad class of conditions, consistent with physical realization, a class of systems exists for which it is possible to develop exact and unique mathematical solutions. These conditions are important since nonlinear differential equations do not in general possess such unique properties although linear differential equations do.

Those systems which are describable by ordinary nonlinear differential equations will be considered, such as:

$$Z(D)x(t)+\{x, \dot{x}, \ldots, x^{(m)}, \ldots\}=g(t) \qquad (1)$$

where $Z(D)$ is a linear integro-differential operator; $F\{x,\dot{x},\ldots,x^{(m)},\ldots\}$ is a nonlinear function of the response and its derivatives; and $g(t)$ is a forcing function. The nonlinear function shall be denoted simply as $F\{x\}$ in this paper and the remarks confined to nonlinearities which are functions of x only. Note that the method is not so limited.[1,2]

Existence and Uniqueness of Solution

In this section certain theorems concerning the existence and uniqueness of solution of a certain class of nonlinear systems are discussed. These theorems are most easily developed by the method of Picard iteration.[1,6,7]

Consider a sequence $x_0, x_1, x_2, \ldots, x_n, \ldots$, each of which are functions of time generated according to the following equations:

$$x_0(t)=\int_0^t g(\tau)y(t-\tau)d\tau \qquad (2)$$

$$x_n(t)=x_0(t)-\int_0^t y(t-\tau)\times F\{x_{n-1}(\tau)\}d\tau;\ n\neq 0 \qquad (3)$$

where $F\{x\}$ and $b(t)$ are known, single valued functions and $y(t)$ is a time function defined next. A limit

$$x(t)=\lim_{n\to\infty} x_n(t) \qquad (4)$$

exists such that $x(t)$ is the solution of a particular class of ordinary nonlinear differential equations provided $F\{x(t)\}$, $y(t)$, and $g(t)$ satisfy certain conditions. (The proof that $x(t)$ defined in equation 4 is a solution of equation 5 is given in Appendix I.) These differential equations may be written as follows:

$$Z(D)x(t)-F\{x(t)\}=g(t) \qquad (5)$$

where $Z(D)$ is a polynomial in the differential time operator D and $y(t)$ previously mentioned is defined by equation 6 as follows:

$$y(t)=\frac{1}{2\pi j}\int_{B_r}\frac{e^{st}}{Z(s)}ds \qquad (6)$$

where B_r is the appropriate Wagner-Bromwich contour in the complex s-plane enclosing the zeros of $Z(s)$.

Not only is equation 4 a solution of equation 5 but, under the conditions specified, it is the unique solution (the demonstration that $x(t)$ is the unique solution is given in Appendix II); and furthermore, it follows that all members of the sequence, though not necessarily the limit, are of exponential type (proof of this statement is demonstrated in Appendix III) converging uniformly to $x(t)$.

The linear operator $Z(D)$ is of the form

$$Z(D)=\sum_{n=N_1}^{N_2} f_nD^n \qquad (7)$$

Paper 59-919, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer and Pacific General Meeting and Air Transportation Conference, Seattle, Wash., June 21–26, 1959. Manuscript submitted October 11, 1957; made available for printing May 12, 1959.

ALFRED A. WOLF is with the Stromberg Carlson Company, a division of General Dynamics, Rochester, N. Y., and was formerly with the University of Pennsylvania, Philadelphia, Pa.

The author is greatly indebted to Dr. Harry Sohon, whose critical reading of the entire paper is much appreciated. He made many useful and pertinent suggestions concerning the body and format of the paper.

The author would like to express his deep appreciation to Dr. Y. H. Ku, who has been a source of constant encouragement and whose advice and guidance have been invaluable. Thanks are due to Dr. J. G. Brainerd and also to Mr. K. Lord of the Stromberg Carlson Company for their support.

The research reported in this paper and its final preparation has been made possible through support and sponsorship extended by the National Science Foundation under Research Grant NSF-G3673.

where

$$D=\frac{d}{dt}; \quad D^n=\frac{d^n}{dt^n} \tag{8}$$

and the coefficients f_n are restricted such that $y(t)$ defined in equation 6 is required to satisfy the condition that

$$y(t)=0(e^{\alpha_1 t}); \; t\geq 0 \tag{9}$$

in which α_1 is a real constant. The coefficients f_n are either constants or functions of time and s is a complex variable in the complex frequency plane corresponding to the differential time operator D. The bounds on the sum of equation 7 are constants which are positive or negative depending on whether $Z(D)$ is a differential, integro-differential, or an integro-operator. Either N_1 or N_2 may also be zero but not both.

The forcing function, $b(t)$, is required to satisfy a condition like equation 9 namely

$$g(t)=0(e^{\alpha_2 t}); \; t\geq 0 \tag{10}$$

where α_2 is a real constant.

Restrictions

A class of nonlinear systems is now defined by the following conditions imposed on $F\{x\}$, $y(t)$, and $g(t)$ which are consistent with physical realizability.

1. $F\{x\}$ is a single valued and uniformly continuous nonlinear function of x and its possible derivatives in some defined region. $F(x)$ is generally written to mean $F(x)=F(x, \dot{x}, \ldots)$.
2. Given a pair of functions $v(t)$ and $w(t)$ which are continuous in t or asymptotically like $e^{-\alpha_0 t}$, $\alpha_0>0$; then an $M>0$ and $a\geq 0$ exist such that

   $$|F\{v(t)\}-F\{w(t)\}|<Me^{-at}|v(t)-w(t)|$$

   is satisfied for all $t\geq 0$.
3. The function $y(t)$ is of exponential type.
4. The function $g(t)$ is of exponential type.

The latter two restrictions are already contained in equations 9 and 10 given previously. For convenience, $F(x)$ will be called a functional, provided restrictions 1 and 2 are satisfied.

The Power Function as a Functional

Consider the case when

$$F(x)=x^k \tag{11}$$

where $k\geq 2$. If

$$v(t)=A_1e^{-a_1 t} \tag{12}$$

and

$$w(t)=A_2e^{-a_2 t} \tag{13}$$

then equation 11 is a functional if $\alpha_1>0$ and $\alpha_2>0$. Since k in equation 11 is arbitrary then,

$$F\{x(t)\}=\sum_{k=2}^{M} a_k x^k(t) \tag{14}$$

also is a functional.

A function like equation 14 covers a broad class of nonlinear functions and hence will be studied in some detail here. In references 1 and 2, $F(x)$ is studied when it is more complicated containing, for example, the derivatives of x, in a manner similar to equation 14.

Analytic Analysis of the Solution x(t)

The following important property of the solution $x(t)$ of equation 5 is given in the following theorem.

Theorem: Under the conditions specified the limit function $x(t)$ is, in addition to its other properties, analytic for $t\geq 0$ in the interval in which F is continuous. (The proof of this theorem is given in reference 1 and follows from the theorem that the iterants $\{x_n\}$ under the conditions specified are all of exponential type as shown in Appendix III.)

Recursion Formulas

In view of the restrictions mentioned previously it is evident from the results of Appendix II that $x(t)$ is the unique solution of equation 5. Consequently, one is justified in developing the following recurrence relations. Indeed it can be shown[1] that in the absence of conditions like those in the section on restrictions of this paper, the results that follow would be false. Therefore, the recurrence equations which are developed as specified are consistent with the previously mentioned restrictions.

First consider the nonlinear function as defined by equation 14. Then expand the forcing function $g(t)$ as follows:

$$g(t)=\sum_{n=0}^{\infty} b_n t^n \tag{15}$$

where the b_n's are the Taylor coefficients of $g(t)$. This expansion is justified since $g(t)$ satisfies condition 4 and hence is analytic.

It is well known that if a function $x(t)$ is analytic, so is any integral power of the function analytic. Hence from the previous section it is seen that equation 14 is also analytic. Furthermore, if two functions are analytic then their difference is analytic.

Let $A(t)$ define an auxiliary forcing function which is single valued and differentiable associated with equation 5 according to the following relation

$$A(t)=g(t)-F(x) \tag{16}$$

From these remarks it is at once seen that $A(t)$ is analytic. Partitioning equation 5 to the right of the linear part and noting equation 16 the following equation results.

$$Z(D)x(t)=A(t) \tag{17}$$

If $A(t)$ were known then equation 17 could be solved explicitly for $x(t)$. The question of how to determine $A(t)$ in general is treated in detail elsewhere.[1] Note since $A(t)$ is analytic, it can be written as the power series which follows.

$$A(t)=\sum_{n=0}^{\infty} C_n t^n \tag{18}$$

Therefore, the solution of equation 5 under these conditions is

$$x(t)=\sum_{n=0}^{\infty} C_n Q_n(t) \tag{19}$$

in which $Q_n(t)$, given by equation 20 are the moments of the folded impulsive response of the linear part of equation 5

$$Q_n(t)=\int_0^t \tau^n y(t-\tau)d\tau \tag{20}$$

and

$$C_n=b_n-\sum_{k=2}^{M} C_n^{(k)} a_k \tag{21}$$

for zero initial conditions, and where $C_n^{(k)}$ is defined as follows:

$$\left[\sum_{n=0}^{\infty} C_n Q_n(t)\right]^k \equiv \sum_{n=0}^{\infty} C_n^{(k)} t^n \tag{22}$$

The $C_n^{(k)}$'s may be evaluated by the following method:

$$C_n^{(k)}=\frac{1}{n!}\frac{d^n}{dt^n}\left[\sum_{n=0}^{\infty} C_n Q_n(t)\right]^k\Bigg|_{t=0} \tag{23}$$

from which it is always possible to obtain $C_n^{(k)}$. It is noticed that when $Q_n(t)$ is a power function, equations 24 to 28 apply. [Since $Q_n(t)$ is an analytic function, this function can always be expanded into a power series if it is not already a power function. This will mean that the C's under the summation signs will themselves be power series. For example, suppose $Q_n(t)=e^{-nt}$, then $Q_n(t)=\sum_{s=0}^{\infty}(-1)^s n^s t^s/s!$ from which $C_n=\sum_{s=0}^{\infty}(-1)^s n^s/s!$. In such cases, it is simpler to use equation 23, or it is possible to develop recurrent relations to fit this case.]

$$C_n^{(0)}=\begin{cases}1; & \text{for } n=0\\ 0; & \text{for } n\neq 0\end{cases} \tag{24}$$

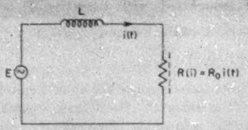

Fig. 1. **An inductive circuit L in series with a nonlinear resistor R(i)**

$$C_n^{(1)} = C_n \tag{25}$$

$$C_n^{(2)} = \sum_{r_1=0}^{n} C_{r_1} C_{n-r_1} \tag{26}$$

$$C_n^{(3)} = \sum_{r_2=0}^{n} \sum_{r_1=0}^{r_2} C_{r_1} C_{r_2-r_1} C_{n-r_2} \tag{27}$$

then

$$C_n^{(k)} = \sum_{r_k-1=0}^{n} \cdots \sum_{r_1=0}^{r_2} C_{r_1} C_{r_2-r_1} \cdots C_{n-r_{k-1}} \tag{28}$$

which can be used in simultaneous solution with equation 21.

It is worth while to point out that if the partition (generally this is a process of rearranging terms of equation 5 such that the left member is linear and contains the highest order derivative) is made at the highest order derivative then the moments $Q_n(t)$ will always be a power function.[1,2] It should also be remarked that the partition process must result in an equation such that the linear member contains the highest order derivative. Otherwise a recurrence relation will result which will require a knowledge of coefficients not yet found and moreover, the results will not converge in those cases where the solution is possible.

The Partition Process

The partition process consists essentially of the following steps satisfying the conditions previously mentioned.

1. The dynamic equation representing the system is partitioned so that the linear terms involving the highest order derivative are contained in one member of the equation.
2. A modified forcing function $A(t)$ is then obtained which consists of the actual forcing function, nonlinear, and possibly, some linear terms.
3. A proper choice is made of the expansion of $A(t)$ according to the particular properties of the linear, nonlinear, and driving functions. An auxiliary equation is thus formed.
4. The properly partitioned differential equation is then solved.
5. Certain coefficients which arise from the auxiliary equation are then calculated.
6. These coefficients, which appear in the partitioned equation, are then eliminated to obtain the exact solution.

An example is given to illustrate how to apply this technique to systems of one degree of freedom.[1]

Simple Application

As an illustration, consider a series circuit composed of an inductance with a nonlinear resistor $R(i)$ which is linearly dependent on the current through it and driven by a constant voltage E as shown in Fig. 1. The dynamic solution is

$$LD \cdot i(t) - R_0 i^2(t) = E \tag{29}$$

or

$$D \cdot i(t) - a i^2(t) = b \tag{30}$$

where

$$a = \frac{R_0}{L}$$

and

$$b = \frac{E}{L}$$

Assume that

$$i(0) = 0$$

Note on comparing equation 30 with equation 5 that $Z(D) = D$ and $F(i) = i^2(t)$ for this particular case. The solution is obtained either by comparing the constants of equation 30 with those of equation 5 and utilizing equations 19 and 21 or else the solution may be obtained directly utilizing the moment theorem given in equation 19 and the auxiliary equation given in equation 16. The latter approach is not only more direct but also is more general. One does not need to remember special formulas. It is only necessary to understand the preceding section. Therefore, the latter approach is given.

Since $Z(D) = D$ then $Z(s) = s$. On applying equation 6, $y(t)$ is recognized as the step function. That is,

$$u(t) = \begin{Bmatrix} 1; & t>0 \\ \frac{1}{2}; & t=0 \\ 0; & t<0 \end{Bmatrix} \text{ step function.}$$

$$y(t) = u(t) \tag{31}$$

and from equation 20

$$Q_n(t) = \frac{t^{n+1}}{n+1} \tag{32}$$

from which on substituting equation 32 into equation 19 gives

$$i(t) = \sum_{n=0}^{\infty} \frac{C_n}{n+1} t^{n+1} \tag{33}$$

The auxiliary equation is

$$\sum_{n=0}^{\infty} C_n t^n = b - a \left[\sum_{n=0}^{\infty} \frac{C_n}{n+1} t^{n+1} \right]^2 \tag{34}$$

Converting the multifold sum of the second member of equation 34 into a single sum yields

$$\sum_{n=0}^{\infty} C_n t^n = b - \sum_{n=0}^{\infty} C_n^{(2)} t^{n+2} \tag{35}$$

from which the nonlinear recurrence relation results:

$$C_n = bC_n^{(0)} - aC_{n-2}^{(2)} \tag{36}$$

Now noting that ($C_j = 0$ when $j<0$)

$$C_{n-2}^{(2)} = \sum_{k=0}^{n-2} \frac{C_k C_{n-k-2}}{(k-1)(n-k-1)} \tag{37}$$

yields

$$C_0^{(2)} = C_0^2$$

$$C_1^{(2)} = C_1 C_0$$

$$C_2^{(2)} = \frac{2}{3} C_0 C_2 + \frac{1}{4} C_1^2 \tag{38}$$

$$C_3^{(2)} = \frac{1}{2} C_0 C_3 + \frac{1}{3} C_1 C_2$$

When equation 38 is substituted into equation 36 the latter can be solved to give:

$$C_0 = b \tag{39A}$$

$$C_1 = 0 \tag{39B}$$

$$C_2 = -b \tag{39C}$$

$$C_3 = 0 \tag{39D}$$

$$C_4 = \frac{2}{3} b^3 a^2 \tag{39E}$$

$$C_5 = 0 \tag{39F}$$

. . .

Eliminating the coefficients C_n from equation 33 on substituting equation 39 yields the following expansion:

$$i(t) = bt - \frac{b^2 a}{3} t^3 + \frac{2}{3} \cdot \frac{b^3 a^2}{5} t^5 - \ldots \tag{40}$$

which is recognized as the expansion of

$$i(t) = \frac{b}{a} \tanh \sqrt{ab} t \tag{41}$$

This is the correct result as can be checked, since the differential equation 29 can be solved easily by separation of variables.

Discussion of Restrictions and Possibility of Generalization

In this paper certain restrictions were imposed upon terms appearing in a nonlinear differential equation. These restrictions define a class of nonlinear systems which have physical significance. In addition, these conditions simplify the demonstration that a particular unique solution exists. Although these restrictions are sufficient, it appears that they may not be necessary. Generally, an analysis that applies conditions that are both necessary and sufficient is considered a more desirable one. Hence, it might be well to inquire whether the restrictions can be relaxed without violating the conclusions drawn.

The two main restrictions imposed on the behavior of the nonlinear function F are quite independent of one another. On the one hand the nonlinear function was required to be a continuous function of the variable x and its various derivatives, if they were present, while on the other hand it was required to satisfy restriction 2. In the first place continuity of F is not necessary for the existence of a continuous solution. All that is really necessary for a continuous solution to exist is that the convolution integral of the functional and the folded impulsive response of the linear part exist and that the functional F be bounded by a function of the exponential type. It is easy to construct examples[1] which show the continuity of F is not sufficient to guarantee uniqueness of solution. Another condition is required. One such condition is the Lipschitz condition. This is a weak sufficiency condition. In this work, this condition has been suitably modified to enable proving certain theorems concerning stability of nonlinear systems.[1,5] This has resulted in restriction 2.

It is possible to substitute other conditions for 1 and 2 given here which are consistent with physical reality, without changing the uniqueness properties. Some work is now under way in this connection and may be the subject of a later paper.

Although the nonlinear term, $F(x)$ in the illustration, is a polynomial, corresponding results can be obtained when $F(x)$ is any function of x satisfying all the limitations of the section entitled, Restrictions. For example $F(x)$ may be a polynomial in the derivatives of x or combinations of polynomials of derivatives of x and polynomials in x. It should be remarked that if for any given t, the modified Lipschitz condition does not exist then the results of the fourth and fifth sections of the paper will generally fail. If for example

$$F\{x(t)\} = e^{-at}|x(t)|,\ a>0$$

then no unique power series expansion will exist at the origin if at $t=0$, $x=0$. However, it is possible to avoid such points by confining the analysis to points which do satisfy the restrictions.

It can be shown that other forms of the auxiliary function, $A(t)$ can be used. One such example would be the Dirichlet series.[1]

Solutions of nonlinear systems which form a complete orthogonal set can be treated in an interesting manner similar to that described.[1] It might be pointed out in this connection that a systematic treatment of analysis of nonlinear systems can be developed when $g(t)$ is a random function. Work in this area of stochastic processes in nonlinear systems belonging to the class described here will be reported on in the near future.[8]

Appendix I. Evaluation of the Limit of $x_n(t)$

This Appendix will outline the proof that $x(t)$ defined in equation 4 is a solution of equation 5. To do this, first consider equation 3. Subtracting the nth iterant from the $(n+1)$st iterant, taking absolute values, and applying the triangle inequality yields the result:

$$|x_{n+1}(t)-x_n(t)| \leq \int_0^t |F\{x_{n-1}(\tau)\} - F\{x_n(\tau)\}|\,|y(t-\tau)|\,d\tau \qquad (42)$$

From restriction 3

$$|y(t)| < Ke^{bt} \text{ for all } t>0 \text{ where the constants } K>0 \text{ and } b \text{ are real} \qquad (43)$$

Now applying equation 43 and restriction 2 to equation 42 yields:

$$|x_{n+1}(t)-x_n(t)| \leq MKe^{-bt} \times \int_0^t e^{-\beta\tau}|x_{n-1}(\tau)-x_n(\tau)|\,d\tau \qquad (44)$$

where $\beta \equiv a+b>0$, and $a>0$.

Since the iterants x_0 and x_1 are of exponential type, it is possible on referring to equation 3 to select a real positive constant q such that for all $t>0$,

$$\max|x_1(t)-x_0(t)| \leq q \qquad (45)$$

is satisfied. Then by the process of successive iterations of equation 44 one shows that for $n=1$:

$$|x_2(t)-x_1(t)| \leq q\frac{MKe^{bt}}{\beta}(1-e^{-\beta t}) \qquad (46)$$

for $n=2$

$$|x_3(t)-x_2(t)| \leq q\frac{M^2K^2e^{2bt}}{2\beta^2}(1-2e^{-\beta t}+e^{-2\beta t}) \qquad (47)$$

and continuing in this manner

$$|x_{n+1}(t)-x_n(t)| \leq q\frac{M^nK^ne^{nbt}}{n!\beta^n}(1-e^{-\beta t})^n \qquad (48)$$

It is evident that for a given $\epsilon>0$ an $N>0$ exists such that for all $n>N$ and $\beta>0$

$$|x_{n+1}(t)-x_n(t)| < \epsilon \qquad (49)$$

It is now desirable to evaluate the limit given in equation 4. Let $x_n(t)$ be written as the following identity:

$$x_n(t) \equiv x_0(t) + \sum_{r=1}^{n-1}[x_{r+1}(t)-x_r(t)] \qquad (50)$$

taking the limit of both sides as n

$$\lim_{n\to\infty}|x_n(t)| - |x_0(t)| \leq \lim_{n\to\infty}\sum_{r=0}^{n-1}|x_r(t)-x_{r-1}(t)| \leq \lim_{n\to\infty}\sum_{r=0}^{n-1} q\frac{S^n}{n!}$$

where

$$S \equiv \frac{MKe^{bt}}{\beta}(1-e^{-\beta t}) \qquad (51)$$

The right member is recognized as the series expansion of q_e^{S}. Then the left member is a uniformly convergent series by the Weierstrass M-test.[9] This shows the existence of the limit in equation 4. To show that the limit in equation 4 satisfies equation 5 one need only show that it satisfies

$$x(t)-x_0(t)-\int_0^t F\{x(\tau)\}\,y(t-\tau)d\tau \qquad (52)$$

which is the integral inversion of equation 5. The problem then is: Given $\epsilon>0$ arbitrarily, to show that there exists an $N>0$, such that for all $n>N$ and for all $t>0$:

$$\left|x(t)-[x_0(t)-\int_0^t F\{x_n(\tau)\}y(t-\tau)d\tau]\right| < \epsilon \qquad (53)$$

This will prove that $x(t)$ satisfies equation 52 identically. Writing the identity

$$x(t)-[x_0(t)-\int_0^t F\{x_n(\tau)\}y(t-\tau)d\tau] \equiv x(t)-[x_0(t)-\int_0^t F\{x_n(\tau)\}y(t-\tau)d\tau] \qquad (54)$$

and adding this to equation 3 gives, on simplifying, taking absolute values and applying the triangle inequality:

$$\left|x(t)-[x_0(t)-\int_0^t F\{x_n(\tau)\}y(t-\tau)d\tau]\right| \leq |x(t)-x_n(t)| + \int_0^t|F\{x_n(\tau)\} - F\{x_{n-1}(\tau)\}|\,|y(t-\tau)|\,d\tau \qquad (55)$$

Consider the second term of the right member of equation 55. Applying the condition of restriction 2 repeatedly for $n=0, 1, 2, \ldots$, etc., in a manner similar to that applied in the case of equation 44 yields

$$\int_0^t|F\{x_n(\tau)\}-F\{x_{n-1}(\tau)\}|\,|y(t-\tau)|\,d\tau \leq q\left(\frac{MK}{\beta}\right)^n\frac{(1-e^{-\beta t})^n}{n!} < \frac{\epsilon}{2} \qquad (56)$$

for all $t \geq 0$.

From equation 49 and noting the result of equation 51, it is evident that

$$|x(t)-x_n(t)| < \frac{\epsilon}{2} \text{ for all } t>0 \qquad (57)$$

Thus, equation 53 follows immediately and the limit in equation 4 satisfies equation 5.

Appendix II. Uniqueness of Solution

To complete the discussion of the properties of $x(t)$ it is shown that equation 4 is unique, that is, no other solution is possible.

Suppose some other solution does satisfy equation 5. Let this be designated as $x_a(t)$. Therefore, it too must satisfy equation 5 or equation 52 identically: Thus,

$$x_a(t) \equiv x_0(t) - \int_0^t F\{x_a(\tau)\}\, y(t-\tau)d\tau \qquad (58)$$

Subtracting equation 52 from equation 58 yields:

$$[x_a(t)-x(t)] = \int_0^t [F\{x(\tau)\} - F\{x_a(\tau)\}]y(t-\tau)d\tau \qquad (59)$$

Applying restriction 2 after taking absolute values results in:

$$|x_a(t)-x(t)| \leq M\int_0^t e^{-a\tau} \times |x_a(\tau)-x(\tau)|\,|y(t-\tau)|\,d\tau \qquad (60)$$

If c represents the maximum difference between the two solutions, and upon repeated iteration similar to that used to obtain equation 61, it is evident that

$$|x_a(t)-x(t)| \leq c\left(\frac{MK}{a}\right)^n \frac{(1-e^{-at})^n}{n!} \qquad (61)$$

for $t \geq 0$.

As $n \to \infty$ the right member approaches zero. Since the left member never can be negative, it follows that

$$x_a(t) \equiv x(t) \qquad (62)$$

Thus, there is one and only one solution.

Appendix III. Demonstration that the Iterants are of Exponential Type

Consider equation 63,

$$x_0(t) = \int_0^t g(\tau)y(t-\tau)d\tau \qquad (63)$$

The transform of equation 63 is

$$X_0(s) = G(s)Y(s) \qquad (64)$$

Since $g(t)$ and $y(t)$ are assumed to be of exponential type, and since $x_0(t)$ can be written as

$$x_0(t) = \frac{1}{2\pi j}\int_{B_r} G(s)Y(s)e^{st}ds \qquad (65)$$

It follows that $x_0(t)$ is of exponential type.[10,11] The first iterant is given by equation 66:

$$x_1(t) = x_0(t) - \int_0^t F\{x_0(\tau)\}\, y(t-\tau)d\tau \qquad (66)$$

$F\{x_0(t)\}$ is of exponential type[10] since the product of two or more functions of exponential type is of exponential type. Thus, $x_1(t)$ is of exponential type since sums of functions of exponential type are of exponential type. It may be concluded that $x_2(t)$ is of exponential type by reasoning similar to that employed in $x_1(t)$. Continuing in this manner, $x_n(t)$ is of exponential type.

Since it has been shown that

$$\lim_{n\to\infty} x_n(t) = x(t)$$

uniformly, it might be supposed that $x(t)$ is therefore also of exponential type. The fallacy in this reasoning lies in the fact that the limiting process may give rise to functions of higher order and not of exponential type. Numerous examples of this can be constructed.

◆

Discussion

Thomas J. Higgins (University of Wisconsin, Madison, Wis.): This is an extremely interesting and well-written paper, whose context comprises account of a unique transform procedure for the solution of nonlinear systems. The discusser looks forward to account of further investigations, remarked in the last section of the paper as now in progress.

A. A. Wolf: The author wishes to convey his thanks to Professor Thomas J. Higgins for his very kind and encouraging remarks in his' discussion of this paper. May I also take this opportunity to thank all those people who were so kind to discuss my paper at the time of its presentation.

Since many people have asked about our work I have collected below a bibliography of both our published and planned work. I hope to resubmit references 2, 3, and 4. These were previously presented as conference papers. In the last section of the paper it was indicated that the present method could be extended to the case of nonlinear systems driven by random processes. Reference 5 deals with this subject and introduces the concept of the transform of a random process. In reference 6 we deal with a formal transform procedure of the method given here. This transform gives, in a formal way, a method of solving nonlinear problems comparable with the Laplace transform used in the solution of linear systems. In reference 7, I expect to deal with the general transform problem arising from the "partition theory." I also expect to present a paper at the forthcoming AIEE Winter General Meeting dealing with synthesis of nonlinear systems and its comparison to the Wiener-Lee-Bose theory.[8]

Among works scheduled for publication is a general paper[9] on nonlinear systems dealing with both deterministic and stochastic processes in analysis and synthesis of such systems. This was written in collaboration with Dr. Y. H. Ku.

A Magnetic-Amplifier–Silicon-Transistor Power Supply for Missile Application

B. MOKRYTZKI
NONMEMBER AIEE

R. A. STUART
NONMEMBER AIEE

THE RECENT development of the first truly high-power silicon transistor and the demand for high-efficiency, regulated, solid-state power supplies have stimulated interest in silicon-transistor–magnetic-amplifier combinations. Apart from the usual ability of silicon devices to survive a higher temperature than their germanium counterparts, the new transistors, due to the high-voltage ratings and low internal losses, can control considerably more power than contemporary silicon units. These devices have proved to be extremely rugged and are virtually comparable with magnetic amplifiers in that respect. Thus, to all the advantages which have already been attributed to transistor-inverter–high-frequency magnetic-amplifier systems, it is now possible to attach the valuable qualities of silicon power transistors.

This paper describes in particular a solid-state power supply which is required to produce seven regulated direct voltages and two rms regulated alternating voltages. All the direct voltages are derived from the same high-frequency transistor inverter by providing several transformer secondaries and using a magnetic amplifier in each channel to regulate the average voltage output. The isolation afforded by the magnetic amplifiers provides capabilities for multichannel operation with only a single voltage reference. For the rms regulated outputs, inverters and magnetic amplifiers are again used along with a novel type of rms sensing circuit that provides a reliable and accurate measure of the rms value of a pulse-width modulated square wave. The resulting system is a high-performance power supply which is both reliable and efficient.

Problem and Over-all Approach

This power supply consists of three separate sections: section 1, the $B+$ supply, has seven independently regulated direct-output voltages for vacuum-tube plate supplies; section 2, the filament supply, delivers regulated a-c filament power to a total of 34 electronic tubes; section 3, the modulator motor supply, delivers regulated a-c power to a small motor. It is also desirable that each output be individually adjustable. The system is fed by two direct-current nominally 28-volt power supplies; input A is used to energize the filament supply only and has a voltage overshoot when it is turned on which may reach 45 volts for approximately 100 ms (milliseconds). Regulation of the filament supply output voltage is not necessary during this period, but the system must operate safely. Input B is turned on sometime after input A and supplies power for both the modulator motor supply and the $B+$ supply. The operating and environmental conditions are listed in the following and the output specifications are given in Fig. 1.

1. Input voltage: 28 volts d-c±10%.
2. Operating ambient temperature range: −40 C (degrees centigrade) to +100 C.
3. Operation at 100 *g* shock of 5.5-ms duration.
4. Operation at 100 *g* sustained acceleration for 20 minutes.
5. Vibration: 0.060 inch, peak to peak, from 10 to 55 cycles and constant 10 *g* acceleration from 55 to 2,000 cycles while operating.

The completed supply must be contained in two aluminum castings having a total volume of approximately 130 cubic inches. In spite of this small size, the over-all efficiency of the unit should approach 80%.

From an analysis of the various output and system requirements, several facts about the final assembly can be determined.

1. The operating ambient temperature range indicates that relatively high temperature components must be used, notably silicon semiconductor devices and wire-wound resistors.
2. The small size of the completed package and the requirement for an over-all efficiency approaching 80% suggests that a minimum number of components be used.
3. Since all the outputs except the modulator motor supply output must be regulated to ±1% of their nominal voltage and they should be individually adjustable, each output will probably have to be individually regulated.
4. The combination of a silicon transistor inverter with a magnetic amplifier offers an efficient and rugged method for deriving each of the required outputs. In order to regulate an input variation of ±10%, the magnetic amplifier need only support a portion of the output voltage, thereby insuring small size and satisfactory efficiency.
5. The total amount of d-c power required can be easily provided by one transistor inverter; therefore, the $B+$ supply can be a single inverter with multiple outputs and regulators.

With these in mind, the over-all system approach can be discussed.

Fig. 1 shows a block diagram of the system described in the following discussion. The $B+$ supply consists of a silicon transistor inverter with a number of output voltages. Each of these voltages is fed to a magnetic amplifier where it is pulse-width modulated. Next, the magnetic amplifier output is filtered to produce the required direct voltage. A portion of the output power is fed back to a control winding on the magnetic amplifier and compared magnetically with a stable reference. The difference between these two signals will control the pulse width of the unfiltered direct voltage to keep the output voltage constant. In order to reduce the gain requirements of the pulse-width modulator, part of the regulation is accomplished by open-loop compensation sensitive to the input voltage. The output voltages can be individually adjusted by potentiometers in the feedback loops. The complete $B+$ supply consists of five magnetic amplifier regulators, each fed from a separate secondary winding on the inverter output transformer. The remaining two outputs, +230-volts and +300-volts 15-ma load, are not individually regulated but are produced by combinations of other outputs. To help minimize the number of components required, a single reference is provided for all the magnetic amplifiers in the $B+$ supply. Also, since the frequency of operation and the sequence of starting allow the $B+$ inverter to be driven from the filament supply, this method is adopted. Not only does this

reduce the number of components in the $B+$ inverter, but it also precludes any starting difficulty which might be encountered with a self-excited circuit.

For the filament supply, a low-power silicon transistor oscillator supplies power to drive a high-power silicon transistor inverter. The square-wave output of the power inverter is pulse-width modulated by a magnetic amplifier to produce the filament output voltage. This output voltage is metered by an rms sensing circuit and compared to a Zener reference in a voltage-error detector. The resulting error signal is fed to a control winding on the magnetic amplifier which then corrects the output. Open-loop compensation is again used to reduce the feedback requirements. In order to withstand the 45-volt overshoot referred to previously, high-voltage transistors are used throughout the filament supply.

The modulator supply inverter is a self-excited inverter circuit in which the frequency of oscillation is determined by the output transformer saturation. This circuit is easy to start and, since it operates at a relatively low power level, the inefficiencies incurred by allowing the output transformer to saturate can be tolerated. The inverter output voltage is regulated by another magnetic amplifier controlled only by an open-loop signal sensitive to the direct-voltage input. No feedback loop is needed since the required voltage regulation is only ±5% of the nominal voltage.

Transistor Specifications

The transistors used in this supply are n-p-n fused junction silicon power transistors, Westinghouse type *WX 1015* and *WX 1016*. The voltage and current ratings available, together with a very low saturation resistance, enable them to handle high switching powers with a minimum of losses. They can be obtained in 2- and 5-ampere current ratings with collector-to-emitter voltage ratings from 30 to 300 volts. The maximum saturation resistance of the 5-ampere unit is 0.5 ohm, and the gain is 10 or greater at the rated current. From an efficiency standpoint, rough calculations showed that each 0.1-ohm unit of transistor saturation resistance decreased the over-all system efficiency by approximately 2%. To keep the efficiency as high as practical, a specification of $R \leq 0.3$ ohm was placed on the 5-ampere transistors used for this supply.

Magnetic Amplifier Design

Although, for the most part, conventional magnetic amplifier design techniques were applied to the synthesis of this unit, a considerable number of unique facets are evident. These are brought about by rather stringent requirements with respect to performance, reliability, size, efficiency, and environmental conditions.

Beyond the requirements already listed are a number of practical ideas which should be included in the design procedure. In essence, these are considerations which would permit standard production techniques to be applied to the finished unit. Included in these are reproducibility of the entire unit performance, availability of basic components such as cores, relative ease of winding, and relative ease of assembly.

In order to transmit an understanding of the problems peculiar to this application, several topics will be discussed in detail in the following section.

The filament and modulator motor supplies, being a-c outputs, require doubler magnetic amplifiers. In the d-c supply bridge magnetic amplifiers are used in all cases except the magnetic amplifier which produces the 150-volt output as a doubler. Bridge circuits are employed because of the high voltages encountered in some outputs; however, center-tap circuits could be used on the 28-volt outputs. The lone, $B+$, doubler is inserted in the d-c supply so that an additional 150-volt output can be generated through an isolation transformer and a rectifier then stacked on the directly formed 150-volt output to create a low-power 300-volt supply. A Zener diode string used in conjunction with a portion of the higher power 300-volt output creates the 230-volt supply.

Cores and Diodes

Assuming that the performance requirements are all met, the prime magnetic amplifier design factor is size. Since the amplifiers will occupy a significant part of the available space, their volume must be minimized. A critical step in satisfying these conditions is the choice of a core material. Two metals which prove suitable for low-power amplifiers are HyMu-80 and Hipernik V. Of the two, HyMu-80 in tape-wound toroidal form is chosen for a number of reasons. However, in this case, the chief asset of HyMu-80 is its ability to retain better its gain at higher frequencies. Although this material has a lower maximum flux density than does Hipernik V, the fact that the amplifier need exercise only partial control of the input due to the relatively small input variations, coupled with the fact that a high-frequency supply does exist, reduces the load-winding requirements to a minimum. It was found by quick trial design that the smallest standard core of either material which could possibly fulfill the volt-second requirements of each output and still allow a reasonable control-winding area was of such a size as to require only a relatively small fraction of its area for the load winding. Later, it will be shown in the case of the d-c supply that a large amount of control-winding space will tend to reduce the size of the reference while also having a beneficial effect on efficiency. Thus, if the majority of the winding area is devoted to control turns, the maximum flux density of a core has a less important effect on its final dimensions.

Results of 2-kc tests which involved HyMu-80 in tape thickness of 1 and 2 mils displayed that the 1-mil tape did not possess any significant advantage over the heavier strip; therefore, 2-mil tape was used throughout.

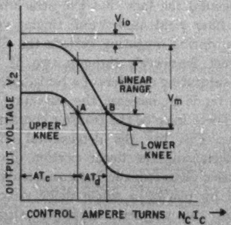

Fig. 2. Magnetic amplifier control characteristics

The filament and modulator motor supplies, utilizing doubler circuits, call for self-saturating diodes of relatively low voltage ratings and not too strict leakage values. However, in the $B+$ supply, the bridge magnetic amplifiers require voltage ratings in excess of those dictated by the nominal value of the peak inverter outputs which are considerably higher than the output voltages since the full magnetic amplifier ranges are not utilized. This is due to the effect of stray capacities working with the filter inductance which generates high ringing voltages comparable to the peak inverter voltages. Utilizing *R-C* spike suppressors to damp out these oscillations, the ringing voltages are reduced and add only approximately 25% to the necessary voltage ratings of the diodes. In some cases, namely the 300-volt channel, two units were used in series. These diodes are chosen to possess extremely low leakage currents in order not to penalize the high gain of the cores at elevated temperatures.

Load and Control Windings

The two magnetic amplifier control characteristics of Fig. 2 display a major portion of the information needed for the entire design. The plots reveal the change of output voltage with respect to control current for the two cases of high and low extremes of input voltage. As the input voltage is raised from its minimum to its maximum value, the operating point on the characteristics will shift downward from *A* to *B*, thus maintaining the output at a constant value. It is apparent from these curves that in order to fully utilize the gain of each core, the operating points *A* and *B* must lie comfortably within the linear range. The necessary magnitude of this region is determined by the magnitude of the input voltage which, in turn, is dependent on: 1. the required output voltage, 2. the magnitude of the upper knee, 3. the saturation induced voltage V_{io}, 4. the internal voltage drops due to winding resistance, diodes, etc., and 5. temperature effects. The total voltage which the amplifier must be capable of supporting is then given by $V_M + V_{io}$ if internal voltage drops are neglected.

For a square-wave supply voltage,

$$V_M+V_{io}=4fN_LB_MA_C\times10^{-8} \qquad (1)$$

where

f = frequency of supply voltage, cycles per second (cps)
B_M = maximum flux density, gauss
A_C = core cross-sectional area, cm^2
N_L = number of load turns

It is important to note here that variations in core characteristics from unit to unit, or with temperature changes, cause V_M to be made large enough to insure operation in the linear range under all conditions.

In order to appreciate the demands of core nonlinearities on load-winding requirements, a comparison may be made between idealized and practical control characteristics. Assuming the absence of nonlinearities and saturated induced voltage, a magnetic amplifier must support a minimum of approximately 22% of the output voltage. In practice, however, a conservative design requires that the load windings be capable of supporting 50% of the output voltage. This corresponds to operation in the central 50% of the control characteristic.

It has been previously mentioned that the control windings occupy a major portion of the available winding space. In determining the design of these windings, it is desirable to obtain the highest circuit gain for the least amount of space. Since the output of each amplifier is to be separately monitored by a closed-loop feedback system, some consideration must be applied to the manner in which the reference and feedback signals are mixed. In the case of the filament supply amplifier, it is advantageous to utilize a Zener bridge reference as a part of an rms voltage-sensing unit. However, in the d-c supply, since several units operate in essentially the same manner, a common Zener voltage reference can be utilized, feeding virtually a constant current to a series connection made up of reference windings from each of the individual cores. Feedback ampere-turns which are derived from the filtered output of an amplifier are fed to a second of its windings and thereby are magnetically mixed with the reference. This method of ampere-turns comparison does away with providing a number of Zener bridge references which would prove to be bulky and would consume relatively large amounts of power on the high-voltage outputs.

For a closed-loop regulation of ±1% for a ±10% input change, a loop gain of approximately 10 is required. Transcribing the required gain to feedback ampere-turns, a 2% change in output must yield enough net ampere-turns variation to allow the magnetic amplifier to swing its entire control range. Thus, AT_d of Fig. 2 is equal to 2% of the required feedback ampere-turns. Note that AT_c is the ampere-turns necessary to drive the core into its linear range and is equal to from one to several times AT_d. Therefore, it can also be assumed that the reference ampere-turns AT_r are approximately equal to the feedback ampere-turns AT_f since $AT_f >> AT_d + AT_e$ and $AT_f - AT_r \leq AT_d + AT_c$, then

$$AT_f = \frac{AT_d}{0.02} \simeq AT_r \qquad (2)$$

The AT_d for a given core is obtainable from test data. Once the reference and feedback requirements are known, the control windings can be designed.

In fitting the load and control requirements which were previously attained to specific cores, it becomes evident that core gain has the most significant effect on the performance and size of an amplifier. It is found that the load windings are easily designed as per previous minimum requirements by providing a wire size which will yield a current density low enough to insure safe operation. On the other hand, the control design is complicated by the fact that the wire size is not firmly tied to the current which flows through these windings. For example, the feedback windings of necessity must draw a minimum of current from the output in order to retain a high over-all efficiency. This implies a high number of turns. If the choice of wire is only based on current density, the resulting wire size is too small to be wound on the core economically. Thus, a somewhat larger wire must be tolerated. This is one factor that tends to amplify the need for cores which provide high gain and sizable amounts of control-winding area. Another item which must be realized is that the reference current, whose maximum value is prescribed by the Zener diodes which are used in the reference circuit, and while determining the number of turns on the windings which it energizes, does not firmly indicate wire size. Power limitations on the reference will cause it to display a relatively low output impedance. Thus, in the reference circuit, the ratio of winding resistances to fixed resistance must be kept small. Or else, the resistance variations, due to the copper in the windings, will become so large as to defy suitable temperature compensation for constant current. Hence, larger wire sizes must again be utilized. All in all, the need is evident for high core gains to reduce the necessary feedback and reference turns while preserving efficiency and retaining a small size.

The description of the design to this point has provided the minimum loop gain which would meet the required performance. To alleviate the necessity of over-design of the feedback loops in order to anticipate variations of core characteristics from unit to unit or with temperature, open-loop compensation of each channel is provided. The effect of this addition is to reduce the output variations to approximately 25% of the values which would exist if the feedback were unaided.

It is important to note that in applying the windings to the cores, the high-frequency square-wave nature of the magnetic amplifier supply brings to light the problem of distributed winding capacities which affect core gains and yield spurious oscillation or ringing, and the high-control to load-turns ratios which cause large voltages to be induced in the control circuits, thus endangering the insulation of those windings. These effects are virtually eliminated by: 1. providing sufficient sectoring of the gate windings to minimize their distributed capacitances, and 2. adopting a winding procedure for the magnetic amplifiers which is carried out by first winding the load turns separately on to each core of a given pair, then stacking the two cores and winding all control windings over both cores simultaneously. Thus, the cores, if closely coupled, will experience practically no induced voltage in the control circuit, and, hence, reflected capacitance effects will also be eliminated.

REFERENCE

The reference circuit itself was designed for economy with respect to efficiency and size. The fact that it is energized from one of the regulated outputs reduces its complexity, the necessary number of Zener diodes, the necessary magnitude of the input impedance and consequently the input power, while retaining a very stable output voltage.

One of the most serious problems of the entire $B+$ supply is an interaction of the magnetic amplifiers through the series-connected reference windings. This detriment is caused by the induced current from each magnetic amplifier which tends to flow in the reference winding loop and results in a degeneration of the gain of the individual magnetic amplifiers by a factor of 3 or 4. It was found that a 0.2-henry choke inserted in that loop tends to restore the gains to approximately one-half their isolated value. Further experimentation disclosed that encircling the 300-volt channel's reference winding and the series choke with a low-impedance capacitive path brought about a further reclamation of gains and thereby virtually eliminated the interaction problem. Since this last measure merely isolated the 300-volt channel from the others, the nucleus of the interaction problem can be attributed to that reference winding.

Although in the a-c supply a Zener bridge reference is used instead of ampere-turns comparison, the magnetic amplifier design procedure is essentially the same as the d-c procedure with respect to load and control windings.

The magnetic amplifier of the modulator motor supply differs in design from the others in the unit. Since the output is controlled entirely by open-loop compensation, core gain is of little consequence in this amplifier; however, linearity and a high maximum-flux density are desirable. Thus, Hipernik V becomes an excellent choice for this output. To further increase linearity while gaining uniformity of performance with varying core parameters, negative feedback is employed. This feedback is achieved by two resistors which shunt the self-saturating rectifiers. Their effect is also such as to bend the transfer characteristic about the lower knee, thus providing suitable biasing.

FILTERS AND STABILITY

The filter inductors for the $B+$ supply are wound on powdered iron cores. Again to reduce stray capacities, the windings contained many sectors. The filter capacitors for the high-voltage outputs are paper which proved in those cases to be more desirable than their electrolytic counterparts. However, on the 28-volt d-c outputs, tantalum units were employed. In general, the design for these elements is based on these factors:

1. Sufficient attenuation must be provided to reduce the output ripple to required amounts.
2. Continuous inductor currents must be insured in order to maintain coupling between the magnetic amplifiers and the loads
3. The size of the filters shall be minimized.

Beyond the fact that the attachment of a filter yields undesirable ringing voltages, during pregating periods the filter current freewheels through two of the self-saturating rectifiers of a bridge circuit and tends to increase the curvature at the lower knee of the transfer characteristic. This has the detrimental effect of decreasing the linear portion of the transfer characteristic but can be alleviated by placing a single diode directly across the magnetic amplifier output. Since the diodes which are used exhibit a virtually constant voltage characteristic, the effect of the freewheeling current is

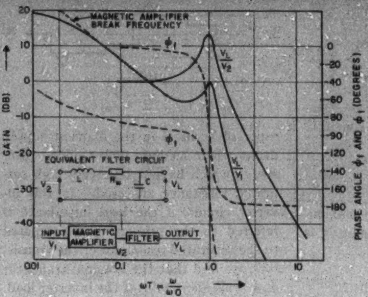

Fig. 3. Normalized Bode plots

reduced to one half its former value and the sharpness of the lower knee is markedly improved.

The design of the magnetic amplifier-filter combination must be such as to insure stability of each individual feedback system. The frequency characteristics of the magnetic amplifiers are accurately described by a single time-constant relationship since the response time is a large multiple of one cycle. The loop gain which is supplied by the amplifier has been specified by the allowable variations of the output. Thus the key to identifying the conditions for stability of the feedback system is the determination of the filter characteristics and the blending of these with the amplifier characteristics. Fig. 3 displays the normalized frequency plots for the gain V_L/V_2 and phase ϕ_f of a typical *L-C* filter. Note that a peaking of the response curve occurs at the filter break frequency and is a function of the damping factor *d*. The transfer function of the filter is derived using the equivalent circuit shown and is given in reference 1 as:

$$\frac{V_L}{V_2}=\frac{1}{\left(j\frac{\omega}{\omega_o}\right)^2+\left(j\frac{\omega}{\omega_o}\right)2d+1} \qquad (3)$$

$$\phi_f=\tan^{-1}\frac{2d\left(\frac{\omega}{\omega_o}\right)}{1-\left(\frac{\omega}{\omega_o}\right)^2} \qquad (4)$$

where

$$\omega_o=\frac{1}{\sqrt{LC}}\equiv\text{undamped natural frequency}$$

and

$$d=\frac{Rw}{2\sqrt{\frac{L}{C}}}\equiv\text{damping factor}$$

The damping effect due to the load is neglected since it is considerably smaller than that presented by *Rw* which is the filter resistance and effective magnetic amplifier output resistance.

Upon establishing the total response characteristic V_L/V_1, Fig. 3, it can be seen that the system is conditionally stable if the peak due to the filter characteristic is somewhat below the zero decibel or unity-gain line. Stability, therefore, is achieved by lag compensation, relying entirely on the single break given by the amplifier to reduce the loop gain to less than 1 before the high phase shift of the filter is expended. Thus the minimum allowable time constant of the magnetic amplifier is determined. This time constant has been shown from reference 2 to be:

$$T=\frac{G_t}{2f}\sum\frac{N_C^2}{R_C}\text{ seconds} \qquad (5)$$

where

N_C = control turns of a given winding
R_C = apparent resistance of that winding
G_t = Roberts' core gain $\left(\frac{\text{volts/turn}}{\text{ampere-turn}}\right)$

Since the feedback windings contribute essentially all the N^2/R the time constant of the magnetic amplifier is easily adjusted by means of a shunting resistor across this winding.

The amplifier time constant is made several times larger than the minimum values which are specified by the plots to allow for deviations of core and filter parameters. The shunting resistors have negligible effect on the feedback current itself.

RMS Sensing

The specifications given for the output voltage of the filament supply require regulation to within ±1% of its nominal rms voltage. For measuring rms values, multiplying devices such as Hall multipliers or square-law devices such as "starved diodes" or inherently rms sensitive elements such as thermocouples could be employed. None of these devices, however, provide a simple and uncritical solution over a wide operating temperature range with an accuracy of better than ±1%. A new type of rms sensing circuit using only small transformers and rectifiers can, however, meet these requirements. Figs. 4(A) and (B), which show a simplified block diagram of the filament system along with the associated voltage waveforms, will be used to explain the action of the rms sensing circuit.

The rms value of the output voltage (V_2) may be written as

$$V_{2_{rms}}=\sqrt{1-\epsilon}\,V_o \qquad (6)$$

where V_o is the peak amplitude of the filament output voltage and ϵ is the fractional part of a half period in which the magnetic amplifier absorbs the inverter voltage. The expansion of equation 6 into a series results in

$$V_{2rms}=V_o\left[1-\frac{\epsilon}{2}-\frac{1\cdot\epsilon^2}{2^2\cdot 2!}-\frac{1\cdot 3\cdot\epsilon^3}{2^3\cdot 3!}-\frac{1\cdot 3\cdot 5\cdot\epsilon^4}{2^4\cdot 4!}-\dots\right] \qquad (7)$$

If a linear approximation is made for $V_{2_{rms}}$ by using the first two terms only, then

$$V_{2rms}\approx V_o\left[1-\frac{\epsilon}{2}\right] \qquad (8)$$

By comparing this first approximation with the exact series representation of $V_{2_{rms}}$, it is obvious that a better approximation can be made; notice that the

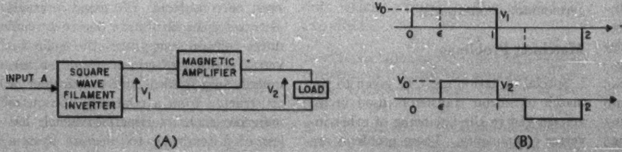

Fig. 4. Filament supply
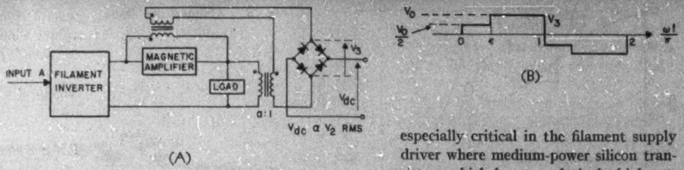
A—Block diagram
B—Waveforms

Fig. 5. Rms circuit (A) and waveforms (B)



error is zero for $\epsilon = 0$ and that the value of the linear approximation suggested is always greater than the exact function for any $\epsilon > 0$. If the approximation is changed so that

$$V_{2_{rms}} \approx V_o[1.003 - 0.56\epsilon] \tag{9}$$

the error will be reduced for larger values of ϵ, i.e., $\epsilon > 0.25$. The maximum ϵ necessary to regulate the output voltage of the filament supply, calculated from input voltage variations and including a small safety margin to account for internal losses, is 0.4. The error over the range of $0 < \epsilon < 0.4$ for the approximation in equation 9 is +0.35%, −0.64% and is compatible with system requirements. Fig. 5(A) shows how the linear approximation can be realized with only two small transformers and a bridge rectifier. The input voltage to the rectifier bridge has the waveform in Fig. 5(B). Its rectified average value corresponds to the expression in equation 9 and is proportional to the rms output voltage.

In the preceding derivation, it was assumed that the filament supply had a zero output impedance. In a practical circuit the peak voltage seen by the rms sensing circuit during the time $0 < t < \epsilon T/2$, when the load draws no current, is higher than the voltage seen between $\epsilon T/2 < t < T/2$ when the load is receiving power. This necessitates the application of a correction factor b, representing the regulation of the filament supply from no load to full load, to equation 9 so it now becomes

$$V_{2_{rms}} \approx V_o\left[1.003 - \frac{0.56\epsilon}{b}\right] \tag{10}$$

and b is defined as $b = V_o'/V_o$, where V_o' is the peak inverter output voltage during time $0 < t < \epsilon T/2$. The evaluation of b is done by experiment or can be calculated since it depends only upon the internal impedance and the load impedance of the filament supply and is not a function of ϵ. The usefulness of this type of rms circuit is restricted by regulation to constant load circuits; i.e., for an application where the load impedance varies, b would vary and introduce a sensing error. The error can be minimized by reducing the internal impedance of the supply as much as is practical.

Starting Conditions

The characteristics of the filament load impose difficult starting conditions on the filament inverter since the initial impedance of the cold filaments is approximately one fourth its normal value. If the filament inverter is self-excited, the transistors must be provided with sufficient drive to remain in saturation during the starting condition in order that oscillations be maintained. The silicon transistors used have a gain of 10 at 5 amperes collector current; at 20 amperes collector current, the gain would be down to 5 or less so that the required drive would be at least eight times normal. A considerable amount of power would be needed to provide the necessary excess drive as dictated by the starting surge. The solution chosen is to use a small oscillator to provide drive to the main inverter and to let the main inverter power transistors limit the output current and voltage during starting by coming out of saturation. The main inverter transistors will limit the load current to some level determined by their drive currents and the output voltage will gradually build up to its normal value as the transistors return to a saturated condition. The starting period requires from 5 to 7 seconds. During this transient, the power dissipation in each of the two transistors reaches a peak of 120 watts. In addition to the unusual load, the input voltage upon starting exhibits an overshoot to 45 volts for as long as 100 ms. The transistors must also be capable of sustaining this high input voltage. These abnormally severe transient conditions underline the superior ruggedness of silicon transistors when compared to their germanium counterparts.

Matching Problems

Special attention must be given to the match of silicon transistors used in inverters and to the balancing of other inverter components. These problems are especially critical in the filament supply driver where medium-power silicon transistors which have a relatively high saturated resistance are used. In this inverter circuit, if the load impedance is referred to the primary and compared to the saturated resistance of the transistors, we find that the nominal transistor drops represent 10% of the inverter load. If the drops of the two inverter transistors are not equal, a different voltage is applied to the timing transformer during opposite half cycles causing a time unbalance of the output voltage; i.e., the time interval for positive output voltage is not equal to the time interval for negative output voltage. When this unbalance is transmitted to the main inverter, the main transistors have unequal conduction times, introducing a direct-voltage component in the main inverter output transformer, causing the transformer to saturate for a time roughly equal to the difference in conduction angles, and resulting in current spikes, distortion of the output waveform, and abnormal losses. It is also possible to have a time unbalance in the driver output voltage due to an unbalanced driver load.

To solve these problems, two things are required. First, the saturated resistance of the driver transistors must be matched; second, the load on the driver must be balanced by matching the input impedances of the main power transistors. When these two parameters are matched, the output of the driver inverter will be a symmetrical square wave. This does not insure, however, that the main output transformer will not saturate from other conditions.

In the main inverter, the saturated resistance of its transistors represents about 5% of the load impedance so that here the problem is less severe. Also, the frequency of oscillation and conduction times have already been determined by the driver so that they are not affected by mismatched transistors in the main inverter; it is the output transformer that must be considered. To avoid intervals of transformer saturation due to a small direct-voltage component, the main inverter transistors are matched for saturated drop. Also, the transformer is constructed from a relatively nonsquare material, such as Hipernik, which has less of a tendency to saturate than a

Fig. 6. System schematic

true square-loop material while retaining the low loss qualities of a narrow loop.

Temperature Compensation

A final, but significant, element in the development of the unit is the temperature compensation since the entire unit is subjected to temperatures ranging from −40 C to +100 C. In all amplifiers the variation of copper resistance in the load circuit is negligible. The d-c supply contains several temperature sensitive elements, the most important being the copper resistance of the reference loop which tends to lower the output by 3% with increasing temperature. Combatting this deviation by different amounts in different channels is the feedback winding resistance. Finally, the Zener diodes of the d-c reference provide a small fraction of a per-cent variation which could be positive or negative. The bulk of the compensation in the d-c supply is achieved by a negative temperature coefficient resistor in the reference loop while trimming in the form of positive temperature coefficient resistors in the feedback is required on the 107- and 150-volt magnetic amplifiers.

In the filament supply, any significant variation of the rms output voltage with temperature is the result of temperature-sensitive elements in the rms sensing circuit and the reference bridge since variations of AT_e or changes of copper resistance in the load circuit become negligible with a high loop gain. For the detector bridge, temperature-stable resistors are used so their variation can be neglected; however, the balance point can vary up to a maximum of ±0.6% due to the temperature variation of the Zener diode voltages. In the rms sensing circuit the winding resistances of the sensing transformers and filter choke will have a positive temperature coefficient, but with proper design this is counteracted by the negative temperature coefficient of the diode forward voltage drops in the rectifying bridge.

When subjected to temperature testing, the modulator magnetic amplifier output displayed a tendency to drift quite radically, enough to exhaust the allowable deviation. However, the gain or linearity held up quite well. Thus, the problem becomes one of compensation for the drift which is traced and attributed to two effects:

1. The variation of the rather high copper resistance of the magnetic amplifier and inverter transformer causes changes in the output voltage.
2. The variation in the magnetic amplifier winding resistance causes an output deviation through the feedback loop, since the amount of negative feedback is proportional to the load current and the winding resistance.

Both of these variations are negative temperature effects when referred to the output; hence by using a higher voltage Zener diode, whose temperature coefficient is higher (and positive), compensation is achieved.

Results

B+ Supply

Fig. 6 displays the complete schematic diagram of the final system. Taking the 107-volt amplifier *SR501* as an example, it can be seen that its output is fed to a filter composed of *L501* and *C502* resulting in a smooth d-c output for this channel. This voltage is then fed through *R502*, *503*, and *504* to a feedback winding of *MA-F*. The reference voltage is formed across the Zener diode combination, *CR806*, *807*, and *808*. The voltage level of the output can be adjusted by potentiometer *R503* which varies the net ampere-turns on each core. *R504* is a temperature-sensitive resistor. Open-loop compensation is accomplished by the network containing *CR805* which furnishes a current through *R803* to an amplifier winding. *R505* is used to increase the N^2/R of the amplifier and there-

by increase the time constant to insure stability. *R501* and *C501* form a spike suppressor which damps out high-frequency ringing voltages which occur due to stray capacities. *CR505* shunts the freewheeling filter current from *CR501* and *CR502*. The operation of all the regulator circuits is essentially the same as the 107-volt channel; however, some small, but significant, differences should be mentioned. First of all, the two identical 28-volt channels, *SR601* and *SR701*, contain two stages of filtering which are necessary to obtain the low ripple content required in these inputs. The voltages encountered in the 300-volt channel necessitate two diodes in series. An additional spike suppressor formed by *C404* and *R413* is used to further alleviate the voltage stress on these rectifiers. The 230-volt output is also derived from the 300-volt channel by the resistive divider, *R402*, *R403*, and *R404*, along with the Zener diode supply which contains *CR407* to *CR410*. *R410* controls the output level of this supply. *R408* and *C403* form an *R-C* filter which is tolerable on this channel since the ripple content of the input is extremely low. The network containing *CR805* accomplishes open-loop compensation for all the amplifiers.

Several factors involved in the reference circuit are worthy of note. The network is fed by the 107-volt supply which is virtually constant. *R808* controls the current through the Zener diodes. Due to the fact that induced currents can flow in the series connection of reference windings, *L802* and *C802* decouple the 300-volt winding from the others.

MODULATOR MOTOR SUPPLY

The inverter for this supply is fed directly off input *B*. This is a conventional self-excited inverter circuit which produces a 250-cycle square wave. The core is a Hipernik V toroid and the transistors are Westinghouse *WX 1015C* types. *R101* and *R103* determine the base drive while *R105* is used to insure starting. A doubler magnetic amplifier, *SR101*, accepts the inverter secondary voltage and regulates the output to approximately 45 volts. The compensation network is composed of a divider, *R102* and *R104* and a Zener diode, *CR101*, which feeds a control winding of the amplifier. Negative feedback is achieved by *R107* and *R108* which shunt the self-saturating rectifiers. *R106* and *C104* are used to inhibit ringing which is caused by the slightly reactive nature of the load.

FILAMENT SUPPLY

The driver portion of this supply uses two medium-power silicon transistors, *Q901* and *Q902*, in a self-excited oscillator. Diodes *CR901* and *CR902* protect the transistors against high reverse emitter-to-base voltage, and also permit the use of a single feedback winding for both transistor drive currents. *R903* provides positive starting by supplying a current from the input line to both transistor bases. The network consisting of *CR903*, *CR904*, *R904*, and *C901* reduces any voltage spikes which tend to appear across the transistors. The driver supplies base current to two high-power silicon transistors (*WX 1016C*), *Q1* and *Q2*, in the filament supply inverter. The secondary voltage of *T1*, the filament supply output transformer, is pulse-width modulated by *SR1*, a magnetic amplifier, to produce the reg-

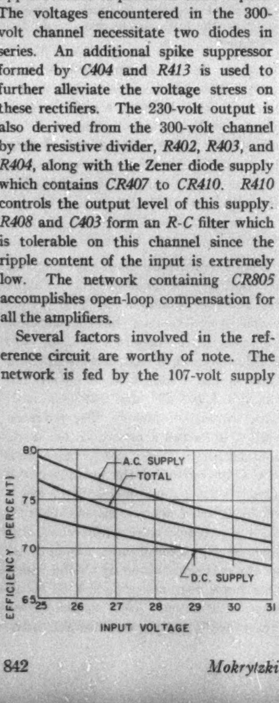

Fig. 7 (left). Efficiencies

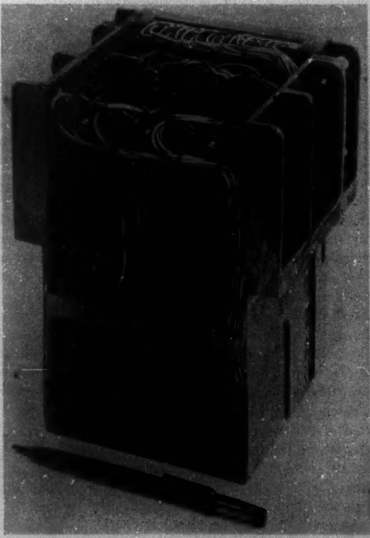

Fig. 8 (right). Completed prototype

ulated output voltage. Transformers *T2* and *T3*, along with a diode bridge and a filtering network, *L2* and *C4* make up the rms sensing circuit and produce a direct voltage proportional to the rms of the filament output alternating voltage. This direct voltage is compared to a Zener diode reference and an error signal produced in the voltage error detector consisting of *CR4*, *CR5*, *CR10*, *CR11*, *R7*, and *R8*. The error signal then controls the pulse width of *SR1*. The magnetic amplifier is open-loop compensated by *R2*, *R4*, and *CR1*. Two low-voltage secondaries on *T1* supply the drive power for the *B*+ inverter.

The results of tests which were performed on the completed unit are shown in Table I. Plots of efficiency versus voltage for the filament supply, the *B*+ supply, and the complete unit are shown in Fig. 7. The maximum over-all efficiency is 77%. Fig. 8 displays the entire unit successfully packaged in the allotted space.

Conclusions

This paper has demonstrated a number of advantages which are realized by the use of multiple-channel magnetic-amplifier regulators in conjunction with high-frequency inverters using the recently developed Westinghouse type *WX 1016* and *WX 1015* high-power silicon transistors. The high-frequency static inverter conveniently supplies a number of output voltages which can be regulated by compact, efficient magnetic amplifiers. The silicon transistors add to the inverter a ruggedness and flexibility previously unattainable in germanium units as well as low losses which are unmatched by contemporary silicon devices. The magnetic amplifiers provide reliable regulators which have isolated inputs so that a single reference can control a number of regulating channels. This alloying of magnetic and semiconductor elements yields an amplification of the qualities of each device and produces a rugged, reliable, efficient and high-performance power supply suitable for use in military applications.

D-C Charged Magnetic Pulse Modulator

E. W. MANTEUFFEL ASSOCIATE MEMBER AIEE

R. E. COOPER ASSOCIATE MEMBER AIEE

AN A-C CHARGED magnetic pulse modulator consisting of a resonant charging stage and several successive pulse-modulating stages is the subject of a paper by W. S. Melville.[1] These pulse-modulating stages employ saturable reactors used as switching elements, and a series of capacitors. This modulator, if designed for a high-pulse repetition frequency, requires a separate frequency converting device whose output frequency must be equal to the desired pulse repetition frequency. Either an alternator or a magnetic frequency multiplier can be employed for this purpose. However, the magnetic frequency multiplier has considerable weight and volume, as well as a low power factor for high ratios of frequency conversion. An alternator, if built for a low speed, will also have a large weight. If designed for high speed, it has a limited life resulting from problems with bearings. To have a jitter-free-operation of the radar system, the voltage and frequency of the supplying power source must be regulated to close tolerances.

Melville also discusses d-c charged modulators employing thyratron tubes as discharges switches. Like many other electronic tubes, thyratons have the disadvantage of being less reliable than comparable solid-state devices. The recently developed controlled silicon rectifier, an essentially solid-state thyratron, opens new possibilities for further development of d-c charged magnetic pulse generators suitable for radar systems.

This paper presents information about investigations on a proposed d-c charged magnetic pulse modulator which partially employs controlled rectifiers as switching elements. A breadboard modulator was constructed which consisted of one charging and two pulse-modulating stages. One controlled rectifier was used in the first stage, two in parallel in the second stage, and a saturable reactor in the output stage. The modulator was capable of delivering a peak power output of approximately 110 kw (kilowatts) into a resistive load under critical damping. When a 5-section pulse-forming network was employed in the output stage, a 50-kw peak-power output pulse of about 3-μsec (microsecond) duration was achieved.

It should be emphasized that the work reported here is only a first step and that experiments were made only with a model-

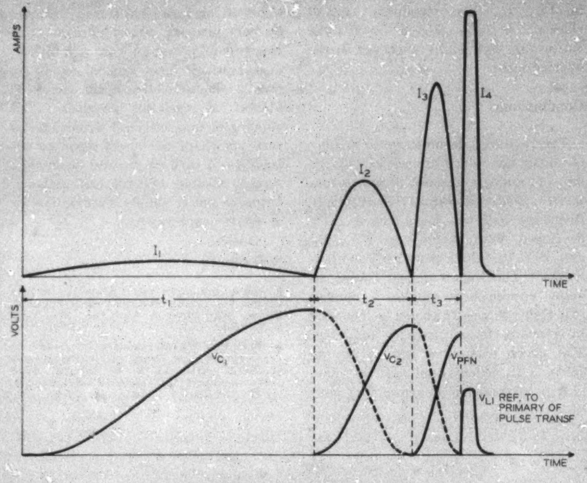

Fig. 2. Current and voltage wave shapes

type modulator. With further developments of controlled rectifiers of larger current ratings, much higher peak output powers than those obtained during this investigation will be possible. No special effort was made to reduce the pulse width to fractions of a microsecond, which would further increase the output power, since means for achieving this goal are described in Melville's paper and other publications.[1,2]

Description of Operation

The basic circuit configuration of the proposed modulator, which consists of several cascaded stages, I, II, III, IV, is illustrated in Fig. 1. The number of stages necessary depends on the required pulse width of the output power pulse. The charging stage 1 which consists of controlled rectifier CSR_1, inductor L_1, and capacitor C_1, is switched on from trigger pulses applied to terminals g_1-c_1, repeating at the required pulse-repetition frequency, and furnished from a small power source of appropriate frequency. During one half-cycle of the natural frequency determined by L_1 and C_1, the voltage on capacitor C_1 will rise to nearly twice the value of the d-c supply voltage V_{DC}. The actual ratio of the voltage V_1 on the capacitor to V_{DC} is determined by the losses occurring in the circuit. A resistor R_p of suitable value must be connected across capacitor C_1 to prevent charging of this capacitor through the anode-cathode resistance of CSR_1 to the supply voltage V_{DC} before trigger pulses are applied.

At the instant when V_1 reaches its maximum value, current I_1 will become zero and the controlled rectifier CSR_1 will return to its nonconducting state. This means that the voltage $V_1 - V_{DC}$ will suddenly appear between the cathode and anode terminals c_1 and a_1 of this rectifier. This sudden voltage step is now applied to a circuit consisting of a small capacitor C, resistor R, diode D, and the primary winding W_1 of a small pulse transformer T. The secondary winding W_2 of T is connected to gate terminal g_2 and cathode terminal c_2 of a second controlled rectifier CSR_2, located within stage II of the modulator. This second stage consists of inductor L_2 and capacitor C_2. A current pulse of short duration will be applied to the gate of rectifier CSR_2, initiating its conduction at the time where voltage $V_1 - V_{DC}$ appears at terminals a_1-c_1. Capacitor C is shunted by a high-ohmic resistor R_3 which allows its discharge between pulses.

After the time $t_2 = \pi\sqrt{C_0 L_2}$, (made by proper choice of the value of L_2 much shorter than the time $t_1 = \pi\sqrt{C_1 L_1}$) the charge of capacitor C_1 will be transferred to capacitor C_2. A current pulse I_2 of large magnitude and short duration will flow within stage II. The value C_0 is determined by

$$C_0 = \frac{C_1 C_2}{C_1 + C_2}$$

At the end of the time interval t_2, the voltage V_2, because of the influence of losses in stage II, becomes somewhat smaller than voltage V_1, and will exist at the terminals of capacitor C_2. At the same time, flow of current I_2 in CSR_2 will cease and this rectifier will return to the nonconducting state.

Shortly after voltage V_2 has attained its maximum value, saturable reactor SR_1 of stage III, whose unsaturated impedance is designed to be many times larger than the apparent impedance of L_2, will become saturated. Transfer of the charge from C_2 into the capacity C_p of the pulse-forming network PFN will take place by way of the saturated inductance L_{s_1} of the saturable reactor SR_1. L_{s_1} is made much smaller than L_2 to achieve further compression of the pulse width. Transfer of pulse power to the load by saturable reactor SR_2 and pulse transformer PT is self-explanatory. Saturable reactors SR_1 and SR_2 and the pulse transformer are furnished with bias windings W_{b_1}, W_{b_2}, and W_{b_3}. These serve to reset the flux during interpulse periods. The cores have a relatively long time available for resetting between pulses; therefore, the bias current and number of bias turns can be small.

The sequence of pulse currents and voltages as they will appear in the described modulator are illustrated in Fig. 2. Actual time compression ratios and differences in magnitude of pulse currents are much larger than shown in this qualitative illustration.

The output power rating of the modula-

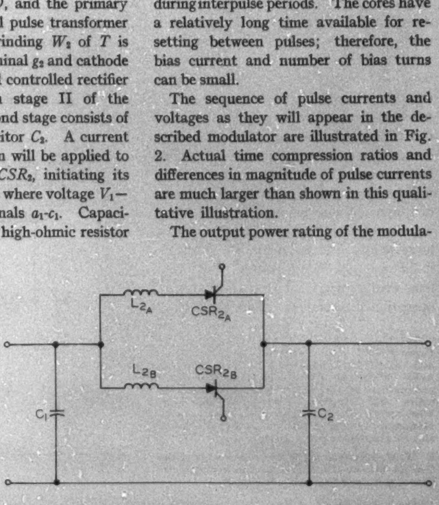

Fig. 3. Parallel operation of controlled rectifiers

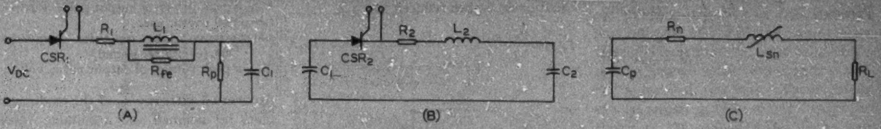

Fig. 4. Circuit diagrams of the various stages

A—First stage
B—Intermediate
C—Output stage

tor can be increased considerably by the use of two or more controlled silicon rectifiers in parallel in the second stage. This is shown in Fig. 3 where two controlled rectifiers, CSR_{2A} and CSR_{2B}, each in series with an inductance L_{2A}, L_{2B}, are arranged in parallel connection. The currents in both rectifiers will be essentially equal if they are triggered simultaneously.

The sequence of events will now be analyzed:

1. *Charging Stage.* The circuit of the charging stage is shown in more detail in Fig. 4(A). The inductance L_1 is shunted by a resistance R_{fe} representing the core losses. Resistor R_1 includes winding resistance and eddy current losses within the winding as well as dissipation in capacitor C_1. The purpose of resistor R_p was mentioned earlier.

Using Laplace notation the charging current I_1 is expressed by

$$I_1(s)=\frac{V_{DC}}{s\left[\dfrac{R_{fe}s}{s+\dfrac{R_{fe}}{L_1}}+\dfrac{1}{C_1}\left(\dfrac{1}{s+\dfrac{1}{R_pC_1}}\right)+R_1\right]} \qquad (1)$$

After rearranging terms and taking into account that R_p and $R_{fe}>>R_1$

$$I_1(s)=\frac{V_{DC}}{R_{fe}}\times \frac{s^2+\left(\dfrac{R_{fe}}{L_1}+\dfrac{1}{R_pC_1}\right)s+\dfrac{R_{fe}}{R_pC_1L_1}}{s\left[s^2+\left(\dfrac{R_p+R_{fe}}{R_pR_{fe}}\dfrac{1}{C_1}+\dfrac{R_1}{L_1}\right)s+\dfrac{1}{L_1C_1}\right]} \qquad (2)$$

This equation is of the form

$$I_1(s)=\frac{V_{DC}}{R_{fe}}\frac{s^2+a_1s+a_0}{s[(s+\alpha)^2+\beta^2]}$$

The solution in the time domain can be found in any table of Laplace transforms. Since the frequency of the damped oscillation will be about equal to the undamped natural frequency $1/\sqrt{C_1L_1}$, the charging current is given as a function of time with sufficient accuracy by

$$I_1(t)=V_{DC}\left[\frac{1}{R_{fe}}+\sqrt{\frac{C_1}{L_1}}\,e^{-\alpha t}\sin\frac{1}{\sqrt{C_1L_1}}\,t\right] \qquad (3)$$

where

$$\alpha=\frac{1}{2}\left[\frac{R_1}{L_1}+\frac{R_p+R_{fe}}{R_pR_{fe}}\left(\frac{1}{C_1}\right)\right] \qquad (4)$$

The voltage across C_1 is expressed as

$$V_{c1}(s)=I(s)\left(\frac{1}{C_1}\right)\frac{1}{s+\dfrac{1}{R_pC_1}} \qquad (5)$$

By combining equations 1 and 5 one obtains

$$V_{c1}(s)=\frac{V_{DC}}{R_{fe}C_1}\times \frac{s+\dfrac{R_{fe}}{L_1}}{s\left[s^2+\left(\dfrac{R_p+R_{fe}}{R_pR_{fe}}\left(\dfrac{1}{C_1}\right)+\dfrac{R_1}{L_1}\right)s+\dfrac{1}{L_1C_1}\right]} \qquad (6)$$

which is of the general form

$$V_{c1}(s)=\frac{V_{DC}}{R_{fe}C_1}\frac{s+a_0}{s[(s+\alpha)^2+\beta^2]}$$

For all practical purposes the voltage V_{c1} as a function of time is given by

$$V_{c1}(t)=V_{DC}\left(1-e^{-\alpha t}\cos\frac{1}{\sqrt{C_1L_1}}\,t\right) \qquad (7)$$

where α is again determined by equation 4.

2. *Intermediate Stage.* The circuit of any intermediate stage is illustrated separately in Fig. 4(B). Notations used are for stage II. Inductor L_2 is not shunted by a resistor in this case, since a pure air-core inductance is assumed. Resistor R_2 represents winding resistance including skin and proximity effects as well as capacitor dissipation. The series equivalent of the magnetizing impedance of the saturable reactor SR_1 of the following stage III may be included in the value of R_2. This assumption can be made since this impedance is essentially of ohmic nature for square-loop reactors. Current and voltages of this circuit are considered for only one half-cycle of operation. Resistor R_p across C_1 can be neglected, since its influence on the transfer of charge is small.

The transient current I_2 of this discharge circuit is given in Laplace notation by

$$I_2(s)=\frac{V_{c1\,\max}}{s\left(L_2s+R_2+\dfrac{1}{C_0s}\right)} \qquad (8)$$

where

$$C_0=\frac{C_1C_2}{C_1+C_2}$$

and $V_{c_1\,\max}$ is equal to the voltage attained at capacitor C_1 at the instant when current I_1 in stage I ceases to flow. After rearranging terms

$$I_2(s)=\frac{V_{c1\,\max}}{L_2\left(s^2+\dfrac{R_2}{L_2}s+\dfrac{1}{C_0L_2}\right)} \qquad (9)$$

or

$$I_2(t)=\frac{V_{c1\,\max}}{L_2\sqrt{\dfrac{1}{C_0L_2}-\left(\dfrac{R_2}{2L_2}\right)^2}}\,e^{-(R_2/2L_2)t}\times \sin\sqrt{\frac{1}{C_0L_2}-\left(\frac{R_2}{2L_2}\right)^2}\,t \qquad (10)$$

Since for all practical purposes the term $(R_2/2L_2)^2$ can be neglected

$$I_2(t)\cong V_{c1\,\max}\sqrt{\frac{C_0}{L_2}}\,e^{-(R_2/2L_2)t}\times \sin\frac{1}{\sqrt{C_0L_2}}\,t \qquad (11)$$

The voltage across capacitor C_2 is defined by

$$V_{c2}(s)=\frac{V_{c1\,\max}}{C_2L_2}\frac{1}{s\left(s^2+\dfrac{R_2}{L_2}s+\dfrac{1}{C_0L_2}\right)}$$

$$V_{c2}(t)\cong\frac{V_{c1\,\max}}{C_2L_2}C_0L_2\left[1-e^{-(R_2/2L_2)t}\times \cos\frac{1}{\sqrt{C_0L_2}}\,t\right] \qquad (12)$$

$$V_{c2}(t)\cong V_{c1\,\max}\frac{C_1}{C_1+C_2}\times \left[1-e^{-(R_2/2L_2)t}\cos\frac{1}{\sqrt{C_0L_2}}\,t\right] \qquad (13)$$

The voltage at capacitor C_1 as a function of time is then determined by

$$V_{C_1}(t) \cong V_{C_1\,\max}\left[1-\frac{C_2}{C_1+C_2}\left(1-\epsilon^{-(R_2/2L_2)t}\times \cos\frac{1}{\sqrt{C_0L_2}}t\right)\right]$$

$$\cong V_{C_1\,\max}\frac{C_2}{C_1+C_2}\left[\frac{C_1}{C_2}+\epsilon^{-(R_2/2L_2)t}\times \cos\frac{1}{\sqrt{C_0L_2}}t\right] \quad (14)$$

The latter equation indicates whether or not complete transfer of charge from C_1 to C_2 during the time of one half-cycle $t_2=\pi\sqrt{C_0L_2}$ has been achieved. This means that the condition

$$C_2=C_1\epsilon^{\pi/2(R_2\sqrt{C_0/L_2})} \quad (15)$$

must be fulfilled for complete discharge of C_1.

3. *Output Stage.* Fig. 4(C) illustrates the circuit of the output stage in a simplified form. The load R_L is referred to the input terminals of the output pulse transformer *PT*; see also Fig. 1. Effects of eddy current losses within the windings of reactor SR_n, the pulse transformer, and dissipation in capacitor C_p are included in the value of resistor R_n. L_{sn} represents the saturated inductance of the final saturable reactor SR_n. Leakage inductance of the pulse transformer should be included in this value.

A pulse-forming network which can shape the output pulse into a fairly rectangular form will replace capacitor C_p and inductance L_{sn} where the latter will be a component of this network. The network will be charged from the preceding stage nearly like a pure capacitor since its distributed inductance is small when compared to the saturated inductance of the reactor located within this stage. Details on design of pulse forming networks are given in reference 3. The simple discharge of C_p through L_s into the load resistor R_L will be discussed here.

The final discharge current I_n is expressed in Laplace notation by

$$I_n(s)=\frac{V_{cp\,\max}/L_{sn}}{s^2+\dfrac{R_L+R_n}{L_{sn}}s+\dfrac{1}{C_pL_{sn}}} \quad (16)$$

$V_{cp/\max}$ is the voltage attained at capacitor C_p at the instant when flux reversal in the previous saturable reactor takes place and current essentially ceases to flow in the preceding stage.

If the discharge takes place in a single unidirectional pulse, the maximum peak power will be obtained for critical damping; that means if

$$R_L+R_n=2\sqrt{L_{sn}/C_p}$$

equation 16 is then reduced to

$$I_n(s)=\frac{V_{cp\,\max}}{L_{sn}}\frac{1}{\left(s+\dfrac{1}{\sqrt{L_{sn}C_p}}\right)^2} \quad (17)$$

or

$$I_n(t)=\frac{V_{cp\,\max}}{L_{sn}}\,t\,\epsilon^{-t/\sqrt{L_{sn}C_p}} \quad (18)$$

The peak current and power will occur at time $t_p=\sqrt{L_{sn}C_p}$ and will have the values

$$I_{n\,\max}=V_{cp\,\max}\sqrt{\frac{C_p}{L_{sn}}}\,\frac{1}{\epsilon} \quad (19)$$

$$P_{\max}=\left(\frac{V_{cp\,\max}}{\epsilon}\right)^2\frac{C_p}{L_{sn}}R_L \quad (20)$$

When underdamped discharge occurs, the maximum obtainable peak power will be furnished to the load during the first half-cycle of discharge if $R_L+R_n=\sqrt{L_{sn}/C_p}$. Under this condition

$$I_n(s)=\frac{V_{cp\,\max}}{L_{sn}}\frac{1}{s^2+\dfrac{1}{\sqrt{L_{sn}C_p}}s+\dfrac{1}{L_{sn}C_p}} \quad (21)$$

or

$$I_n(t)=V_{cp\,\max}\sqrt{\frac{4C_p}{3L_{sn}}}\,\epsilon^{-(1/\sqrt{4L_{sn}C_p})t}\times \sin\sqrt{3/4L_{sn}C_p}\,t \quad (22)$$

The peak current and power will then occur at the time

$$t=\frac{2\pi}{3\sqrt{3}}\sqrt{L_{sn}C_p}$$

and will have the values

$$I_{n\,\max}=V_{cp\,\max}\sqrt{\frac{C_p}{L_{sn}}}\,\epsilon^{-\pi/3\sqrt{3}} \quad (23)$$

$$P_{\max}=(V_{cp\,\max})^2\frac{C_p}{L_{sn}}\,\epsilon^{-2\pi/3\sqrt{3}}R_L \quad (24)$$

The peak power resulting from equation 24 is approximately 10% larger than the peak power for critical damping as given by equation 20. This holds true if R_n is negligibly small in comparison to R_L.

The latter case of discharge was discussed because it represents the condition of a single section pulse forming network. In practice, pulse forming networks of five L-C (inductance-capacitance) sections are used. In this case, the load resistance is also made equal to the network impedance.

Design Considerations

The following main data are, in general, available:

$P_{\max}$ = peak power of output pulse, watts
t_p = pulse width, μsec
f_r = maximum pulse repetition frequency, cps (cycles per second)
$V_{\max}$ = peak voltage of output pulse, volts

An over-all efficiency η_m of the modulator must be assumed and a suitable value of the supply voltage V_{DC} must be determined. The value of η_m is based on previous experience. The voltage V_{DC} must be chosen so that neither the forward breakover voltage nor the peak inverse voltage of the controlled rectifiers of the first and second stage are exceeded.

The value of capacitor C_1 of the charging stage is found with fair approximation to be

$$C_1=\frac{P_{\max}t_p}{2V_{DC}^2\eta_m}\ \text{(microfarads)} \quad (25)$$

Inductance L_1 of the first stage may be determined as follows: The maximum time allowed for charging of capacitor C_1 is determined by the required maximum pulse repetition frequency f_r. This time should be somewhat (10%) smaller than the time $t_r=1/f_r$ elapsing between pulses, allowing complete discharge of the succeeding stages before a new charging of the first is initiated. This yields

$$t_1=\pi\sqrt{L_1C_1}=0.9\frac{1}{f_r}$$

or

$$L_1\cong\frac{0.81(10^3)}{\pi^2 f_r^2 C_1}\cong\frac{82}{f_r^2C_1}\ \text{(millihenrys)} \quad (26)$$

where f_r is given in kilocycles/sec and C_1 in microfarads (μf). The relatively long charging time t_1 keeps the peak power drawn from the supplying d-c source small. The charging time t_2 of stage II can be chosen as short as the surge current rating of the controlled rectifier CSR_2 will permit. Neglecting losses occurring in stage II the peak current resulting from the equation 11 will amount to

$$I_{2\,\max}=V_{c1\,\max}\sqrt{C_0/L_2}$$

where

$$C_0=\frac{C_1C_2}{C_1+C_2}$$

L_2 can be found from this relationship, time t_2 is then $t_2=\pi\sqrt{C_0L_2}$. The value of C_2 should be chosen so that equation 15 will be satisfied. Time compression ratios t_1/t_2 from 50 to 100 will be achievable in practice. This will result in a reduced number of stages and better efficiency when compared with the Melville modulator.

occurring within the second stage it may be mentioned at this point that with different breadboard modulators peak charging currents of 80 amperes for a 15-μsec half-cycle and about 120 amperes for an 8-μsec half-cycle flowing through a single controlled rectifier, type *ZJ-39A* were measured. Because of limited facilities, repetition rates not higher than 500 cps were used during this investigation. No failures of controlled rectifiers because of these currents were experienced during breadboard evaluation.

Design principles for succeeding stages which employ saturable reactors as switching elements are given in sufficient detail in the existing literature. For a practical design it will be advisable to step up the voltage of the output capacitor C_2 of the second stage by means of an intermediate pulse transformer. The output transformer *PT* will then be designed further to step up the voltage to the values required for a magnetron or a traveling wave tube.

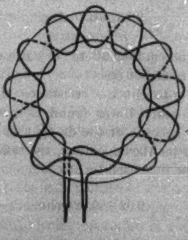

Fig. 6. Winding arrangement of saturable reactor

Further design considerations will be made in connection with the following discussion of an actual breadboard modulator, constructed and tested during the course of this work. The circuit of this modulator is pictured in Fig. 5. The modulator consists of three stages and employs two controlled rectifiers in parallel within stage II. Design values of components are given in Fig. 5. The R-C (resistance-capacitance) networks connected in parallel to the controlled rectifiers CSR_{2A} and CSR_{2B} were found necessary to suppress voltage spikes when these rectifiers interrupt flow of current. Since a finite time elapses until a controlled rectifier blocks flow of current, this current may overshoot zero to about 15% of its peak value and then be abruptly cut off. Thus, a large rate of change of current will exist and since this current flows through inductors L_{2A} and L_{2B} large reverse voltage spikes will appear across the controlled rectifiers. These spikes can be suppressed effectively by proper choice of the values of resistance and capacity. Best conditions are achieved if the shunting resistor is made about equal to the value of critical damping determined by either inductance and the shunting capacitor. Various R-C networks were tried for achieving an acceptable value of overshoot (approximately 10–15%) for the smallest capacitor required.

Special winding techniques were employed for the saturable reactor of the final stage. It is important that the ratio of unsaturated to saturated impedance be made as large as possible and that additional copper losses because of skin effect should be reduced to a minimum. To reduce the saturated inductance a winding arrangement as shown in Fig. 6 was used. With a conventional winding not only the number of turns wound around the core case contribute to the saturated inductance but there is "one turn" equal in diameter to the mean diameter of the core. Since the enclosed area of this turn is large and the path length for the flux relatively small, it could contribute considerably to the over-all saturated inductance of the reactor. This is especially true because the actual number of turns wound around the core must be kept small. With the winding arrangement of Fig. 6 the effective inductance of this one turn is cancelled. In the breadboard modulator only four turns wound on a Deltamax core no. *6100-D1* were necessary. To more evenly distribute the winding around the core and to reduce copper losses six windings in parallel were used.

Reduction of additional copper losses due to skin effect was achieved by using 7-strand no. 25 litz wires instead of solid wires. Total losses occurring in the final discharge stage were reduced by approximately 15%.

The type of capacitors must be care-

fully chosen to minimize losses within the modulator. Pyranol capacitors exhibit extremely high dissipation under the condition of pulse operation. It was found that standard 400-volt d-c paper capacitors operated much more satisfactorily.

The circuit of the breadboard modulator of Fig. 5 was later modified by replacing the output capacitor C_2 with a 5-section pulse forming network as illustrated in Fig. 7. Details for the design of such networks are given in reference 3. No particular effort for an ultimate design of this network was made since it was not the objective of this investigation and experiments were performed only on the basis of a simulated load. The saturated inductance of the saturable reactor within the final stage, which represents a portion of this network, should have been about 40% smaller than it actually happened to be. An output pulse transformer, to match the modulator to an available 51.5-ohm radio-frequency load, was also constructed and used during tests. A Deltamax core no. *4180-D1* was employed with a 4-turn primary and a 41-turn secondary winding. The primary winding was wound with four 7-strand no. 25 Litz wires in parallel. The transformer was furnished with a bias winding of 10 turns to reset its flux during interpulse periods.

Experimental Results

At the beginning of this investigation a few breadboard modulators using only one controlled silicon rectifier within the second stage were tested to study peak values of discharge currents that could be tolerated without causing damage to the controlled rectifiers. As mentioned earlier, suitable means were determined to suppress the voltage spikes at the controlled rectifiers. The breadboard modulator shown in Fig. 5 was then built. Results of experiments performed with this modulator will be reported here.

Since it had first been intended to operate the modulator up to pulse-repetition frequencies of 2,500 cps the first stage was designed for a relatively short charging time (about 0.33 millisecond). Based on preliminary experiments, it was estimated that an output pulse of approximately 0.15 watt-second energy could probably be achieved with a modulator using two controlled rectifiers within the second stage. If an over-all efficiency of $\eta=0.65$ and an input voltage $V_{DC}=165$ volts is assumed (with due regard to losses in the first stage), a voltage at capacitor C_1 not higher than 300 volts would result. Then the capacity C_1 resulting from equation 25 becomes

$$C_1=\frac{0.15(10^6)}{2(165^2)(0.65)}\cong 4.25\ \mu f$$

With a chosen $L_1=2.5$ millihenrys the charging time of stage I is

$$t_1=\pi\sqrt{2.5(4.25)(10^{-9})}=324\ \mu\text{sec}$$

A Silectron *C*-core no. *AJH114* was used for the inductor L_1 of the first stage, wound with 167 turns no. 20 wire. Unfortunately, only *C* cores of 4-mil lamination thickness were available. This resulted in relatively large core losses for this inductor at an apparent frequency of about 1,500 cps.

Resistor R_{fe}, see Fig. 4(A), representing these core losses was estimated from core loss characteristics to be approximately 500 ohms. The earlier mentioned shunting resistor R_p for the first capacitor C_1 had value of 1,000 ohms. Resistor $R1=0.84$ ohm was calculated to take into account eddy current losses within the winding and a capacitor dissipation factor $D=0.007$. Since the actually measured forward breakover voltage of both controlled rectifiers CSR_{2A} and CSR_{2B} will exceed 400 volts (although these rectifiers were of the type *ZJ39A-300*), it was considered safe to use an input voltage $V_{DC}=180$ volts instead of 165 volts during experimentation.

With these values, subtracting one voltage for rectifier drop from V_{DC} one obtains from equations 4, 3, and 7:

$$\alpha=\frac{1}{2}\left[\frac{840}{2.5}+\frac{1{,}500}{1{,}000(500)(4.25)(10^{-6})}\right]\cong 522\ \text{sec}^{-1}$$

$$I_{1\,\max}=179\left[\frac{1}{500}+\sqrt{\frac{4.25(10^{-3})}{2.5}}=\epsilon^{-522(162)(10^{-6})}\right]$$

$$=179[0.002+0.0412(0.919)]=7.15\ \text{amperes}$$

$$V_{C_1\,\max}=179(1+\epsilon^{-522(324)(10^{-6})})=330\ \text{volts}$$

Fig. 8 indicates the voltage at C_1 during the charging interval t_1, the voltage at C_2 during time t_2 is also shown as a narrow spike.

Inductors L_{2A} and L_{2B} of stage II were each designed for an inductance of 6.8 microhenrys. They were made of two layers of no. 12 stranded insulated wire with a total of 13 turns. The coils had a mean diameter of 4 cm (centimeters) and a length of about 2.3 cm. Capacitor C_2 had a value of 5 μf. The transmission time of stage II became

$$t_2=\pi\sqrt{\frac{4.25(5)}{9.25}(3.4)}=8.75\ \mu\text{sec}$$

which is equivalent to a natural frequency of 56,900 cps.

The apparent a-c resistance of both coils in parallel was found to be 0.056 ohm.[4] Because of the dissipation factor $D\cong 0.02$ for the capacitors, the resistance has to be increased by

$$\frac{10^6}{56{,}900(2\pi)2.3}(0.02)\cong 0.024\ \text{ohm}\ (C_0=2.3\mu f)$$

The series equivalent of the magnetizing impedance of the saturable reactor of

stage III has to be added to the sum of the foregoing values (about 0.013 ohm for an approximate magnetizing current of 6 amperes). Thus one obtains for R_2 [see Fig. 4(B)]:

$$R_2=0.056+0.024+0.013=0.093 \text{ ohm}$$

With the foregoing values the peak discharge current I_2 and the voltages V_{c_2} and V_{c_1} at the end of the transition interval t_2 can be found from equations 11, 13, and 14 as follows

$$\frac{R_2}{2L_2}=\alpha=\frac{0.093(10^6)}{2(3.4)}=13{,}650 \text{ sec}^{-1}$$

$$I_{2\,\max}\cong 329\sqrt{2.3/3.4}\,\epsilon^{-13650[8.75/2(10^{-6})]}$$

$$\cong 329(0.822)(0.942)\cong 255 \text{ amperes}$$

$$V_{c_2} \text{ (at time } t_2)\cong 329\left(\frac{4.25}{9.25}\right)\times$$

$$[1+\epsilon^{-13650(8.75)(10^{-6})}]$$

$$=151[1+0.888]\cong 285 \text{ volts}$$

$$V_{c_1} \text{ (at time } t_2)\cong 329\left(\frac{5}{9.25}\right)\times$$

$$\left[\frac{4.25}{5}-0.888\right]\cong -6.6 \text{ volts}$$

This minor value of voltage at C_1 at the end of time t_2 is of negligible importance, expecially if one considers uncertainties in determining the value of R_2.

The oscillogram of Fig. 9 shows the voltage at capacitor C_2 during the transition period. Peak value and time are in good agreement with the foregoing calculation. In its lower trace this oscillogram shows the voltage at the load of the modulator for nearly critical damping. The oscillogram of Fig. 10 exhibiting a double trace is a picture of the voltages occurring at controlled rectifiers CSR_{2A} and CSR_{2B} during operation of the modulator. Both voltages are nearly the same. The lower portion shows the voltage at the instant of firing while the upper portion indicates the reverse voltages. Winding and core data for the saturable reactor of the output stage have been given already in the section on "Experimental Results." With these data the calculated saturated inductance, assuming a relative permeability of $\mu_r=1$, becomes

$$L_s\cong 0.032 \ \mu\text{henry}$$

Actually it was found from measurements of time $t_p=\sqrt{L_sC_2}$ for the critically damped condition, that the actual saturated inductance amounted to

$$L_s\cong 0.13 \ \mu\text{henry}$$

The peak discharge current into the load was about 600 amperes. With four turns and a mean path length of 24 cm of core no. *6100-D1* the peak magnetizing force amounted to about 100 ampere-turns/cm. The measured value of L_s indicates that the average permeability was even with this relatively high magnetizing force still about $\mu_r\cong 4$. For the values of C_2 and L_s, the value of total resistance R_L+R_3 [see Fig. 4(C)] becomes for critical damping

$$R_L+R_3=2\sqrt{\frac{0.13}{5}}\cong 0.32 \text{ ohm}$$

For a rise time $t_p=\sqrt{0.13(5)}\cong 0.8$ μsec equivalent to a frequency $f\cong 313{,}000$ cps the a-c resistance of the saturable reactor winding was calculated as

$$R_{SR}\cong 0.003 \text{ ohm}$$

With an approximate dissipation factor $D=0.032$ for capacitor C_2, an equivalent series resistor R_d of

$$R_d=0.032\left[\frac{10^6}{313{,}000(2\pi)5}\right]=0.0032$$

has to be added to R_{SR} resulting in a total

$$R_3\cong 0.006 \text{ ohm}$$

A load resistor $r_L=0.315$ ohm was used. Using the foregoing values one obtains from equations 19 and 20

$$I_{3\,\max}=285\sqrt{5/0.13}(1/\epsilon)=650 \text{ amperes}$$

and

$$P_{\max}=650^2(0.315)=133 \text{ kw}$$

The peak value of the load voltage is therefore

$$V_{L_{\max}}=650(0.315)=205 \text{ volts}$$

The oscillogram of Fig. 11 shows, on an extended time scale of 1.0 μsec/division, the load voltage and the voltage at capacitor C_2 during the final discharge period. The load voltage can also be seen in the oscillogram of Fig. 9. From the maximum slope of the capacitor voltage, indicated by a straight line in Fig. 11, the peak discharge current can be determined as

$$I_{3\,\max}=\frac{\Delta v}{\Delta t}\,C_2=\frac{300}{2.5}(5)\cong 600 \text{ amperes}$$

resulting in a peak output power of

$$P_{\max}=600^2(0.315)\cong 113 \text{ kw}$$

Peak current and power determined from the voltage across the hairpin-shaped load resistor of 0.315 ohm are the same. Agreement with previously calculated values can be considered fair for this type of measurement if one also considers that the core losses of the saturable reactor during the interval of saturation had not been taken into account.

Fig. 12 shows an oscillogram of the load voltage, when capacitor C_2 had been replaced by the pulse forming network of Fig. 7. Averaging out the first small excursion at the start of the pulse, the peak power amounts to approximately

$130^2/0.315 \cong 53.5$ kw

The total pulse energy in watt-seconds transferred to the load is found to be about

$W_L = 0.17$ watt-second

From equation 25 the over-all efficiency of the modulator yields

$$\eta_m = \frac{W_L}{2(V_{DC})^2C_1} = \frac{0.17(10^6)}{2(180^2)(4.25)} \cong 62\%$$

Fig. 13 shows an oscillogram of the voltage across a standard radio-frequency load of 51.5 ohms, when this load was matched to the modulator by the output pulse transformer, described earlier, with a known ratio of 51/4. The peak power is approximately 50 kw. With a total energy of about 0.16 watt-second transferred to the load, the over-all efficiency of the modulator becomes

$\eta_m \cong 58\%$

If a more sophisticated design for a practical application of the modulator is used, even higher efficiencies can be achieved. Further reduction in output pulse duration will result in an increased output power. The total weight of components for the breadboard modulator including the output pulse transformer was 4 pounds.

During the course of experiments, one major modification of the basic circuit of Fig. 1 was investigated. The first controlled rectifier CSR_1 was replaced by an ordinary silicon rectifier and the parallel controlled rectifiers were fired directly from a trigger source. In general, the circuit performed as satisfactorily as expected. However, on several occasions this kind of circuit was not observed to be as fail-safe as the original circuit. Blowing of fuses, located in the incoming supply line, was experienced several times. This never occurred with the original circuit. The modulator operates most safely therefore if a controlled rectifier is used in the first stage since this arrangement effectively isolates the second stage from the line. Controlled rectifiers CSR_{2A} and CSR_{2B} cannot conduct unless controlled rectifier CSR_1 is turned off.

Conclusions

Experiments have demonstrated that it is possible to construct with presently available controlled silicon rectifiers small power radar modulators, capable of furnishing a pulse output power in the order of about 100 kw to the load. A pulse width of approximately 1.5 μsec is hereby assumed. Further development of controlled rectifiers to larger current ratings will probably result in peak output power ratings one order of magnitude larger than the foregoing value.

The reliability of such a modulator will be much improved in comparison to modulators employing thyratron tubes, eliminating the need for heating power.

A source of relatively low d-c voltage can be used to supply the modulator.

Analysis of Magnetic Amplifiers Using a Resistive Reactor Model

SHIMSHON FRANKENTHAL
NONMEMBER AIEE

THE LACK of a simple and reasonably accurate model for the behavior of magnetic materials has been the major source of difficulty in all the attempts to analyse and predict the behavior of magnetic amplifiers. In several cases, even a qualitative understanding of the operation of certain circuits was impossible to achieve because of the lack of such a model.

However, upon reviewing some of the past efforts in this area, one is struck by the fact that some of the neatest analyses of the performance of relatively simple amplifiers were made possible by the use of a resistive model to represent the behavior of the reactor.[1,2] One is, therefore, tempted to explore the following questions: First, can such a model lead to a quantitative understanding of the operation of relatively complicated magnetic amplifiers, such as the polyphase circuits? Second, can it be used to predict the performance characteristics of these amplifiers in terms of the properties of the reactor core material? The latter question cannot be answered intelligently unless one is familiar with the assumptions and approximations involved in the development of the resistive model from ferromagnetic theory, and this report will therefore open with an outline of one possible development of this sort.

Development of the Resistive Model

Woodson has described the development of a simplified mathematical model for toroidal thin-tape reactor cores.[3] One of the conclusions of that work is that the rate of change of flux in a reactor which is in the midst of a flux-reversal process may be expressed as

$$\frac{d\varphi}{dt} = 2B_s g(r) \frac{dr}{dt} \tag{1}$$

In this expression, B_s represents the saturation flux-density; whereas, r represents an averaged and normalized domain-wall dimension, which essentially measures the position of an "average" domain wall. The function $g(r)$ indicates the rate of growth of the reverse-saturated region with respect to the position of this average domain wall. Woodson finds that, in toroidal Orthonol cores with a high ID (inside diameter) to OD (outside diameter) ratio, the average domain-wall velocity dr/dt is approximately related to the intensity H of the

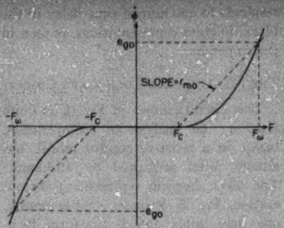

Fig. 1. Rate of change of flux versus applied mmf

applied magnetic field by the following expression

$$\frac{dr}{dt}=K(H-H_c)^2 \tag{2}$$

where K is a material constant and H_c the d-c coercive force. Knowing that such a reactor will maintain a constant field intensity H when normally excited by a sinusoidal voltage, one may deduce the form of the function $g(r)$ to be

$$g(r)=\frac{\pi}{2}A_c\sin\pi r \qquad 1>r>0 \tag{3}$$

where A_c is the effective cross-sectional area of the core. As a by-product of this development, the relation between the a-c loop width H_ω and the frequency of excitation ω is found to be

$$H_\omega-H_c=\sqrt{\frac{1}{K\pi}}\,\omega \tag{4}$$

A similar relation exists between the average width of the hysteresis loop along which the core operates when excited by a square-wave voltage.

Some simplification of these equations may be achieved if one approximates the sinusoidal function $g(r)$ by its average $g_a(r)$ over the range $0<r<1$. One thus obtains a rectangular pulse whose amplitude is

$$g_a(r)=A_c \qquad 1>r>0 \tag{5}$$

Equation 1 then simplifies to read

$$\frac{d\varphi}{dt}=2KB_sA_c(H-H_c)^2 \tag{6}$$

implying that the reactor will require a constant field intensity to maintain a *constant* rate of change of flux. This is equivalent to the statement that the rate of change of flux at any moment depends only on the value of H at that moment. In their "exact" form, equations 1 through 3 imply that there is also a dependence on the past history of H, which is embodied in $g(r)$.

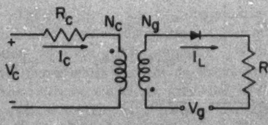

Fig. 2. Half-wave magnetic amplifier

Equation 6 is plotted in Fig. 1, with magnetomotive force (mmf) F replacing field intensity H. It is known that a reactor incorporated, say, in a full-wave self-saturating circuit may operate at different points on this curve during its reset period, even if the amplifier is controlled by a direct voltage and excited by a square-wave gate-supply voltage. In order to allow the calculations to be based on average control currents and rates of change of flux, one would prefer to approximate the parabolic relation of Fig. 1 by a straight line. One possible choice of such an approximation is indicated in dashed lines in Fig. 1. It is arrived at by recognizing that a reactor may be operated anywhere between the point of no reset ($\dot{\varphi}=0$, $f=\pm F_c$) and the point of full reset ($\dot{\varphi}=\pm\dot{\varphi}_{\max}$, $f=\pm F_\omega$). When operated at the latter point, the reactor is carried from positive to negative saturation during the reset interval, and the magnitude of its average rate of reset $\dot{\varphi}_{\max}$ is given by the number of volts-per-turn required for the so-called "normal" excitation. If the duration of the reset interval is one-half cycle of the gate-supply frequency ω, then

$$\dot{\varphi}_{\max}=e_{go} \tag{7}$$

where

$$e_{go}\triangleq\frac{2}{\pi}\omega B_sA_c \tag{8}$$

In this case, the slope of the linear approximation indicated in Fig. 1, which, dimensionally, is a resistance, is given by

$$r_{mo}=\frac{e_{go}}{F_\omega-F_c}=\frac{2}{\pi}-\frac{B_s}{H_\omega-H_c}\cdot\frac{A_c}{l_c}=2\sqrt{\frac{K}{\pi}}\,B_s\frac{A_c}{l_c}\sqrt{\omega} \tag{9}$$

where l_c is the mean length of the magnetic path. Thus, a piecewise linear approximation of the curve of Fig. 1 leads to a resistive model for the reactor, which consists of the magnetizing resistance shunted by a current source and several diodes to take care of the break-points.

Needless to say, other linear approximations are possible. It is, however, impossible to determine *a priori* which one, if any, is the best. One may therefore just as well accept the one presented here for the purpose of the analysis.

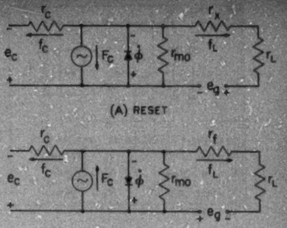

Fig. 3. Equivalent circuits for half-wave magnetic amplifier

Before proceeding to describe the results of the analyses which employ this model, it may be well to indicate briefly the way in which it enters the analysis and study some of its implications. Consider, then, the half-wave circuit, shown in Fig. 2, which is controlled by a direct voltage V_c and supplied with a square voltage of amplitude V_g. To simplify the construction of equivalent circuits for this amplifier, it is convenient to normalize the voltage, current, and resistance present in each winding with respect to the number of turns N in that winding, by letting

$$e=\frac{V}{N},\ f=NI,\ r=\frac{R}{N^2} \tag{10}$$

Remembering that, in practical cases, the control voltage is negative (it should tend to reset the reactor), one first constructs the model representing the left branch ($f<0$) of the flux-rate versus mmf curve and inserts it instead of the reactor. Theoretically, one should introduce an ideal 1:1 transformer to decouple the control and gate circuits; but the elimination of this transformer is permissible in most cases. One thus obtains an equivalent circuit for the reset interval. The equivalent circuit for the prefiring portion of the gating interval, during which the reactor is being set, may be obtained by inverting the direction of the current source and the diode incorporated in the model, in order to simulate the right-hand branch of Fig. 1. In this case, one lumps the series resistance of the gate winding and the resistance of the conducting gate rectifier in the symbol r_f; see Fig. 3.

During the reset interval, the reactor presents its magnetizing resistance to the control circuit, provided that the reverse resistance of the gate rectifier is infinite. The rate of change of flux is then deter-

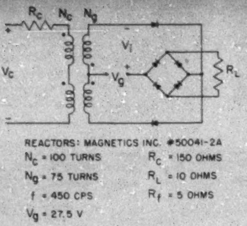

Fig. 4. Single-phase full-wave amplifier

mined solely by the voltages present in the control circuit, which are simply shared between r_c and r_m. Note that, after the diode incorporated in the model blocks, as it should if reset is to take place, the effective control voltage is

$$e_c' = e_c + r_c F_o \tag{11}$$

During the prefiring portion of the gating interval, the control voltage has little effect on the rate of change of flux, provided that the condition

$$r_f + r_g << \frac{r_m r_c}{r_m + r_c} \tag{12}$$

is satisfied. The rate of change of flux is then determined by the gate-supply voltage, which is almost totally impressed across the reactor. As far as the control circuit is concerned, the setting reactor reflects a voltage source having virtually no series resistance.

After saturation, the reactor is properly represented by a short circuit, which decouples the windings. The gate-supply voltage is then shared by the load resistance r_L and the total series resistance r_f. It is now convenient to define the internal voltage e_i, which is the amount by which the gate-supply voltage e_g exceeds the reactor voltage φ_{sat} during the gating interval. Averaging over the gating interval, one obtains the relation

$$\overline{e_i} = e_g - \overline{\varphi_{sat}} \tag{13}$$

in which the bar denotes the averaging operation.

This information is sufficient to allow the analysis of magnetic amplifiers with only rare need actually to draw an equivalent circuit. The actual procedure of the analysis is discussed in the Appendix, and its application to the amplifiers discussed in this work is relatively straightforward.[2,4] Suffice it to state, at this point, that the analysis leads to block-diagram representations which relate the average control voltage to the average internal and output voltage. The averaging is performed over suitably chosen intervals, the selection of which will be discussed later. In their exact form, these representations involve discrete time delays and require the use of difference equations, or Z transforms. The transition from this kind of representation to continuous-data "language" is simple when the signal frequencies are low compared to the gate-supply (carrier) frequency.[5]

Analysis and Experimental Observations

In this section, the results of a theoretical study of the operation of three self-saturating magnetic amplifiers are presented and compared with experimental evidence. The normalized variables defined in equation 10 are used throughout this discussion, being both illuminating and economical in space. The symbols r_m and F_o are adopted to designate the magnetizing resistance and the current source which constitute the reactor model. These will be related to r_{mo} and F_e as the need arises.

The assumptions and definitions involved in the analysis are the following:

1. The waveform of the gate-supply voltage is square, and its amplitude is the one required for normal excitation of the reactors.
2. The reverse resistance of the gate rectifiers is negligibly large compared to the magnetizing resistance. However, the total series resistance r_f of the gate circuit may be comparable with the load resistance r_L.
3. The control voltage remains constant throughout any representative interval. The duration of this interval is T/k for a circuit which incorporates k reactors and excited by a gate-supply voltage whose period is T. The same duration also corresponds to one unit of time delay in the block-diagram representations as seen in the Appendix.

THE SINGLE-PHASE FULL-WAVE CIRCUIT

This circuit, shown in Fig. 4, is quite familiar; an analysis of its operation, based on a resistive reactor model, has already been presented by Hubbard.[2] The block diagram representing its operation, Fig. 5, is linear; consequently, one may apply the Z-transform technique to obtain an exact transfer function

$$\frac{\Delta e_i(Z)}{\Delta e_c(Z)} = \frac{r_m}{r_c} \cdot \frac{Z}{1 + \frac{r_m}{r_c}(1 - Z)} \tag{14}$$

relating increments of the internal voltage and the control voltage within the range of control of the amplifier. At sufficiently low signal frequencies, one may approximate

$$Z = e^{-\frac{T}{2}s} \sim \frac{1}{1 + \frac{T}{2}s} \tag{15}$$

in which case the transfer function becomes

$$\frac{\Delta e_i(s)}{\Delta e_c(s)} = G_i \frac{1}{1 + \tau s} \tag{16}$$

where the internal voltage gain G_i is

$$G_i = \frac{r_m}{r_e} \tag{17}$$

and the time constant τ is

$$\tau = \left(1 + \frac{r_m}{r_c}\right)\frac{T}{2} \text{ sec} = \left(1 + \frac{r_m}{r_c}\right)\frac{1}{2} \text{ cycles} \tag{18}$$

It is interesting to note that an exact step response of this amplifier, which may be calculated from equation 14, will involve transients of the form

$$\left(\frac{r_m}{r_c + r_m}\right)^n$$

where n is the sequence number of the half cycle. If one allows $t = nT/2$, this form may be re-expressed as an exponential

$$\left(\frac{r_m}{r_c + r_m}\right)^n = e^{\frac{2}{T} \ln \frac{r_m}{r_c + r_m} t}$$

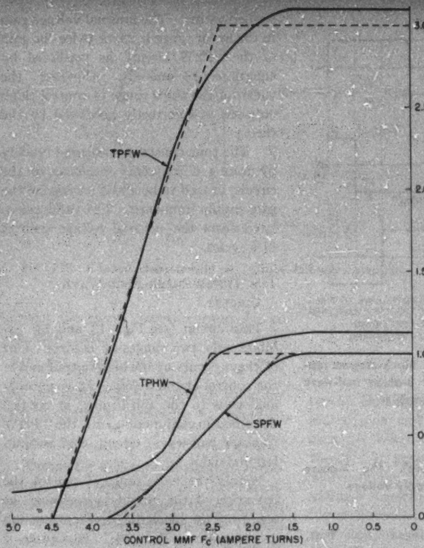

Fig. 6 (left). Experimental control characteristics of various amplifiers

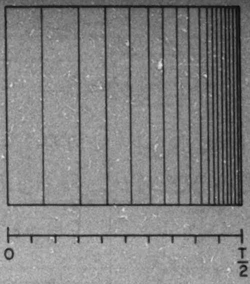

Fig. 7 (right). Step response of single-phase full-wave amplifier

THE VERTICAL LINES INDICATE THE SATURATION-TIME OF A REACTOR DURING SUCCESSIVE CYCLES OF THE TRANSIENT.

One may now identify a time constant τ' such as

$$\frac{1}{\tau'}=-\frac{2}{T}\ln\frac{r_m}{r_c+r_m}=\frac{2}{T}\ln\left(1+\frac{r_c}{r_m}\right)$$

and recognize that, when $r_m >> r_c$, both τ' and τ, as given by equation 18, approach the limit

$$\frac{r_m}{r_c}\frac{T}{2}$$

The reset period of this circuit is one-half cycle. Under minimum output conditions, the magnitude of the average rate of reset is equal to the magnitude of the gate-supply voltage. Thus, for normal excitation, this amplitude should be

$$e_{gn}=e_{go} \tag{19}$$

where e_{go} is given by equation 8. One may now identify the magnetizing resistance r_m with r_{mo} as given by equation 9, and recognize that linear control of the amplifier is possible for control voltages which lie within the range

$$-r_cF_\omega<e_c<-r_cF_c \tag{20}$$

The analysis is thus seen to provide a block diagram which relates the gain and time constant of the amplifier. If one further assumes that the development of the resistive model, as presented in the previous section, is legitimate, one may expect to be able to predict the value of the gain, as well as the shape of the control characteristic, from the available data about the reactor core material. The objective of the experimental work is to check both.

The parameters of the circuit used in the experimental work are given in Fig. 4. The experimental control characteristic, plotting the normalized internal voltage versus the control mmf, is shown in Fig. 6. The transient response to a step of control voltage, which drove the output from maximum to minimum, is shown in Fig. 7. The pertinent experimental observations may be summarized as follows:

1. The control characteristic is linear over most of the range of control. The internal voltage gain in the linear region is 11.5, and the magnetizing resistance calculated from it is 0.173 ohms per turn.[2]
2. The observed time-constant is 6 cycles; see Fig. 7. The time constant predicted by the analysis, $G_i/2$ cycles, is 5.75 cycles.
3. The limits on the range of control, in terms of the control mmf, are 1.35 and 3.8 ampere-turns. The limits on the extrapolated linear portion of the control characteristic, the dashed lines in Fig. 6, are 1.6 and 3.6 ampere-turns. The lower limit of either set agrees reasonably well with the d-c coercive mmf of 1.44 ampere-turns, calculated from manufacturer's data. Manufacturer's data about the a-c loop width at 60 cps (cycles per second) and 400 cps were used, in conjunction with equation 4, to calculate a value of 3.8 ampere-turns for the a-c loop width at the operating frequency (450 cps).

THE THREE-PHASE HALF-WAVE CIRCUIT

The analysis of this circuit (see Fig. 8) is complicated by the fact that it exhibits three ranges of control (see Figs. 6 and 11). Within the first range, corresponding to internal voltages

$$0<e_i<\frac{e_g}{2}$$

the operation of the amplifier is nonlinear; and its gain is rather low. The block diagram pertaining to this range is indicated in Fig. 9(A). This is a time-domain representation, and the symbol Z appearing in it should not be interpreted as a transform variable. It merely denotes a time-delay of one third of a cycle.

Within the second range of control, corresponding to internal voltages

$$\frac{e_g}{2}<e_i<e_g$$

the circuit operates in a linear fashion.

Fig. 9 (left). Block-diagram representation of 3-phase half-wave amplifier

Fig. 10 (above). The 3-phase gate-supply voltage

An exact transfer function may be obtained from the block diagram of Fig. 9(B). However, if one assumes $r_m>>r_c$ and considers sufficiently low signal frequencies, the following simplified transfer function may be derived:

$$\frac{\Delta e_i(s)}{\Delta e_c(s)} \sim 2\frac{r_m}{r_c}\cdot\frac{1}{1+\frac{r_m}{r_c}\cdot Ts}\cdot r_c \tag{21}$$

The internal voltage will equal the gate-supply voltage when each reactor is saturated for one third of a cycle; see the waveforms of Fig. 10. Under this condition, a continuous current

$$\frac{e_I}{r_f+r_L}$$

is delivered to the load. If the resistance r_f is not zero, the magnitude of the control voltage e_{c3} required to produce this condition is somewhat higher than r_cF_o; see Fig. 11. As the magnitude of the control voltage decreases below e_{c3}, the firing angle of each reactor progresses. During part of the time, the load current is delivered through one saturated reactor having a series resistance r_f; and during the other part, it is delivered through two simultaneously saturated reactors in parallel. As a result, the average output current varies somewhat with the control voltage, until the latter reaches the value of $-r_cF_o$, at which time each reactor is saturated half the time. The gain in this range is sufficiently low, and the variation of output current sufficiently small, that it may be ignored completely. It is, however, gratifying to note that, as r_f approaches zero, the value of e_{c3} approaches $-r_cF_o$, so that this range of control disappears completely, as it should. Note also that r_f has no effect on the internal voltage gain in the linear range of control; it just shifts it bodily to the left as shown in Figs. 11 and 6.

Under minimum output conditions, reset is achieved at a uniform rate e_g during one half cycle. The normal excitation voltage of this circuit is again e_{go}, as given by equation 8.

The circuit used in checking these results incorporated the same components used in the experimental SPFW (single-phase full-wave) circuit (shown in Fig. 4). The experimental observations may be summarized as follows:

1. The control characteristic in Fig. 6 exhibits the three ranges of control described earlier. The internal voltage gain in the linear range is 23, or twice the gain of the SPFW circuit, as predicted by equations 17 and 21. However, the width of the third range of control (high outputs) is incorrectly predicted by the theory.
2. The time constant, measured crudely by taking a frequency response of the circuit, proved to be about 9 cycles of the gate-supply frequency. The value calculated from the internal-voltage gain is 11.5 cycles.

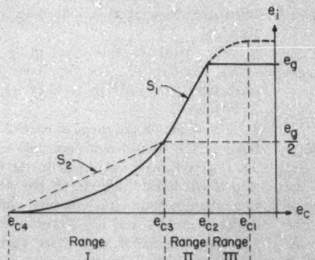
The Three-Phase Full-Wave Circuit

This circuit (see Figs. 12 and 13) exhibits only two ranges of control. One of them occurs at the high-output end of the control characteristic. It is entirely analogous to the third range of control described in conjunction with the TPHW (3-phase half-wave) circuit, and is similarly trivial.

Within the main range of control, the operation of the circuit is nonlinear, as seen from the block diagram representing its operation, Fig. 14. However, if $r_m>>r_c$, the deviation from linearity is very small; and one may readily derive the following approximate transfer function; see the Appendix

$$\frac{\Delta e_I(s)}{\Delta e_c(s)} \sim \frac{r_m}{r_c}\cdot\frac{1}{1+\frac{r_m}{r_c}\frac{T}{2}s} \tag{22}$$

This expression is identical in form with the transfer function of the SPFW circuit. However, the mode of operation of the circuit is such that, under minimum output conditions, each reactor is reset at a rate $2e_g$ during one sixth of a cycle as seen in Fig. 15. Thus, the normal excitation voltage for the circuit is 1.5 e_{go}; and the maximal rate of reset has a magnitude 3 e_{go}. If the parabolic relation between the flux rate and the mmf, as plotted in Fig. 1, is correct, one may



$$S_1 = \frac{r_m(3r_c+4r_m)}{2r_c(r_c+r_m)} \xrightarrow[r_m>>r_c]{} 2\frac{r_m}{r_c}$$

$$S_2 = \frac{1}{2}\frac{r_m(3r_c+4r_m)}{2(r_c+r_m)(r_c+2r_m)} \xrightarrow[r_m>>r_c]{} \frac{1}{2}$$

$$e_{c1} = -r_cF_o$$

$$e_{c2} = -r_cF_o - \frac{r_c(r_c+2r_m)}{r_m(3r_c+4r_m)}K_f e_g$$

$$e_{c3} = e_{c2} - \frac{e_g}{2S_1}$$

$$e_{c4} = -\left(1+\frac{r_c}{r_m}\right)e_g$$

Fig. 11. Control characteristic of 3-phase half-wave amplifier

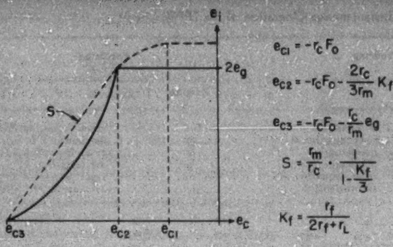


Fig. 12. Control characteristic of 3-phase full-wave amplifier

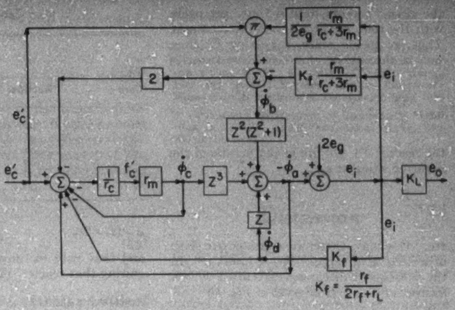

Fig. 14. Block-diagram representation of the 3-phase full-wave amplifier

expect the cutoff control current F_ω' to be such that

$$F_\omega' - F_c = \sqrt{3}(F_\omega - F_c) \qquad (23)$$

At the same time, the proper value for the magnetizing resistance r_m should be $\sqrt{3}r_{mo}$

Except for a change in the load resistance, the components of the experimental circuits were again the ones given in Fig. 4. The experimental control characteristic shown in Fig. 6 is the result of normalizing the internal voltage and taking account of the fact that its nominal maximum value is 3 e_{go}. The experimental observations may be summarized as follows:

1. The internal voltage gain over the linear portion of the range of control is 34. The value predicted on the basis of the gain of the SPFW circuit is 20. Correspondingly, the observed value of the cutoff control mmf, 4.5 ampere-turns, is remote from the value, 5.5 ampere-turns, predicted by equation 23.
2. The observed time constant is 15 cycles of the gate-supply frequency. Using the observed value of the internal voltage gain, equation 22 yields a "theoretical" value of 17 cycles.

Conclusions

A review of the experimental observations reported in the previous section reveals that the relation between the observed gain and time constant of each circuit is indeed the one predicted by the theory. It appears, then, that the resistive model is indeed capable of providing a correct quantitative understanding of the mechanism of operation of magnetic amplifiers, embodied here in the block-diagram representations for these amplifiers. Unfortunately, no such statement can yet be made regarding the prediction of the gain and time constant in terms of the core-material properties.

With regard to this question, it will be noted that the theoretically derived model does indeed predict the shape of the control characteristic, hence, the gain, of the SPFW circuit, as well as the gain of the TPHW circuit. This is, perhaps, not surprising. The reactors in both amplifiers operate over the same range of flux-reset rates, so that any linear approximation should hold equally well in both cases. The exact nature of the relation between the reset-rate and the mmf, which is basically dependent only on equation 2, is immaterial in this case, provided that it is amendable to a linear approximation, which apparently it is.

However, in expecting a similar prediction of the gain of the TPFW (3-phase full-wave) amplifier, whose reactors operate over a wider range of reset rates, one is actually testing the validity of the relation between the reset rate and the mmf or, specifically, of equation 2. The discrepancy between the predicted and the observed gains casts some suspicion on this relation. There already exists a certain amount of conflicting experimental evidence pertaining to it, and it therefore appears that any attempt to settle the discrepency at this time may be premature.[6,7] Nevertheless, one may expect that, once a more refined understanding of the relation between the reset rate and the mmf is achieved, a fully reliable utilization of the resistive reactor model, along the lines described here, will be possible.

Appendix

Analysis of the Three-Phase Full-Wave Amplifier

In studying the operation of this circuit in Fig. 13, it is advantageous to associate each reactor with its gate-supply waveform. The reactors $X1$, $X2$, and $X3$ are associated with the waveforms e_{g1}, e_{g2}, and e_{g3}, respectively (see Fig. 10). The $Y1$ reactors are associated with the negatives of these waveforms. Symmetry considerations then lead to the conclusion that the pattern of operation of

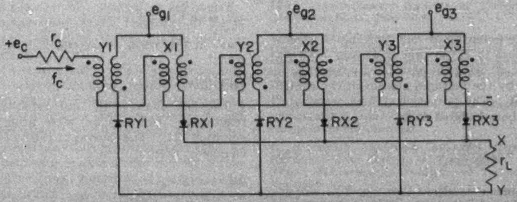

Fig. 13. The 3-phase full-wave amplifier

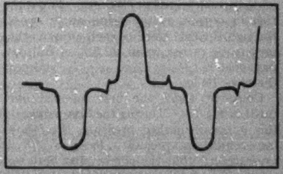

Fig. 15. Voltage across a reactor in 3-phase full-wave amplifier at minimum output

the circuit repeats itself 6 times per cycle, with the roles of the reactors interchanged. Thus, at steady state, if reactor $X1$ fires, say, in the middle of the positive swing of e_{g1}

$$t_{fX1}=\frac{3T}{4}$$

the reactor $Y1$ will fire in the middle of the negative swing of e_{g1}

$$t_{fY1}=\frac{T}{4}$$

etc. One may, therefore, consider one sixth of a cycle as a representative interval. In the subsequent discussion, attention will be focused on the first interval of Fig. 10

$$\frac{T}{6}>t>0$$

One may further state that, in order that an output current pulse may flow, at least one X reactor and one Y reactor must be saturated simultaneously. If only one reactor, say $Y3$, were saturated, any appreciable current through the load would be prevented by reactors in which the flux is changing.

Thus, if firing takes place at the beginning of the last third of each gate-voltage swing

$$t_{fX1}=\frac{5T}{6}\ t_{fY1}=\frac{T}{3},\ \text{etc.}$$

no output current can flow. As the firing angle sweeps through the middle third of each swing, the output increases. If the resistance r_f of the windings and rectifiers were zero, maximum output would be attained when the firing angle reached the beginning of the middle third of each swing

$$t_{fX1}=\frac{2T}{3},t_{fY1}=\frac{T}{6},\ \text{etc.}$$

since a voltage $2e_g$ would then be continuously switched on to the load. Since r_f is not zero, the actual output voltage at this point is

$$\frac{2r_L}{2r_f+r_L}e_g$$

and the maximum voltage

$$\frac{2r_L}{\frac{3}{2}r_f+r_L}$$

will be reached when the firing angle reaches the beginning of each swing, at which point two X reactors and one Y reactor (or vice versa) are saturated at all times. The variation in output as the firing angle sweeps through the first third of each swing is thus seen to be rather small, 12.5% of full output, even if r_f is as large as $r_L/2$, and may therefore be ignored.

Consider, then, the first interval indicated in Fig. 10. During the first portion of this interval, marked prefiring, the following conditions prevail: Reactor $Y3$ is saturated, so that the potential at both terminals X and Y is only slightly higher than $-e_g$. It is, therefore, clear that the gate rectifier $RX2$ will unblock, allowing the reactor to be set at a rate

$$\dot{\phi}_{X2}{}^1(t)=2e_g \tag{24}$$

and that gate rectifier $RY2$ will block requiring that reactor $Y2$ be reset at a rate

$$\dot{\phi}_{Y2}(t)=-r_m f_c'^1(t) \tag{25}$$

where

$$f_c'=f_c+F_o \tag{26}$$

The status of the gate rectifiers $RX1$, $RX3$, and $RY1$ is yet undetermined, since e_{g1}, e_{g3}, e_x, and e_y are almost identical. One may settle this question by the following reasoning: Suppose that rectifier $RX1$, for example, is blocked. The reactor $X1$ should then be reset by the current present in the control circuit. However, any substantial rate of reset in the reactor will establish a voltage across it which would tend to unblock the gate rectifier, thus violating the initial assumption. One is therefore forced to conclude that the rectifier actually conducts. A negligible resetting voltage e_x-e_{g1} is established across its gate winding, and insofar as the control circuit is concerned, it serves as a pure voltage source (short circuit). The same reasoning applies to all other rectifiers in question.

A bird's-eye view of the behavior of the various components is provided by Table I, in which information about the state of the gate rectifiers and the rate of flux change in the associated reactors is presented in a concise fashion.

Table I. Instantaneous Operation of the TPFW Circuit

	Prefiring (q)		Postfiring ($1-q$)	
Core	**Rectifier**	$\dot{\phi}$	**Rectifier**	$\dot{\phi}$
$X1$	on	no change	off	reset (equation 33)
$X2$	on	set (equation 24)	on	saturation
$X3$	on	no change	off	reset (equation 33)
$Y1$	on	no change	on	set (equation 31)
$Y2$	off	reset (equation 25)	off	reset (equation 33)
$Y3$	on	saturation	on	saturation

At some time t_f reactor $X2$ saturates, allowing a pulse of voltage whose magnitude $2e_g$ is now available to produce a load current. This available voltage is defined as the internal voltage e_i of the circuit. If the prefiring portion occupies a fraction q of the interval, then the average internal voltage during the interval is

$$\bar{e}=(1-q)2e_g \tag{27}$$

The actual load voltage is then

$$\bar{e}_o=K_L\bar{e}_i \tag{28}$$

where

$$K_L=\frac{r_L}{2r_f+r_L} \tag{29}$$

The potential at load terminal X is now up close to e_g, so that $RX1$ and $RX3$ unblock, allowing the associated reactors to be reset by the voltages present in the control circuit. The potential at load terminal Y may be calculated to be

$$e_y{}^2(t)=e_g\frac{r_L}{2r_f+r_L} \tag{30}$$

and since it is higher than e_{g1}, $RY1$ will unblock and the associated reactor will be set at a rate

$$\dot{\phi}_{Y1}{}^2(t)=e_y-e_{g1}=2K_fe_g \tag{31}$$

where

$$K_f=\frac{r_f}{2r_f+r_L} \tag{32}$$

The voltage reflected across this reactor into the control circuit will aid the control voltage in resetting reactors $X1$, $Y2$, $X3$. Since each of these reactors now presents its magnetizing resistance r_m to the control circuit, the total resistance in that circuit is r_c+3r_m. The rate of reset in each reactor is, then,

$$\dot{\phi}_{X1}{}^2(t)=\dot{\phi}_{X3}{}^2(t)=\dot{\phi}_{Y2}{}^2(t)=\frac{r_m}{r_c+3r_m}\times[e_c'(t)-2K_fe_g] \tag{33}$$

This completes the detailed description of the behavior of the circuit. Inspection of Table I now reveals that there are four significant modes of flux change. The first is associated with the gating reactor ($X2$ in the particular interval under consideration). The average rate of change of flux $\dot{\phi}_a(n)$ associated with this mode is such that

$$e_i(n)=2e_g-\dot{\phi}_a(n) \tag{34}$$

The second mode of flux change is the one exhibited by reactors $X1$ and $X3$, which are subjected to postfiring reset, at a rate given by equation 33. The average rate of reset in this mode is

$$\overline{\dot{\phi}_b}=\frac{r_m}{r_c+3r_m}[e_c'(t)-2K_fe_g](1-q) \tag{35}$$

and using equation 27 for q, one gets

$$\dot{\phi}_b(n)=\frac{r_m}{r_c+3r_m}\frac{e_i(n)}{2e_g}e_c'(n)-\frac{r_m}{r_c+3r_m}K_fe_i(n) \tag{36}$$

The third mode is the one assumed by reactor $Y2$, which is reset throughout the interval with its gate rectifier blocked. The instantaneous rate of reset given by the resistive model

$$\dot{\phi}(t)=r_m(f_c(t)-F_o)=r_mf_c' \tag{37}$$

may, in this case, be averaged directly to read

$$\dot{\phi}_c(n)=r_mf_c'(n) \tag{38}$$

The last mode is the one exhibited by reactor $Y1$, which is set after firing; see equation 31. The average rate of flux change is, then,

$$\dot{\phi}_d(n)=2K_fe_g[1-q(n)]=K_fe_i(n) \tag{39}$$

In addition to these relations, the control circuit imposes the requirement that

$$e_c'(n)=r_cf_c'(n)+\phi_a(n)+2\phi_b(n)+\phi_c(n)+\phi_d(n) \qquad (40)$$

One now observes that the pattern of operation is repeated in the following interval $T/6<t<T/3$. Reactor *Y*1 now operates in mode *a* (gating); reactor *X*1, in mode *c* (reset throughout interval); reactors *Y*2 and *Y*3, in mode *b* (postfiring reset); and reactor *X*3 in mode *d* (postfiring 'set'). Reactor *X*2 is saturated throughout the interval.

One further observes that, following the interval in which it gates, each reactor remains saturated for one interval; and that, in the succeeding five intervals, its flux varies according to modes *b*, *c*, *b*, *d*, and *a* in that order. During this period, the reactor undergoes a full cycle of operation; and the net change in its flux is zero. Consequently, the sum of the average rates of flux change is zero; or,

$$0=\phi_a(n)+\phi_d(n-1)+\phi_b(n-2)+\phi_c(n-3)+\phi_d(n-4) \qquad (41)$$

This equation brings out the memory, or time delay, associated with the circuit. Together with equations 34 through 40, it forms a complete set of describing equations, which account for both the steady state and the dynamic operation of the circuit. A block diagram representation may readily be obtained from these equations, as demonstrated in Fig. 14.

To obtain the steady-state control characteristic, one simply solves the describing equations ignoring the cycle sequence number. The result is best presented in normalized form, as follows:

$$\frac{e_t}{2e_g}=\frac{1+\dfrac{r_m}{r_c}\dfrac{e_c'}{2e_g}}{1-\dfrac{r_c+r_m}{r_c+3r_m}K_f-\dfrac{2r_m}{r_c+3r_m}\dfrac{e_c'}{2e_g}} \qquad (42)$$

At minimum output, $e_t=0$, which requires immediately that the control voltage satisfy the relation

$$e_{c3}'=(e_{c3}+r_cF_o)=-\frac{r_c}{r_m}.2e_g \qquad (43)$$

On the other edge of the control characteristic, firing at the beginning of the middle third of each gate voltage swing, $e_t=2e_g$; and hence, the control voltage is given by

$$e_{c2}'=e_{c2}+r_cF_o=-\frac{r_c}{3r_m}K_f.2e_g \qquad (44)$$

Note that, if K_f is zero ($r_f=0$), maximum output is indeed reached here, since equation 44 then expresses the condition under which the control voltage does not contribute to the reset of the reactors. If K_f is not zero, actual maximum output will be reached with $e_c'=0$.

The circuit is said to be normally excited when, under minimum output conditions, the gate-supply voltage is just sufficient to carry each reactor between negative and positive saturation. One notes that under these conditions only modes *a* and *c* exist, so that both the reset and the setting action take place during one sixth of a cycle. The voltage which produces these changes in flux is then $2e_g$. Since, by definition, e_{go} is the voltage to set fully, or reset, the reactors during one-half cycle, as seen in equation 8, it follows that

$$e_{gn}=\frac{3}{2}e_{go} \qquad (45)$$

Some simplification of the transfer function is possible if one ignores K_f and assumes voltage control of the amplifier ($r_c \ll r_m$). Under these conditions, one may first obtain the incremental gain by differentiating equation 42

$$G_{inc}=\frac{\dfrac{r_m}{r_c}+\dfrac{2r_m}{r_c+3r_m}}{\left[1-\dfrac{2r_m}{r_c+3r_m}\dfrac{e_c'}{2e_g}\right]^2} \qquad (46)$$

The values of $e_c'/2e_g$ are next substituted from equations 43 and 44 to obtain the values of the incremental gain at the maximum and minimum output points. These are

$$\frac{r_m}{r_c}\left(1+\frac{2r_c}{r_c+3r_m}\right) \text{ and } \frac{r_m}{r_c}\Big/\left(1+\frac{2r_c}{r_c+3r_m}\right)$$

respectively. If r_m is reasonably large compared to r_c, both values reduce to r_m/r_c, which is also the average gain. In other words, it appears that under these conditions the deviations from linearity are negligible, which implies that the reset achieved in the nonlinear mode *b* is negligible compared to the reset achieved in mode *c*. One, therefore, ignores the nonlinear portion of the block diagram and arrives at a simple transfer function

$$\frac{\Delta e_t(Z)}{\Delta e_c(Z)}=\frac{\dfrac{r_m}{r_c}Z^3}{1+\left(1-\dfrac{r_m}{r_c}\right)Z^3} \qquad (47)$$

One now recognizes that

$$Z^3=e^{-\frac{T}{2}s}\sim\frac{1}{1+\dfrac{T}{2}s} \qquad (48)$$

where the approximation holds for slowly varying signal frequencies. Equation 47 then simplifies to read

$$\frac{\Delta e_t(s)}{\Delta e_c(s)}=\frac{r_m}{r_c}\cdot\frac{1}{1+\dfrac{r_m}{r_c}\dfrac{T}{2}s} \qquad (49)$$

Discussion

G. C. Feth (General Electric Company, Schenectady, N.Y.): In this paper the question is raised whether the resistive model can be used to predict performance characteristics of relatively complicated magnetic amplifiers *in terms of the reactor core materials*. However, the ensuing treatment of the magnetic behavior of the core material appears to be considerably oversimplified; some of the objections are outlined below:

1. The relation of rate of change of core flux $d\phi/dt$ to the magnetic intensity is approximated as $d\phi/dt$ proportional to $(H-H_c)^a$, in which a is fixed as 2. In similar work reported in reference 1 the corresponding value of the exponent was found to vary between approximately 3 and 5 for four sets of cores of this same alloy. Thus, one would question whether the exponent 2 really has any generality.

2. The form function $g(r)$ used with the assumption of constant dr/dt at constant applied field is assumed sinusoidal. Used in this way $g(r)$ is essentially the form of the functional relationship between $d\phi/dt$ and ϕ. However, a sinusoidal relationship does not appear to fit well the observed relationship between $d\phi/dt$ and ϕ as reported in Fig. 6 of reference 2; the observed peak ϕ' occurs more nearly at $\phi=\phi_s/2$ rather than at $\phi=0$ as in the sine approximation, and the form is really not much like a sinusoid, its observed inflection point occurring at $\phi\cong0$, $d\phi/dt\cong(1/3)[d\phi/dt]_{\text{peak}}$ rather than at $\phi=-\phi s$, $d\phi/dt=0$ as in the approximation.

3. This whole development, which appears intended to relate core behavior to ferromagnetic theory, is then discarded in favor of the simplification that $g(r)$ is constant and therefore $d\phi/dt$ is independent of ϕ when the core is unsaturated.

In view of these simplifications it is not surprising that, as concluded in the paper, when there is much latitude in the variation of reset rates, $d\phi/dt$ is encountered in a given circuit the accuracy of predictions based on this treatment of core behavior is affected noticeably. In fact, when considering circuits with sinusoidal excitation voltage or with time-varying control voltage one would expect the wide variation of reset rates to be a major deterrent to obtaining accurate quantitative information with this method.

Elimination of Coupling Problems in Multistage Magnetic Amplifiers

WILLIAM MCMURRAY
ASSOCIATE MEMBER AIEE

WHEN TWO or more magnetic amplifiers are cascaded, it is generally found that the over-all characteristic cannot be accurately predicted from the individual stages. The cascaded gain is less than the product of the separate gains. There may be abrupt changes in the slope of the cascaded control characteristic, and sometimes "snap-action" occurs. The over-all transfer function has a time constant lag term for each stage and perhaps additional time constants introduced by the interstage coupling network, for example, where filtering is employed.

While satisfactory performance can, in most cases, be achieved with conventional coupling methods by judicious design, the choice of the coupling circuit and its parameters often requires considerable experimentation. This increases the time required to develop a new multistage magnetic amplifier. Moreover, the performance will be less than the optimum, attained by employing a coupling method which eliminates the basic problems.

The source of the trouble is the prefiring voltage induced in the control windings of the second stage, which disturbs the resetting of the first stage. Also, the output voltage waveform of the first stage may not be ideal for efficient control of the second stage, particularly when the amplifier is push-pull.

The Synchronous Switch Coupling Method

The coupling problem can be solved by the circuit arrangements shown in Figs. 1, 3, and 9. Each gate winding of the first stage is connected in series with the control winding of the oppositely-phased reactor of the second stage. A rectifier-type synchronous switch effectively couples the stages during the gating half cycle of stage 1 (the resetting half cycle of stage 2) and decouples the stages during the resetting half cycle of stage 1 (the gating half cycle of stage 2). The decoupling action is effected by increasing the gate-limiter voltage of stage 1, thus preventing the pefiring voltage induced in the control winding of stage 2 from disturbing the resetting of stage 1.

The use of synchronous switches to improve the performance of magnetic amplifiers has been reported by a number of authors.[1-7] In particular, Voice[1] describes the application of switched diodes to coupling half-wave half-cycle response magnetic amplifiers. The basic building-block of these circuits, and of the full-wave circuits analyzed in the present paper, is the 2-stage half-wave amplifier shown in Fig. 1.

Operation of the arrangement is easily explained, with reference to Fig. 2. During the gating half-cycle of stage 1 (voltage polarities as indicated in Fig. 1) the switch diode conducts and the switch voltage e_{S1} appears across the current-limiting resistance R_{S1}. Thus, point B is effectively connected to point A (Fig. 1) and stage 1 is set by the voltage e_1 applied to its gate winding. It is assumed that the prefiring gate current required by stage 1 is much less than the control current required to reset stage 2:

$$\frac{H_{C1}l_{Fe1}}{N_{G1}} \ll \frac{H_{C2}l_{Fe2}}{N_{C2}} \tag{1}$$

When stage 1 saturates or "fires" at some angle α_1, the voltage e_1 is applied to reset stage 2 at its gate-limited rate. The necessary conditions for gate-limited reset of stage 2 are:

$$e_1 - \frac{H_{C2}l_{Fe2}}{N_{C2}}(R_{G1}+R_{C2}) > e_2\frac{N_{C2}}{N_{G2}} \tag{2}$$

$$\frac{e_{S1}}{R_{S1}} > \frac{H_{C2}l_{Fe2}}{N_{C2}} \tag{3}$$

Then in the next half cycle, stage 2 will fire at an angle α_2, where

$$\alpha_2 = \pi - \alpha_1 \tag{4}$$

The voltage polarities now being reversed, the switch diode will block, effectively connecting point B to point C (Fig. 1). The prefiring voltage e_2N_{C2}/N_{G2} induced in the control winding of stage 2 will not limit the resetting of stage 1, provided that

$$e_{S1} > e_2\frac{N_{C2}}{N_{G2}} \tag{5}$$

The winding voltage of stage 1 during reset is determined by the applied control voltage, the control circuit resistance R_{C1}, the dynamic core properties and the gate-limiter voltage. The conditions differ from the single-stage case only in the extension of the gate-limiter voltage, particularly after stage 2 fires at the angle α_2. This will have very small effect if half-sine wave voltage control is used, but may have appreciable effect when current-source control is employed. In any case, the effect will not be detrimental to gain or response.

Under steady-state conditions, the gate volt-second area induced during reset of stage 1 will equal the integral of the voltage e_1 up to the previously assumed firing angle α_1. In Fig. 2, an arbitrary but typical shape of the resetting voltage is sketched.

It is seen from equation 4 that the output of stage 2 decreases as the output of stage 1 increases. The over-all control characteristic is similar in shape to the inverted characteristic of stage 1 alone. A change in the output of stage 1 results in a corresponding change in the output of stage 2 during the next half-cycle. Thus stage 2, and any subsequent stages, has half-cycle response. A multistage amplifier exhibits the control circuit time constant of the first stage, plus a delay time of one half-cycle times the number of stages.

Synchronous Switch Coupling of Full-Wave Amplifiers

The operation of the coupling method with full-wave circuits is generally similar to the half-wave case, since the interstage connections are essentially half-wave. However, when the final stage is a center-tap circuit, a complication in the mode of operation can occur as a result of the increase in the gate-limiter voltage of the resetting reactor after the gating reactor saturates. A 2-stage full-wave d-c single-ended amplifier is shown in Fig. 3 and is analyzed in the Appendix. Both stages employ the center-tap circuit with the addition of a synchronous switch.

The switch in stage 2 is not necessary for coupling the stages but affords some improvement in performance by increasing the gate-limiter voltage of stage 2. This effect has been termed "firing angle amplification"[1] or "pulse stretching"[3] and

WILLIAM MCMURRAY is with General Electric Company, Schenectady, N. Y.

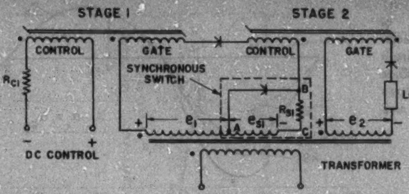

Fig. 1 (above). Two-stage half-wave magnetic amplifier with synchronous switch coupling

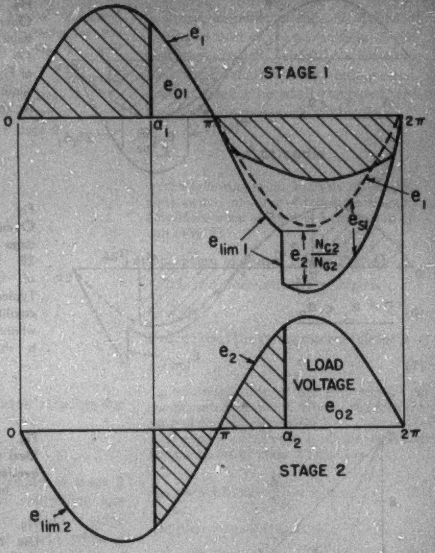

Fig. 2 (right). Operation of half-wave magnetic amplifiers with synchronous switch coupling. Gate winding voltage is shaded area

enables full-range control of stage 2 to be obtained with less than full-range control of stage 1. The stage 2 switch current is inductively filtered, enabling the unimpeded passage of the "rectangular blocks" of gate current required by the inductive load. An almost similar result could be achieved by increasing the magnitude of unfiltered switch current, but at the expense of greater switch dissipation.

Control and bias of stage 1 are obtained by control windings wound around both cores in the normal manner, with mode of operation and time constant identical to that of a conventional full-wave circuit, except as influenced by the modified gate-limiter voltage. Typical voltage wave forms are sketched in Figs. 4 and 5. The stage 1 resetting voltage is shown for the ideal low-impedance control circuit case.[8]

Ideal normalized transfer characteristics, relating the per unit output voltage of stage 2 to the per unit output voltage of stage 1, are shown in Fig. 6 for several typical values of circuit parameters. Use of the transfer characteristics to predict the over-all control characteristic from the characteristic of the first stage is illustrated in Fig. 7. It is seen that the effect of the center-tap connection of stage 2 is to increase the over-all gain when $\alpha_1 > \alpha_2$ and to decrease the over-all gain when $\alpha_1 < \alpha_2$. Since the gain of stage 1 is generally highest in the lower part of its output range ($\alpha_1 > 90$ degrees), the cascaded characteristic accentuates the nonlinearity of the first stage. However, the low gain region is often avoided in normal operation and the increase in the maximum gain is welcome. The modification of the characteristic is dependent upon the ability of stage 1 to reset stage 2 at a rate greater than the minimum requirements, that is, the parameter k must be greater than unity. Without a switch in stage 2, the condition $k=2$, $s_2=0$ (Fig. 6) represents the limiting transfer characteristic obtainable.

When a switch is employed in stage 2 the gain can be further increased and the nonlinearity reduced. The high gain region of stage 1 can be used to control stage 2 over its full range (see Fig. 7).

A typical over-all control characteristic, without a switch in stage 2, is shown in Fig. 8. The coupling parameter k is approximately 1.3. The first stage employs Supermalloy cores, and the second stage Deltamax cores. The resemblance to an inverted single-stage characteristic is obvious (no bias is used).

Full-Wave Push-Pull Circuit

Two similar single-ended circuits can be combined in a push-pull connection of the stage 1 control windings and of the stage 2 load, but the interstage push-pull connection of conventional circuits is avoided. The synchronous switch circuit is common to both sides, as shown in Fig. 9. The coupling of each side operates independently in the manner described for the single-ended circuit of Fig. 3.

Typical cascaded control characteristics, with a Supermalloy core first stage and a Deltamax core second stage, are shown in Fig. 10. Curve A is obtained without a switch in stage 2 ($k=2$, $s_2=0$), and curve B illustrates the effect of adding a switch in stage 2 ($k=2$, $s_2=1/2$). With the switch, the linear range is extended to the saturation level. The load is a torque motor with twin windings

A previous design using the same cores, but with conventional dummy load coupling, had insufficient dynamic gain to meet the specifications of the application, and poor linearity. Attempts to increase the gain produced bistable regions in the characteristic. Linearity could be improved only at the expense of gain. Both problems were solved by the use of synchronous switch coupling.

Conclusions

The properties of the synchronous switch coupling method can be summarized by listing the advantages and disadvantages of the method.

ADVANTAGES

1. Stage 2 is prevented from influencing the resetting of stage 1. The tendency toward nonlinearities which occurs with conventional methods (such as dummy load coupling of push-pull amplifiers) is eliminated.
2. No interstage time constant is introduced. Stage 2 has half-cycle response.
3. Since the stage 2 reactors are voltage reset, and effectively slaves of stage 1, the effects of drift and mismatch of the stage 2 cores are reduced to second-order importance. Only the drift and matching of stage 1 cores are critical.
4. No bias is required for stage 2.
5. The synchronous switch circuit can serve as a d-c bias source for stage 1, as shown in Fig. 9.
6. The theory of coupling is simple and performance is predictable.
7. The method is equally applicable to half-wave, full-wave, single-ended, or push-pull circuits.
8. Problems caused by inductive loading are eliminated by the mode of resetting stage 2. Silicon commutating rectifiers, with high forward voltage drop, cause no trouble. No snap-action occurs, even without commutating rectifiers, although in the latter case the control characteristic is drastically altered.
9. None of the output power of stage 1 need be wasted in coupling resistors. The gate winding resistance of stage 1 can be matched approximately to the equivalent excitation resistance of stage 2 referred to its control winding. This results in minimum size and shortest response for stage 1.

DISADVANTAGES

1. The full range of output of stage 2 cannot be obtained by controlling less than the full range of the output of stage 1, except to a limited extent when a synchronous switch is also used in stage 2. This restriction, however, also applies to most other methods of coupling without interstage filtering.
2. Power is dissipated in the switch. However, an equal amount of power may normally be required to bias stage 2, and is generally a relatively small amount. If a switch is used in stage 2 its power dissipation is a definite drawback if the load is large or the source is of limited capacity.
3. The "center-leg" method of self-biasing push-pull amplifiers cannot be used with an even number of stages.
4. The method cannot be used for coupling single phase to polyphase stages, or stages operating from different supply frequencies.
5. Due to the inversion of the characteristic, the minimum load current may be rather large especially when the core material of stage 1 has a low ratio of residual to saturated flux density, such as Supermalloy. This fault can be overcome by using a switch in stage 2.
6. The method cannot be applied to standard magnetic amplifiers which are already wound with a common control winding.

It is seen that the benefits gained by synchronous switch coupling are many, while the disadvantages listed are often not applicable or not serious. The method offers a solution to the problem of extending the performance of multistage magnetic amplifiers. The shunt-coupled magnetic amplifier circuits of Hubbard[9] also have most of the advantages of synchronous switch coupling. However, they require that the gate winding resistance of stage 1 be small compared with the excitation resistance of stage 2.

Appendix

The following is an analysis of synchronous switch coupling of full-wave magnetic amplifiers when stage 2 is a center-tap circuit (Fig. 3).

Operation of Stage 1 (see Fig. 4)

The synchronous switch voltage is

$$e_{S1}=s_1e_1 \tag{6}$$

Before firing, the gating reactor voltage is

$$e_{G1}=e_1 \tag{7}$$

(The forward drop of the gate rectifier is compensated approximately by the forward drop of the switch rectifier.)

The gate limiter voltage of the resetting reactor is, before stage 2 fires at α_2

$$e_{\lim 1}=(1+2s_1)e_1-\frac{N_{C2}}{N_{G2}}e_2 \tag{8}$$

and after stage 2 fires at α_2

$$e_{\lim 1}=(1+2s_1)e_1 \tag{9}$$

From equation 8, in order to prevent stage 2 from affecting stage 1, requires $e_{\lim 1}>e_1$.

$$2S_1>\frac{N_{C2}}{N_{G2}}\frac{e_2}{e_1} \tag{10}$$

Operation of Stage 2 (see Fig. 5)

The commutating rectifier forward drop is neglected.

A. WITH SYNCHRONOUS SWITCH VOLTAGE

$$e_{S2}=s_2e_2 \tag{11}$$

Before firing, the gating reactor voltage is

$$e_{G2}=e_2 \tag{12}$$

After firing, the load voltage is

$$e_{L2}=e_2-i_{L2}R_{G2} \tag{13}$$

The gate limiter voltage of the resetting reactor is, before the gating reactor fires at α_2

$$e_{\lim 2}=(1+2s_2)e_2 \tag{14}$$

and after the gating reactor fires at α_2

$$\begin{aligned} e_{\lim 2}&=(1+2s_2)e_2+e_{L2}\\ &=2(1+s_2)e_2-i_{L2}R_{G2} \end{aligned} \tag{15}$$

B. WITHOUT SYNCHRONOUS SWITCH

Without the synchronous switch, $s_2=0$

Equations 12-15 become, respectively,

$$e_{G2}=e_2-e_f \tag{12A}$$

$$e_{L2}=e_2-e_f-i_{L2}R_{G2} \tag{13A}$$

$$e_{\lim 2}=e_2+e_f \tag{14A}$$

$$\begin{aligned} e_{\lim 2}&=e_2+e_f+e_{L2}\\ &=2e_2-i_{L2}R_{G2} \end{aligned} \tag{15A}$$

IDEAL NORMALIZED TRANSFER CHARACTERISTIC

The per unit output of stage 1 is

$$\underline{E}_{o1}=\frac{E_{o1}}{E_1}=\frac{1+\cos\alpha_1}{2} \tag{16}$$

The per unit output of stage 2 is

$$\underline{E}_{o2}=\frac{E_{o2}}{E_2}=\frac{1+\cos\alpha_2}{2} \tag{17}$$

The per unit reset of stage 2 required is

$$\frac{E_{G2}}{E_2}=1-\underline{E}_{o2}=\frac{1-\cos\alpha_2}{2} \tag{18}$$

Define the parameter k after stage 1 fires at α_1 as

$$k=\frac{e_{C2}}{e_2}\frac{N_{G2}}{N_{C2}} \tag{19}$$

where

$$e_{C2}=e_{o1}-i_{C2}(R_{G1}+R_{C2}) \tag{20}$$

In order to control stage 2 over its full range we require $k \geq 1$. The maximum value of k is gate limited to

$$k_{\max}=\frac{e_{\lim 2}}{e_2} \tag{21}$$

CASE I

$1<k<1+2s_2$

No discontinuity will be caused by the center-tap circuit of stage 2. The per unit reset of stage 2 is $k\underline{E}_{o1}$

Equating this to the required value of equation 18, one obtains

$$\underline{E}_{o2}=1-k\underline{E}_{o1} \tag{22}$$

Thus

$\underline{E}_{o2}=0(\alpha_2=\pi)$

when

$$\underline{E}_{o1}=\frac{1}{k}\left(\cos\alpha_1=\frac{2}{k}-1\right)$$

CASE II

This occurs only with the center-tap circuit, where the gate-limiter voltage changes at α_2.

(a). When

$$\alpha_1>\alpha_2,\ 1+2s_2<k<2(1+s_2)-\frac{i_{L2}R_{G2}}{e_2}$$

Equation 22 is valid in this range.

When $\alpha_1=\alpha_2=\alpha_c$, one obtains from equation 22

$$\frac{1+\cos\alpha_c}{2}=1-k\ \frac{1+\cos\alpha_c}{2} \tag{23}$$

from which

$$-\cos\alpha_c=\frac{k-1}{k+1} \tag{24}$$

and

$$\underline{E}_{o2}=\underline{E}_{o1}=\frac{1}{1+k} \tag{25}$$

(b). When $\alpha_1<\alpha_2$

$k=1+2s_2$ from α_1 to α_2

$1+2s_2<k<2(1+s_2)-\dfrac{i_{L2}R_{G2}}{e_2}$ from α_2 to π

The per unit reset of stage 2 is

$$(1+2s_2)\frac{(1+\cos\alpha_1)}{2}+(k-1-2s_2)\frac{(1+\cos\alpha_2)}{2} \tag{26}$$

Equating this to the required value of equation 18 one obtains

$$1-\underline{E}_{o2}=(1+2s_2)\underline{E}_{o1}+(k-1-2s_2)\underline{E}_{o2} \tag{27}$$

from which

$$\underline{E}_{o2}=\frac{1-(1+2s_2)\underline{E}_{o1}}{k-2s_2} \tag{28}$$

Thus

$\underline{E}_{o2}=0(\alpha_2=\pi)$

when

$$\underline{E}_{o1}=\frac{1}{1+2s_2}\left(\cos\alpha_1=\frac{2}{1+2s_2}-1\right)$$

Typical conditions of Case II are shown in Fig. 5. From the foregoing information, the normalized transfer characteristic may be constructed for particular values of s_2 and k. Examples are shown in Fig. 6, and the application of the transfer characteristic to predict the control characteristic of the cascaded amplifiers is illustrated in Fig. 7.

Without the synchronous switch in stage 2, $(s_2=0)$ the equations are simplified:

CASE I

$k=1$

$$\underline{E}_{o2}=1-\underline{E}_{o1} \tag{22A}$$

CASE II

(a). When

$$\alpha_1>\alpha_2,\ 1<k<2-\frac{i_{L2}R_{G2}}{e_2}$$

$$\underline{E}_{o2}=1-k\underline{E}_{o1} \tag{22}$$

(b). When $\alpha_1<\alpha_2$

$k=1$ from α_1 to α_2

$1<k<2-\dfrac{i_{L2}R_{G2}}{e_2}$ from α_2 to π

$$\underline{E}_{o2}=\frac{1-\underline{E}_{o1}}{k} \tag{28A}$$

A deviation from half-cycle response occurs under Case II conditions when $\alpha_1<\alpha_2$. This is due to the change in gate-limiter voltage of the center-tap circuit when the gating core fires. Since the latter firing is predetermined during the previous half-cycle, and affects the resetting during the present half-cycle which determines the output during the next half cycle, a channel for the hold-over of information for more than one half-cycle is established.

For transient conditions, equation 27 becomes

$$\begin{aligned}1-\underline{E}_{o2}[(n+1)\text{th half-cycle}]\\ =(1+2s_2)\underline{E}_{o1}[n\text{th half-cycle}]+\\ (k-1-2s_2)\underline{E}_{o2}[n\text{th half-cycle}]\end{aligned} \tag{29}$$

After a sudden change in $\underline{E}_{o1}$, the value of $\underline{E}_{o2}$ will fluctuate every half-cycle, eventually settling down to the new steady-state value. It was not possible to verify this effect in the test circuits, since it is swamped by the relatively long time constant of the first stage.

Calculation of Coupling Parameters

The control voltage of stage 2 is given by equation 20. If the power output of stage 1 is resistance limited, rather than thermally limited, the power matching theorem may be applied. Minimum size for stage 1 is obtained when

$$e_{C2}=\frac{e_{o1}}{2}=i_{C2}(R_{G1}+R_{C2})=ke_2\frac{N_{C2}}{N_{G2}} \tag{30}$$

However, since the control current of stage 2 with square-loop core material is approximately constant, while the output voltage of stage 1 is part of a sine wave, to obtain good control near the ends of the range ($\alpha=$ 0+ or $\pi-$) it is desired that

$$E_1>2I_{C2}(R_{G1}+R_{C2}) \tag{31}$$

where

$$I_{C2}=\frac{H_{C2}l_{Fe2}}{N_{C2}} \tag{32}$$

As a design guide, one may choose

$$N_{C2}\approx\frac{E_1}{E_2}\frac{N_{G2}}{2} \tag{33}$$

and check that condition 31 is satisfied. An approximate average value for the parameter k may now be calculated.

$$k=\frac{E_1-I_{C2}(R_{G1}+R_{C2})}{E_2}\cdot\frac{N_{G2}}{N_{C2}} \tag{34}$$

Whether or not k will be gate-limited to a value smaller than that given by equation 34 is determined by the upper limit of the inequalities given for the conditions of Case I or Case II operation.

Nomenclature

e = gate supply voltage, absolute instantaneous value
E = gate supply voltage, half-cycle average value
e_C = control winding voltage, absolute instantaneous value
e_f = forward voltage drop of diode
e_G = gate winding voltage, absolute instantaneous value
E_G = gate winding voltage, half-cycle average value
e_L = load voltage, instantaneous value
$e_{\lim}$ = gate limiter voltage: maximum magnitude of gate winding voltage during reset half-cycle, instantaneous value
e_o = gross output voltage, absolute instantaneous value
E_o = gross output voltage, half-cycle average value
$\underline{E}_o$ = per unit output voltage E_o/E
e_s = synchronous switch voltage, absolute instantaneous value
H_C = coercive force of core material, ampere-turns per cm (centimeter)

i_C = control current, absolute instantaneous value
I_C = control current, half-cycle average value
i_L = load current, instantaneous value
k = parameter defined by equation 19
l_{Fe} = mean magnetic circuit length of core, cm
L_L = load inductance
L_S = synchronous switch inductance
N_C = number of turns in control winding
N_G = number of turns in gate winding
R_C = conrol circuit resistance
R_G = gate winding resistance
R_L = load resistance
R_S = synchronous switch resistance
s = ratio e_S/e
α = firing angle measured from beginning of gating half cycle, electrical radians at a-c supply frequency
π = 3.14...
Subscripts 1,2 designate amplifier stages 1 and 2
A,B,C,D designate reactors in full-wave circuits

Miniature High-Frequency Magnetic Amplifiers for Magnetic Memory Sensing

G. R. BRIGGS
NONMEMBER AIEE

K. C. HU
ASSOCIATE MEMBER AIEE

AMPLIFIERS of the magnetic modulator type have been found useful for amplifying signals as small as 10^{-18} to 10^{-17} watts.[1,2] The most common design utilizes balanced cores and a flux-coupled output circuit separate from the excitation circuit. The output is the difference output of the cores and is predominantly second harmonic in content. The zero drift is small because core unbalance results only in generation of a fundamental output component which can be supressed by filtering,[3] and the elimination of "series-connected" loads in the excitation circuit reduces drifts arising from excitation amplitude fluctuations.[4] Parallel connection of windings which introduces problems of d-c resistance balancing, and the use of output rectifiers which results in drifts arising from d-c feedback, are also avoided to reduce zero drift further.

In optimizing the circuit in these ways to obtain drift-free operation, the amplifier becomes inherently simple in design. This simplicity implies that this type of amplifier should exhibit fast response. Lufcy and his co-workers pointed out some time ago[5] that as few cores and as few paths for d-c flow as possible are desirable to obtain fast response, because it is necessary to keep the effective flux and the number of current paths having significant L/R (inductance-resistance) time constants to a minimum. The balanced-core magnetic modulator satisfies these requirements well and therefore, should exhibit a minimum response time nearly as small as the minimum possible of one half of the excitation period. Because of this potential speed possibility, it was felt desirable to investigate this circuit as an output-signal detector for a magnetic memory. This application requires the use of excitation frequencies greater than 100 kc, but very little has been published concerning response for frequencies greater than 400 cps (cycles per second). Kletsky[6] has recently reported gain measurements at 6,000 cps, but he did not report measurements of response time. The lack of high-frequency data has prompted the present investigation in the frequency range of 100 kc to 4 mc (megacycles).

At such high frequencies of excitation it might be expected that useful voltage and power gains could be obtained with small cores having small fluxes and wound with few turns of wire. The measurements to be reported were made on amplifiers constructed of ferrite and metal tape cores approximately 0.050 inch in diameter, wound with single-turn control windings. To keep the circuit simple, no filtering to remove the fundamental component of excitation frequency in the output was provided. This limitation, in conjunction with the effects of core unbalance caused by high-frequency heating and the use of an asymmetric mode of excitation to obtain greater gain and gain stability, reduced the zero stability in comparison with low-frequency designs. A signal power sensitivity of about 10^{-10} watts can be obtained. This moderate power sensitivity is accompanied by a high voltage senstivity (noise is less than 0.1 μv (microvolts) equivalent at the input) and a response time less than 10 μsec (microseconds), making the device attractive for applications involving low level voltage signals of moderate current.

General Considerations

CIRCUIT

A schematic diagram of the amplifier is shown in Fig. 1. The circuit shown is similar to one described by Wennerberg.[7] In this circuit a diode shunted by a resistance, R_s, is connected in series with the excitation winding to obtain an asymmetrical excitation current. This will later be shown to result in more gain and less dependence of gain on excitation amplitude as well as faster response. The output and control windings have the same winding sense, with the result that output appears across both. The input circuit, therefore, loads the output. if the source impedance, R_c in Fig. 1, is sufficiently high, the output loading is negligible, but if R_c is small, the output

G. R. BRIGGS and K. C. HU are with Radio Corporation of America, Princeton, N. J.

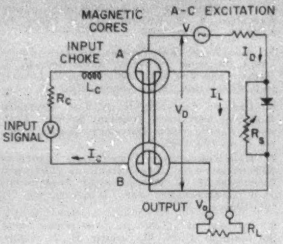

Fig. 1. Simplified schematic diagram of balanced-core magnetic amplifier

may become too heavily loaded and isolation between the source and output is then required. This can be either resistive or inductive or a combination of the two. Inductive isolation is usually chosen to preserve the maximum possible gain. This inductance is shown as L_c in Fig. 1. The time constant L_c/R_c will mainly determine the response time, as will later be shown, when this time is large compared to one-half period of the excitation and if the cores are operated in a saturating mode.

The output load is a resistance, R_L. The use of rectifying circuits here is avoided to eliminate circuit analysis complications introduced by the resulting d-c feedback and to obtain fastest response. A resistive load is a close approximation to the load actually used in the memory sensing application for which the amplifier was developed.

SYMMETRICAL EXCITATION

The symmetrical mode of excitation obtained when $R_s=0$ is the common one for low-frequency operation and will be described for later comparison with other modes (see Fig. 2). For this mode the excitation amplitude is made sufficiently large to switch both cores alternately from one saturation level to the other, and both cores switch equally in flux. Assuming the hysteresis loop of each core is the same, their outputs will exactly cancel if the control current, I_c, is zero, as indicated in Fig. 2(B). However, if a control current is applied, the output waveforms of the cores will become asymmetrical and a net even-harmonic waveform will appear at the output. The asymmetry is a result of differences in switching delay and differences in switching speed between the cores caused by the control-current bias. Note that the voltage-time integral of the output of each core remains the same whether I_c is zero or not.

If a step of control current is applied to the amplifier the full difference output will be obtained within one-half cycle of the excitation frequency. The only additional limitation on response is determined by those control circuit parameters which act to limit the rate of change of I_c.

NONSATURATING EXCITATION

If the amplitude of the symmetrical excitation is increased beyond that required to saturate the cores, the control sensitivity decreases, because the cores tend to switch more nearly at the same rate and in the same time, producing more complete cancellation at the output. This is clearly shown by data presented in the paper already mentioned by Kletsky.[6] His results indicate that this effect becomes more important at higher frequencies of excitation. To avoid this decrease in gain with increase in excitation drive, it is best to drive the cores just to saturation. Greater gain can even be obtained by operating with a drive insufficient to saturate, but if this is done the possibility of unstable operation arises. This is characterized by an excessive dependence of gain upon drive amplitude[1] and by a large response time accompanied by considerable nonlinearity between the output and input, even for small signals. How this can happen will be explained with the aid of Fig. 3. Assuming that I_d is insufficient to saturate the cores in either of their two saturation levels, the flux excursions which occur upon application of I_c can be quite complex, as indicated by the flux excursion paths shown drawn dashed in Fig. 3(A). Assume that a step-function I_c is applied. This causes the fluxes, starting at the points indicated by *a* in the figure, to follow complex minor loop excursions on succeeding excitation cycles until the equilibrium points *d* are reached. This may take a number of cycles dependent upon the excitation and signal amplitudes. This "creeping" of unsaturating minor loops is especially marked with square-loop materials[8] and results in an output response of the form indicated in Fig. 3(B). Referring to this figure, before the control current step is applied the cores operate with symmetrical equilibrium minor loops and the net output is zero. When the step is applied considerable unbalance immediately occurs and output is obtained on the next excitation half-cycle following the step. On following cycles, however, the output does not remain constant, but continues to change until a new minor loop equilibrium condition has been re-established. This results in a long response time which is both excitation- and signal-amplitude dependent. In addition, the total amount of creep is also dependent upon these parameters and causes the final output to be nonlinear with respect to the input.

NONSYMMETRICAL EXCITATION

To avoid the aforementioned difficulties and yet obtain high gain, it is possible to use asymmetrical excitation which saturates the cores in one direction only (see Fig. 4). The saturating polarity of drive insures operation without creeping of the operating point, whereas the nonsaturating drive of opposite polarity presets the cores to sensitive operating points on their hysteresis loops. This mode of operation is common for high-level magnetic amplifiers. Wennerberg has described a mode of operation similar to this for amplifying signals in the millivolt range.[7] As indicated in Fig. 4(A), the flux change in each core is now no longer the same when I_c is applied. This difference in flux, accompanied by differences in switching rate and switching delay, now determines the net output as shown in Fig. 4(B). Note that the output is no longer even harmonic, but contains the fundamental and odd harmonics

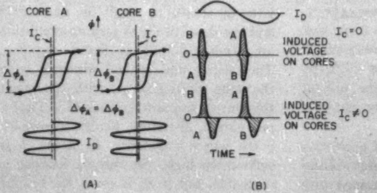

Fig. 2 (left). Operation with symmetrical, saturating excitation

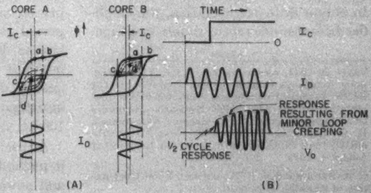

Fig. 3. Operation with symmetrical, nonsaturating excitation

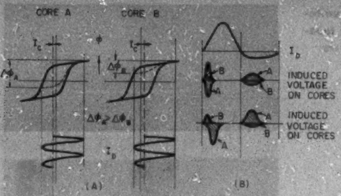

Fig. 4 (left). Operation with assymmetrical excitation

of the excitation frequency as well. The gain can be high, because if the cores are preset by the drive to a flux level of about one half of the total switching flux, the operating points are placed in regions of high incremental permeability. The gain also remains high at high excitation frequency in contrast to the symmetrically-driven amplifier, because the gain now is not as strongly dependent upon differences in switching rate and delay of the cores, effects which tend to diminish as the frequency increases.

The dependence of gain upon excitation amplitude with asymmetrical drive is as follows. Increase of the saturating polarity of drive current causes the flux differences set by I_c to be switched at a faster rate, generating greater peak voltages which increase the voltage gain and, to a lesser extent, the power gain. The effect of increasing the presetting polarity of drive current is more complex. If the cores are preset less than halfway by the drive, increased drive increases the gain, whereas if the cores are set more than halfway, increased drive decreases the gain. By setting more than halfway and by maintaining a constant ratio between saturating and setting current peak values it is possible to make the opposing gain-drive dependences cancel each other over a considerable range of excitation-source amplitude (see Fig. 5). The shunted diode shown in Fig. 1 accomplishes this; R_s is adjusted until the best operation is obtained.

The previously mentioned advantages of asymmetric excitation are offset to some extent by a greater dependence of zero balance on core temperature with this excitation mode. In the symmetrically-driven amplifier, variations in both core remanent flux and coercive force due to temperature changes result in the generation of a fundamental frequency output component which can be removed by filtering. In the asymmetrically driven amplifier, on the other hand, variations in the relative coercive forces of the cores due to temperature changes result in effects which are identical with those of true signals and these cause unavoidable zero drift. In memory applications, the high-gain high-frequency performance is usually found to be more important than zero stability and asymmetrical drive is therefore of most interest here.

Experimental Results

Ferrite-Core Amplifier

Ferrite cores of 0.050 inch outside diameter, 0.030 inch inside diameter, and 0.015 inch thickness were wound and tested in the circuit which is shown in Fig. 6. The ferrite is a low-drive type having a coercive force of about 0.06 oersted and exhibits a hysteresis loop of moderate squareness. The cores are designated as Radio Corporation of America type *XF-4008*. Switching time data for these cores obtained from rectangular pulse measurements are presented in Fig. 7. For switching rates in the frequency range near 1 megacycle which are of interest here, these data yield a switching coefficient, *Sw*, of 0.46 oersted-μsec.[9] The switching flux of each core is about 2.8 maxwells.

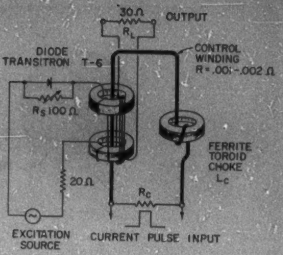

Fig. 6. Experimental test circuit for ferrite or metal core amplifier

The control winding is a single short length of no. *28* wire (see Fig. 8). The choke (not shown) is wound with even heavier wire to keep the total control circuit resistance small (0.002 ohm) to obtain a high input voltage sensitivity. The choke core is a small toroid of ferrite having low loss characteristics and low remanent flux (General Ceramics type *H*, no. *259* core). (Inductance values are given in the table associated with Fig. 13.) The control signal source for test purposes was a constant-current pulse generator. This was shunted by R_c to obtain a voltage-source circuit. An excitation winding of two turns and an output winding of four turns were used.

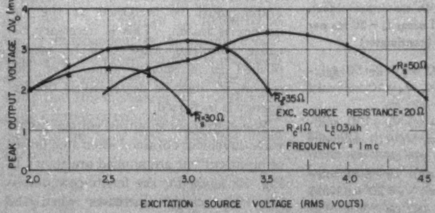

Fig. 5. Output versus excitation source voltage for different values of diode shunt resistance R_s. Data for ferrite-core amplifier

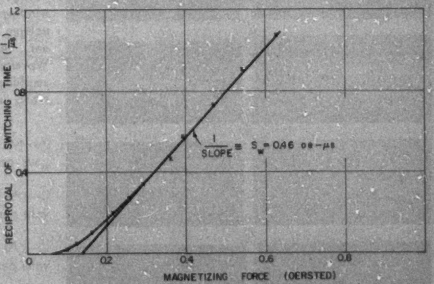

Fig. 7. Switching rate versus switching magnetic field for ferrite amplifier core

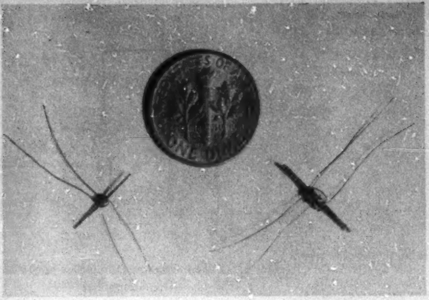

Fig. 8 (left). Ferrite-core and metal tape-core amplifiers

METAL-TAPE CORE AMPLIFIER

Metal-tape bobbin cores were also tested using the same circuit. These cores are stainless steel bobbin types wound with 22 wraps of 1/8-mil *4-79* molybdenum permalloy tape, 1/32 inch in width. The mean diameter is 0.052 inch. This diameter is considerably greater than the mean diameter (0.040 inch) of the ferrite cores, but the coercive force for the metal is less, about 0.04 oersted, so it is reasonable to expect comparable sensitivities from amplifiers constructed using the two types of cores. The switching flux of each metal core is approximately 7 maxwells. This flux is considerably larger than that of the ferrite core. With the larger flux, it is reasonable to expect a greater output and gain per turn and a slower response. However the same value of load resistance, $R_L=30$ ohms, was used in both cases, with the result that the greater output was forced to supply more load current which reduced the gain. Comparison of the amplifier gains, therefore, did not justify the use of normalization.

A photograph of the metal-core amplifier is included in Fig. 8. The larger core diameter permits the use of a heavier control conductor of lower resistance. An input resistance of 0.001 ohm could be obtained in this case.

AMPLIFIER WAVEFORMS

Typical waveforms of excitation current I_d, excitation winding voltage V_d, and output voltage V_o are shown with phase relationships preserved in Fig. 9. In all waveform photographs, time increases toward the left. These waveforms were observed for the ferrite-core amplifier with no input signal. V_o in this case is that due to core unbalance. This waveform changes in amplitude but remains relatively unchanged in form when an input signal is present. Waveforms for the metal-core amplifier are similar. Waveforms for four different excitation frequencies are presented. At low frequency, the cores in being driven to saturation switch in a small fraction of a cycle time and generate sharp spikes of voltage. At high frequency, this switching occupies a larger fraction of the cycle because the switching time remains nearly constant (constant saturating drive being assumed). For this reason also, the output voltage does not increase linearly with frequency, but at a lesser rate.

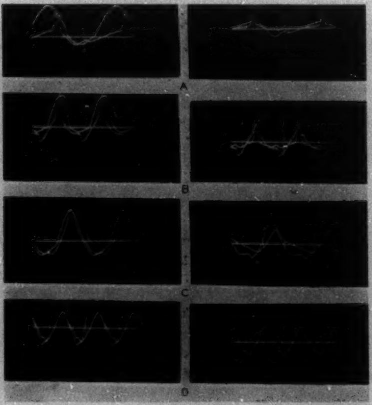

Fig. 9. Waveforms of excitation current I_d and excitation winding voltage V_d (left) and excitation winding voltage V_d and output voltage V_o (right) for four different excitation frequencies. Waveforms for ferrite-core amplifier with no input signal. Note: in all cases $I_d=50$ ma per cm (centimeter)

A—(At 100 kc) $V_d=50$ millivolts per cm, $V_o=10$ millivolts per cm
B—(At 500 kc) $V_d=100$ millivolts per cm, $V_o=10$ millivolts per cm
C—(At 1 mc) $V_d=200$ millivolts per cm, $V_o=20$ millivolts per cm
D—(At 3 mc) $V_d=500$ millivolts per cm, $V_o=20$ millivolts per cm

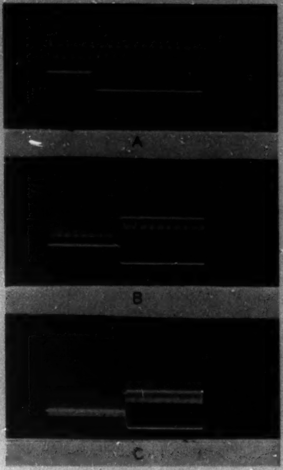

Fig. 10. Waveforms of output voltage carrier wave envelope for input current steps of increasing amplitude. Waveforms for ferrite-core amplifier. Vertical scale = 25 millivolts per cm, horizontal scale = 2 μsec per cm, excitation frequency, 1 mc

A—$I_s=1$ ma
B—$I_s=5$ ma
C—$I_s=10$ ma

The waveforms of Fig. 9 show that the presetting polarity of I_d, the excursions of I_d below the base lines in the photograph, must be increased as the frequency is raised. This is necessary because presetting must then be accomplished in a shorter time. For this reason, R_s must be decreased as the frequency is increased.

Waveforms of the output voltage carrier wave envelopes obtained when step pulses of input current are applied are shown in Fig. 10, again for the ferrite-core amplifier. The carrier increases when the signal is applied, more for one output polarity than for the other because of the asymmetric excitation. Waveforms for

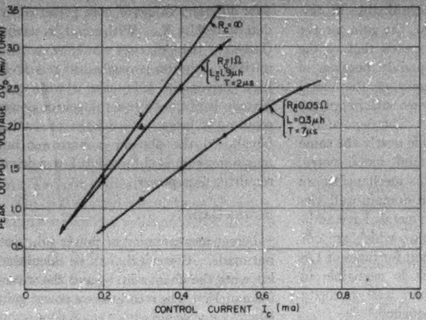

Fig. 11. Output versus input for small input signals. Curves for ferrite-core amplifier

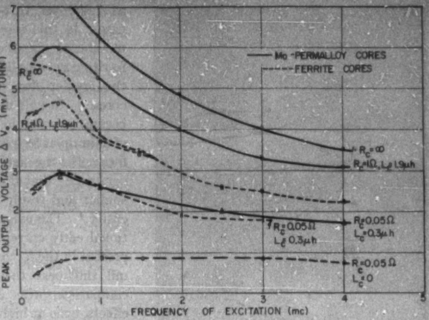

Fig. 12. Output versus excitation frequency for different input circuit R_c and L_c parameters. $I_c=1$ ma for all curves

1-, 5-, and 10-ma (milliamperes) input pulses are shown; corresponding increases in peak output are 10, 43, and 67 millivolts. These indicate some lack of output linearity for current pulses in this range of amplitude. For inputs less than 1/2 ma, however, the linearity is excellent (see Fig. 11).

The waveforms of Fig. 10 were obtained with a large value of R_c so that the L/R time constant of the input circuit was small. It is evident from the uppermost waveform of the figure that one-half cycle response is obtained in this case.

NOISE AND SIGNAL SENSITIVITY

From Fig. 10 it is apparent that signals of 1 ma can easily be detected above the no-signal carrier output level. Using care in selecting cores and in maintaining reasonably contant temperature (an oil bath was found very helpful here), sensitivities of 200 μa are possible for both the ferrite- and metal-core amplifiers. This represents an input power of less than 10^{-10} watts.

The fluctuations in output due to Barkhausen and other sources of noise were measured qualitatively. The total input equivalent noise voltage was found to be about 0.1 microvolt for both types of amplifier. This voltage was found to be nearly independent of operating conditions with the exception that it increased slightly for small values of R_c. The possibility that this increase is due to a thermal noise current circulating in the input circuit can be calculated. The rms noise current is

$$I=\sqrt{\frac{4kT\Delta f}{R}}=1.28\times10^{-10}\sqrt{\frac{\Delta f}{R}}\ \text{amperes} \qquad (1)$$

at room temprature, where k=Boltzmann's constant$=1.37\times10^{-23}$ joule per degree Kelvin (K), T=absolute temperature in degrees K, Δf=frequency range of noise, and R=total input loop resistance. Using a typical value of $R=0.01$ ohm and $\Delta f=2$ mc (see next section), one calculates $I=2$ μa which corresponds to an input voltage of 4×10^{-9} volts. Such a voltage is less than that observed by a factor of more than 10.

A better explanation for the increase in noise is that it results indirectly from the decrease in gain due to the increase in output loading as R_c is decreased (see Fig. 12). Since the Barkhausen fluctuations in flux are independent of loading, the output voltage noise is not reduced by loading, with the result that the signal-to-noise ratio decreases and the equivalent input noise current and input noise voltage increase as R_c is reduced.

The observed input noise power level is about 5×10^{-12} watts. This is a factor of 10^6 greater than that which has been obtained at low frequency[3] using large cores. The reason for this is that the Barkhausen jumps in flux are a much larger percentage of the total switching flux for the small cores used here. Reduction of the Barkhausen noise voltage by a factor of 20 by improvements in materials could reduce the noise power to a limit of about 10^{-14} watts determined by thermal fluctuations, for the case $R_c=0.01$ ohm. Accompanying improvements in zero stability would be needed, however, before this would result in a useful increase in signal sensitivity.

VOLTAGE GAIN

The steady-state voltage gain is

$$G_v=\frac{\Delta V_o}{I_cR_{in}} \qquad (2)$$

where

ΔV_o=change in peak output voltage caused by steady signal current I_c

R_{in}=input resistance of amplifier = resistance of L_c plus resistance of control winding

In the measurements of gain obtained for Figs. 5 and 12 through 16, square pulses of input current=1.0 ma were used. This means that the gain for the ferrite-core amplifier is 500 for 1 millivolt of output voltage change per output turn; for the metal-core amplifier the gain is twice as much because R_{in} is only one half as great.

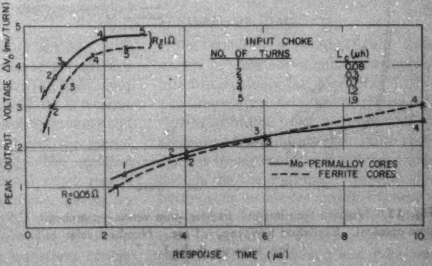

Fig. 13. Output versus response time for excitation frequency of 1 mc and input current=1-ma step. Response time for 63 percent change of output

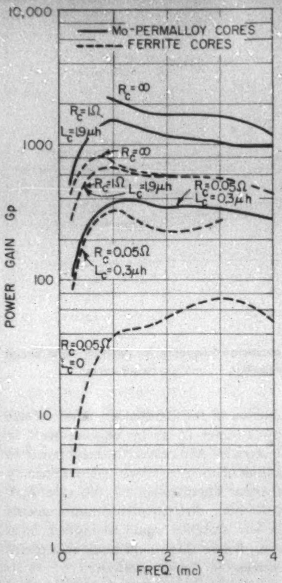

Fig. 14. Steady-state power gain G_p versus excitation frequency. G_p calculated from G_v measurements; values approximate only

For all measurements $R_L=30$ ohms was used. The core saturation excursion of I_d was also maintained constant at a peak value of 150 ma, corresponding to a magnetomotive force of 300 ma-turns.

In Fig. 12 are shown curves of ΔV_o per turn as a function of excitation frequency for different values of R_c and L_c. The greatest gain is obtained for largest R_c; this is expected because the loading effect of the input circuit upon the output is then negligible. Voltage gain as great as 7,000 per turn is obtainable in this case. In this case also, the gain for the metal-core amplifier exceeds that of the ferrite-core amplifier mainly because of the greater flux capacity of the metal cores. The gain decreases with frequency because of core losses. The dependence of gain upon frequency is nearly the same for both the ferrite and metal cores, confirming that their loss mechanisms are similar and result from domain-wall viscosity.[9] The magnetic metals have additional eddy current losses which are not present in the ferrites, but for tapes of 1/8 mil thickness this loss is negligible in comparison with domain wall viscosity effects, even at high frequency.[9]

With values of R_c less than about one ohm the gain is reduced because of output loading. The gain curves now also decline at lower frequency. This might be expected because the isolation afforded by L_c between R_c and the output decreases with frequency. Gains as great as 3,000 per turn can be obtained with values of R_c as small as 0.05 ohm and with values of L_c sufficiently small that response in less than 10 μsec can be obtained (see Fig. 13).

In Fig. 13 the dependence of V_o upon the parameters L_c and R_c is presented in a different way. In this figure ΔV_o is plotted as a function of the response time obtained using $R_c=0.05$ or 1 ohm in combination with various values of L_c. The numbers in the figure refer to the number of turns on the choke. Fig. 13 shows rather dramatically that the price paid in obtaining high gain with low source impedance is longer response time. Apparent discrepancies between the data used for Figs. 12 and 13 can be noted; these resulted because different amplifiers were used to obtain the data for each figure.

Curves of voltage gain as a function of excitation voltage are shown in Fig. 5 for different values of core presetting as determined by R_s. With small presetting (large R_s) the gain rises slowly with drive until a maximum is reached at relatively high drive; in this case a wide gain plateau is obtained but the source power required is large. With large presetting (small R_s) the plateau is narrower but maximum gain is obtained at lower drive, requiring less power.

POWER GAIN

Direct measurement of power gain was not made. Power gain can be calculated knowing the change in V_o and the waveform of V_0. The steady-state power gain is

$$G_p=\frac{1}{I_c^2R_{in}T_1}\int_{\text{cycle}}\frac{(v_o'^2-v_o^2)}{R_L}dt \tag{3}$$

where

v_o' = instantaneous output voltage with constant signal I_c
v_o = instantaneous output voltage without signal
T_1 = period of excitation

By expanding $v_o'^2-V_o^2$, equation 3 can be split into two terms:

$$G_p=\frac{1}{I_c^2R_{in}R_LT_1}\left[\int\Delta v_o^2dt+2\int v_o\Delta v_o dt\right] \tag{4}$$

where Δv_o = instantaneous change in output voltage $=v_o'-v_o$. Since v_o appears in the second part of this equation, G_p depends upon the degree of amplifier balance. With small input signals the observation was made that the waveform of v_o with and without the signal is of the same form. This means that the second term in equation 4 is positive and that unbalance increases the power gain. A lower limit for G_p can therefore be calculated by assuming perfect balance ($v_o=0$) and by numerically calculating the first term in equation 4 using the output volt-

age waveshapes of Fig. 9 normalized to have peak values corresponding to ΔV_o. This was done for the output data plotted in Fig. 12, and the results are shown in Fig. 14. It should be emphasized that the values of G_p calculated in this way are only approximate because the same v_o waveshape was assumed for all values of R_L and L_c. The validity of this assumption was not critically checked.

The power gain calculations shown in Fig. 14 are for one value of load resistance only, $R_L = 30$ ohms; this value was chosen because it decreased the open circuit output voltage only moderately. Quantitative measurements to find a power maximum with R_L as a variable were not made. For this reason, and also because of the simplifying assumption of perfect balance, the values of G_p given in Fig. 14 should not be considered the maximum obtainable. The curves of G_p indicate that the power gain decreases very rapidly as R_c is reduced and that higher frequency operation is required to obtain maximum gain for small R_c. With R_c sufficiently large that output loading is negligible, a power gain maximum of greater than 2,000 is obtained at a frequency of about 1 mc.

RESPONSE

The waveforms of Fig. 10 show that one-half cycle response is obtained when R_c is large. However, for R_c a few ohms or less the L/R time constant of the input circuit limits the rate at which I_c can build up or decay to such an extent that the response time becomes greater than one-half period of the excitation. The L/R time constant then becomes the limiting factor in determining the response. For a given R_c, the fastest response results when $L_c = o$, but the loading effect of the input circuit then causes a reduction in gain as shown by the curves of Figs. 12 and 13. In practice, for each value of R_c a compromise must be made between gain and response time in choosing a value of L_c.

The inductance of the input circuit is composed of L_c plus any signal source and amplifier control winding inductance. Care was taken to maintain the signal source inductance associated with R_c very small; in this case $L = L_c + L_{in}$ only, where L_{in} is the inductance of the control winding. L_{in} was measured by observing the response with $L_c = o$ and with R_c sufficiently small that the response was much longer than one-half cycle of the excitation. Data were obtained for the ferrite-core amplifier only. With $R_c =$ 0.05 ohm, the response time obtained was 1.2 µsec measured at an excitation frequency of 3 mc for which the one-half cycle time is only 0.17 µsec. From this response time, a value of $L_{in} = 0.06$ microhenry was calculated. This value of L_{in} is negligible compared with L_c when the latter is sufficiently large to provide effective isolation.

VOLTAGE-TIME INPUT REQUIREMENTS AND VOLTAGE-TIME TRANSFER RATIO

Input voltage, current, and power comparisons have thus far been made assuming steady-state conditions. During transient conditions when I_c is changing, the instantaneous input voltage e_{in} is

$$e_{in} = L\frac{di_c}{dt} + i_c R_{in} \tag{5}$$

where i_c = instantaneous control current. If the input voltage applied is a step equal to the steady-state value $I_c R_{in}$, i_c increases according to differential equation 5 exponentially from zero to the steady-state value I_c with the time constant $L/R_{in} = (L_c + L_{in})/R_{in}$. For the amplifiers tested, this time ranged between 30 and 240 µsec. In practice, it is usually desirable to supply more than the steady-state input voltage during the transient period to support a greater inductive drop and therefore to increase di_c/dt and reduce the response time. This means that the instantaneous voltage gain will be less than the steady-state gain. An exact calculation of the instantaneous gain requires a specification of the waveform of the input voltage applied and in general is complicated.

Another way to consider the transient operation is in terms of the volt-second transfer ratio.[10] This is defined as the change in the half-cycle output voltage-per-turn time integral divided by the change in the input voltage-per-turn time integral required to produce the output change. It is, therefore, a measure of the output flux change produced by an effective input flux change. The input integral is obtained by integrating equation 5:

$$\int_{T_2} e_{in}dt = LI_c + R_{in}\int_{T_2} i_c dt \tag{6}$$

where T_2 = duration of the transient response.

Since fast response ($T_2 << L/R_{in}$) is usually desired in practice and is obtained by considerably overdriving the input during the transient period, the first terms on the right-hand sides of equations 5 and 6 are then predominant and the second terms can be neglected. The modified input volt-second integral which results is thus that for an amplifier having an ideal control winding of zero resistance. This integral, not involving i_c, is independent of input waveform parameters and depends only upon L and the steady-state value of control current. The transfer ratio calculated using the simplified input integral then is a simple constant which can be used to calculate input volt-second requirements given specified output conditions. Curves of voltage-time integral transfer ratio calculated using this simplification are given in Fig. 15, utilizing the data for Fig. 13 and the waveforms of Fig. 9. The assumption that the output waveform with signal is of the same form as the waveform without signal was again made in calculating the output voltage-time integrals.

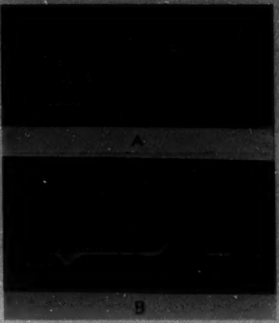

Fig. 17. Partial switching output voltage waveforms for 10 ferrite and 10 metal tape cores

A—(Ferrite cores) vertical scale = 5 millivolts per cm, horizontal scale = 0.2 µsec per cm

B—(Mo-Permalloy cores) vertical scale = 16 millivolts per cm, horizontal scale = 0.5 µsec per cm

The voltage-time integral transfer ratio curves of Fig. 15 show that transfer ratios greater than 1.0 are obtained if L_c is sufficiently small. That such flux gains are possible at high frequency has also recently been shown by Crane[11] in experiments with coupled magnetic logic elements.

TEMPERATURE STABILITY

The stability of voltage gain with respect to variation in ambient temperature was measured (see Fig. 16). To obtain temperature data, the amplifiers, including mounting bases, were operated in a constant-temperature oven; core cooling was by air convection and heat conduction via the windings. The gain stability of the metal-core amplifier is nearly constant over the range indicated, which is to be expected. The gain stability of the ferrite-core amplifier is also quite con-

stant over a narrower temperature range (20-50 C) for excitation frequencies of 1 mc or less.

The amplifier zero balance is also dependent upon temperature and excitation frequency. Quantitative measurements of zero drift were not made, but it appears to be satisfactory over the same range of temperature and frequency for which gain stability is obtained.

The gain and zero stability for the ferrite amplifier, especially at higher frequencies of excitation, is considerably improved by immersing the amplifier in cooling oil. Quantitative data concerning this were not obtained.

UNIFORMITY

Amplifiers were constructed using pairs of cores picked at random and compared for gain and zero balance. The uniformity of balance was found to be considerably better for the ferrite-core than for the metal-core amplifiers. To investigate this further, pulse switching data were obtained for a number of cores of each type picked at random; superimposed switching output waveforms are shown in Fig. 17. The cores were driven to saturation by one polarity of drive and preset approximately 50% by the other polarity which was of constant amplitude. The uniformity of flux switched under these conditions is better for the ferrite than for the metal cores.

In Table I are given balance and sensitivity data for five amplifiers of each type constructed using randomly selected cores and operated at room temperature with air-convection cooling. Results are also given for two values of R_e. It is probable that the gain and zero balances vary too much for many applications; for these better uniformity can be obtained by core matching.

The molybdenum permalloy cores used here were chosen from a different lot than those used in obtaining the data reported earlier in the paper and exhibited a lower coercive force and a poorer squareness. The amplifier sensitivities with these cores were greater by a factor of more than two compared to the sensitivities for the metal cores used earlier.

Magnetic Memory Sensing Application

The very low input impedance of this type of amplifier and its great voltage sensitivity lead one to suggest its use as an input mixing sensing amplifier for random-access magnetic memories. Conventional magnetic-core memories have typical access times of about 10 μsec and require a sensing amplifier response time of 1 or 2 μsec. This type of magnetic amplifier will satisfy such a response requirement if its input L/R time constant is small enough. A possible system is outlined in Fig. 18. Sensing of a single digit plane core array of a memory is shown as representative. Information storage and interrogation is done conventionally; e.g., by X-Y current coincidence, as shown in the figure, or by a linear mode of selection. However, rather than sensing conventionally by using a single transistor- or vacuum-tube amplifier coupled to a sensing winding which links every core of the array, in this system the sensing winding is split into shorter windings each sensing only a few cores and the outputs of these are mixed together in groups (via the resistances R indicated in the figure) and each group is fed into a magnetic amplifier. Only a limited number of sensing winding outputs can be mixed per magnetic amplifier without slowing down the response of the amplifier too greatly due to input shunting. Further mixing is done by series connecting the outputs of the magnetic amplifiers to a common output transformer. In this latter mixing operation, only one of the amplifiers is excited at a time (excitation of A or B or C in Fig. 18) to avoid the cumulative effects of amplifier zero unbalances.

The noise problem will be considered next. During the memory-reading operation many unselected memory cores generate small disturb signals. In each sensing winding these disturbs can be made to cancel by favorable choice of a sensing polarity configuration, but statistical fluctuations in the disturbs cause this cancellation to be imperfect and small net disturb signals usually result which may be additive in the amplifier input mixing circuits. To maintain a satisfactory signal-to-noise ratio in each amplifier, it is therefore necessary, for this reason (as well as for the response time reason previously mentioned), to limit the number of sensing winding outputs which are mixed into a single amplifier. A satisfactory over-all signal-to-noise ratio is then obtained by exciting only the one magnetic amplifier of the array which is being signalled by the wanted storage information. All unexcited amplifiers remain inactive and do not contribute noise in the output circuit loop. To do this,

A—"1" information: vertical scale = 10 millivolts per cm
B—"0" information: vertical scale = 10 millivolts per cm

additional logical circuitry associated with that of memory addressing for locating the correct amplifier to excite is necessary, and the excitation circuits must each transmit sufficient power to drive the amplifier cores adequately. Magnetic logic devices appear to be promising for this purpose, especially those using transfluxors to gate the carrier.[12]

The necessary system with magnetic sensing of using split sensing windings has another advantage. A sensing winding which links many cores acts as a delay line. An information signal generated at the far end of such a line may be seriously delayed in reaching the amplifier and, because the delay depends upon the interrogated location, time strobing of the output may be difficult. By splitting the sensing winding into shorter sections, the signal delay in reaching the amplifier is greatly reduced and the delay becomes predominantly the constant delay due to the response of the magnetic amplifier itself. Transmission in the amplifier output loop could introduce another variable delay, but in practice this is negligible because relatively few magnetic amplifiers are coupled and single-turn output loops can be used to reduce the delay per amplifier. Single-turn loops result in low voltage gain, but this can be increased by the use of a step-up transformer as shown in Fig. 18.

The design steps to determine the number of cores which can be sensed per winding and the number of windings which can be mixed per amplifier are outlined in the following.

The resistance R must first be chosen to obtain sufficient signal current to be detected by the amplifier from the "1" state voltage generated by the memory core during interrogation. However, this current must not exceed a value which could alter the information state of other cores. The number of cores which can be linked by a single sensing winding is next found, considering the contribution to R due to the winding resistance and the signal voltage drop due to inductive effects in the cores. External resistance can be eliminated if the winding resistance itself is made equal to R. The number of sensing windings which can be mixed are finally determined. Aside from the disturb noise consideration, the main consideration here, as already mentioned, is the response time. The shunt resistance of the paralleled sensing winding circuits must be great enough to yield a sufficiently small response time for the L_c value used. Signal-current shunting by the inactive windings is not usually important because the amplifier input resistance is in general negligible compared to the shunting resistance. If long response times are permissible in the design, however, signal shunting should be also be considered.

For the amplifiers to have good gain, some input choke L_c is required. This is usually lumped, but in some cases the self-inductances of the sensing windings themselves are sufficiently large that their paralleled inductance is enough to reduce the output loading to a tolerable value without the need for additional series inductance in the control circuit.

During excitation, carrier-frequency voltages induced on the control windings of the amplifiers cause carrier-frequency currents to flow in the sensing windings. These currents, if sufficiently large, could alter the information states of the cores. However, in practice, because of the choking action of L_c and the paralleling of sensing windings, the individual currents flowing in each winding are negligible.

In Fig. 19 are shown typical waveforms of the "1" and "0" information output signals obtained from a ferrite core sensing amplifier. The input signal was furnished by a small slow-switching memory core for purposes of experimental convenience. The excitation frequency was 500 kc, the horizontal sweep 10 μsec per centimeter, and $R_c = 0.3$ ohm. The peak value of control current was 1 ma.

Another advantage of magnetic amplifier sensing with respect to conventional methods is the capacity of this type of amplifier to recover quickly after a large input signal has been applied. Such inputs can occur when inhibiting current pulses are applied to the memory core array during the information writing portion of the memory cycle. With transistor or vacuum-tube low-level amplifiers having several capacitance coupled stages the recovery time may be prohibitively long. To obtain sufficiently fast recovery d-c coupling must usually be resorted to and this introduces zero-drift difficulties. With magnetic amplifiers on the other hand, only a single stage is needed and the output response is sufficiently nonlinear that the amplifier is self-limiting. This action is illustrated with the aid of the waveform photograph of Fig. 20. This shows the output carrier wave envelope obtained for a 1-ma input pulse applied soon after a saturating input pulse of 100 ma. The input L/R time constant of the amplifier was 4 μsec. This time constant, although too large for a practical system, was chosen for demonstration purposes. Small-signal response was nearly complete in two time constants, or about 8 μsec. From the figure it can be seen that the recovery of the amplifier was nearly complete about 20 μsec after the termination of the saturating pulse (both the output envelope and the current pulse waveforms were off scale on the oscilloscope during the saturating pulse interval). This recovery time is only slightly greater than twice the small signal response time. Recovery in less than 20 μsec to make the device practical could of course be obtained by reducing the L/R input time constant.

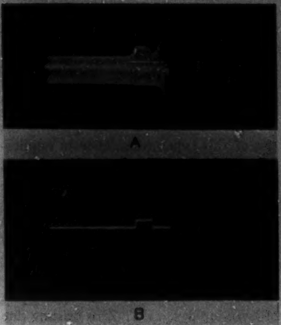

Fig. 20. Recovery of magnetic amplifier after application of 100-ma input pulse. Time scale = 20 μsec per cm

A—Output voltage = 10 millivolts per cm
B—Input current pulses = 2.5 ma per cm

Conclusions

High-frequency magnetic amplifiers of magnetic modulator design, asymmetrically excited and constructed of small ferrite or metal tape cores, show promise for stable amplification of signals as small as 10^{-19} watts with response times of 10 μsec or less.

A voltage sensitivity of less than 1 μv can be obtained which permits the use of this type of amplifier in applications, such as computer memory sensing, in which considerable signal voltage division occurs because of mixing. High voltage gain and a moderate power gain can be obtained even with only a few turns on the output winding. Carrier gating of the amplifier is feasible. Recovery is rapid after the application of large input signals. Zero drifting due to heating of the magnetic cores during excitation and the necessity for core matching to obtain best zero balance are difficulties for which complete solutions can undoubtedly be found.

A Mathematical Model for a Magnetic-Amplifier Reactor Core

H. H. WOODSON
ASSOCIATE MEMBER AIEE

Vol. 7
Pt. 1
1959

IN THE ANALYSIS and design of self-saturating magnetic amplifiers, the flux-resetting characteristics of the saturable reactors must be known either analytically or graphically. In the past, the reactor flux-resetting characteristic has been represented by a single, unique relation between flux and resetting magnetomotive force.[1–3] Such a restrictive reactor representation has limited usefulness because changes in operating conditions such as control voltage waveform, relative control circuit impedance level, and supply frequency cause considerable change in the flux-resetting characteristic.

More recently, several studies have been aimed at improving the representation for a saturable reactor to include the dynamic properties. Several of these studies[4–8] have dealt with the experimental behavior of saturable reactors over a wide-range of operating conditions. The principal shortcoming of these studies is that they are purely experimental; consequently, without a theoretical model to use for extrapolation, experimental information must be obtained for every conceivable operating condition. Friedlander has been concerned with the prediction of flux-resetting characteristics by using ferromagnetic theory and making some assumptions about the statistical nature of a polycrystalline sample.[9] The types of mathematics encountered in this treatment restrict the analyses to simple, constant-current resetting characteristics, thus, the results are applicable to a restricted class of magnetic-amplifier problems. Still other workers have determined or assumed empirical expressions describing flux resetting and have used them in magnetic-amplifier analyses.[10] Such an approach suffers from the lack of a model of the physical processes that would reduce the amount of experimentation necessary for the description of a given problem.

This paper will describe the derivation of a mathematical model for a saturable reactor core. The starting point is domain theory of ferromagnetism and the object is equations which are simple enough to have engineering applicability. In essence, the approach is the following: 1. flux reversal is assumed to occur by the growth of a large number of domains; 2. the walls of each domain are assumed to move against linear damping forces; 3. the domains are assumed to be uniformly distributed throughout the material; 4. all domains are assumed identical except for their starting fields; 5. the starting fields are assumed to have some distribution function. This approach has the elements of the one cited previously by Friedlander,[9] who assumed that all domains are identical in all respects but that there is a distribution of domain positions throughout the sample. In addition he assumed all nucleation of domains to occur at material surfaces. Friedlander's treatment and this paper represent only two of a variety of ways in which the behavior of a single domain can be averaged over some statistical property to obtain a representation for a polycrystalline sample.

In any treatment of this sort the assumptions are of necessity speculative because of the present state of knowledge in the field. The use of these assumptions to obtain plausible explanations for observed phenomena not only serves present day engineering needs but also indicates areas where fundamental research may yield useful results in either verifying or proving invalid the various assumptions.

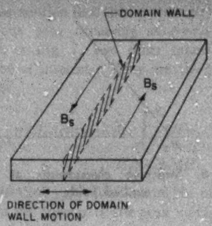

Fig. 1. Illustration of domain wall movement

Theoretical Basis for Model

The starting point for the derivation of the mathematical model for a polycrystalline ferromagnetic material is domain theory of ferromagnetism.[11–13] In this theory a material consists of domains in which the material is magnetically saturated. The directions of the magnetization in the domains are the directions of easy magnetization of the material. The domains are separated by domain walls through which the direction of magnetization changes abruptly. When a specimen is completely saturated in one direction, only one domain covering the entire specimen exists; when a reverse field is applied to reverse the magnetization, small domains of reverse magnetization form and their walls move irreversibly perpendicular to the direction of magnetization to effect a flux reversal. This is illustrated in Fig. 1, where B_s represents the saturation flux density.

From this discussion it is apparent that there are three characteristics of a domain that must be described: 1. The field necessary to form or nucleate domains of reverse magnetization in a sample that has been previously strongly saturated. 2. The minimum field (starting field) necessary to make the walls of the domain move through the material to change the net flux. 3. The mechanisms which impede the motion of a domain wall through the material.

The process of nucleation is not well understood although there have been theoretical[14,15] and experimental[13,16] studies to determine some of the characteristics of the process. The assumptions to be made here are given in the next section.

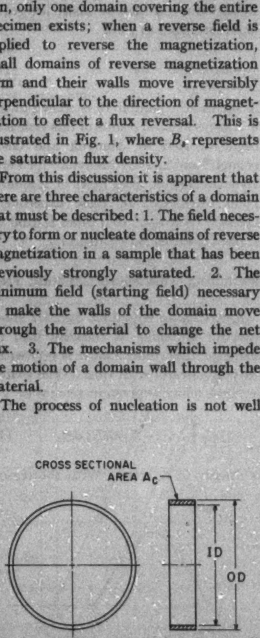

Fig. 2. Geometry of specimen for analysis

It is well accepted that the motion of an element of an existing domain wall can be described by the equations[16–18]

$$f(\delta)\frac{d\delta}{dt}=K_1(H-H_s),\ \text{for}\ H>H_s \tag{1}$$

where

δ = distance of domain wall from nucleating site
$f(\delta)$ = position dependent damping factor
K_1 = material constant
H = applied magnetic field
H_s = starting field

Equation 1 is simply a first-order differential equation expressing the fact that the force that drives the wall (right-hand side) is all absorbed by a dissipative damping mechanism whose factor $f(\delta)$ depends on position.

In the light of present understanding, equation 1 should include an inertia term; however, it has been shown experimentally that inertia terms become appreciable only at much higher frequencies than are of interest here.[19]

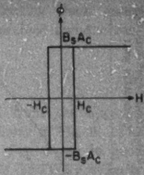
In general the several factors in equation 1 are impossible to describe in detail for every element of every domain wall in a polycrystalline material. For instance the damping factor not only depends on spin relaxation damping which is thought to be an inherent property of a material[15,16] but also on macroscopic eddy currents which in turn depend on the detailed configuration of all domain walls relative to material surfaces. The reduction in local magnetic field caused by macroscopic eddy currents is included in the $f(\delta)(d\delta/dt)$ term. The field H_s necessary to start the domain wall moving depends mostly on the detailed structure of a material because domain walls tend to become attached to imperfections. Thus, for generality, the starting field should be a function of wall position. Since little is known about the nature of these quantities, plausible assumptions will be made in the next section.

When an element of a domain wall moves it changes the flux density from the saturation value B_s in one direction, to B_s in the other direction. Thus the rate of change of flux due to motion of the element is

$$\frac{d\phi_1}{dt}=2B_s\frac{dA_1}{dt} \tag{2}$$

where

Fig. 3. Hysteresis loop assumed for material



$\frac{d\phi_1}{dt}$ = contribution to total rate of change of flux made by domain wall element
B_s = saturation flux density
$\frac{dA_1}{dt}$ = rate at which area perpendicular to domain wall is swept out by element of wall

Equations 1 and 2 form the theoretical basis for the mathematical model to be derived. The type of information necessary for applying these expressions to the analysis of a polycrystalline sample is not available; consequently, assumptions must be made to complete the model.

Assumptions

1. The specimen to be analyzed is the toroidal geometry shown in Fig. 2. The inside-diameter–outside-diameter ratio is assumed very near unity so that the applied field is uniform throughout the material. The easy direction of magnetization is around the circumference; thus, all magnetization will be in this direction and domain walls will move radially or axially.
2. The nucleating field for each domain is less than its starting field.
3. The d-c hysteresis loop for the specimen is rectangular as shown in Fig. 3. That is, if a field infinitesimally greater than H_c is applied when the material is saturated negatively, the flux will reverse completely. When the specimen is completely magnetized in either direction, no further flux change can occur.
4. The rectangularity of assumption 3 states that at least one domain has a starting field H_c (coercive field) which remains constant throughout the material, and that H_c is the minimum starting field for the material. It is furthermore assumed that all domains have starting fields $H_s > H_c$ which are constant throughout the domain wall motion.
5. All flux changes occur irreversibly.
6. Before any flux change, the material has been saturated strongly to establish uniform initial conditions for a subsequent flux change. This assumption agrees well with conditions found in most self-saturating magnetic amplifiers.

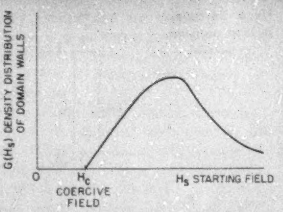


Fig. 4. Distribution of starting fields

7. All domains are assumed identical and uniformly distributed over the cross section of the specimen except that the starting field H_s varies among domains according to some distribution function which is independent of applied field.
8. Each domain is described by equations of the form of equations 1 and 2.
9. The domain wall damping factor $f(\delta)$ is independent of wall position, $f(\delta)=1$ in equation 1.
10. The time rate of change of applied field is small so that no large, abrupt changes in the amount of domain wall occur during a flux change. This assumption disagrees with the type of operation found in full-wave self-saturating magnetic amplifiers.

The Mathematical Model

To complete the mathematical model with the use of equations 1 and 2 and the above assumptions, some averaging must be done. In assumption 7 it is stated that the starting field for the domain walls varies over some distribution. Assume that this distribution function defined by $G(H_s)$ is some general curve shown in Fig. 4. The function $G(H_s)$ expresses how many elements of domain wall have starting fields between H_s and H_s+dH_s.

Now, multiply both sides of equation 1 by $G(H_s)$ and integrate over H_s to obtain

$$\frac{d}{dt}\int_{H_c}^{H}\delta G(H_s)dH_s=\int_{H_c}^{H}K_1(H-H_s)G(H_s)dH_s \qquad (3)$$

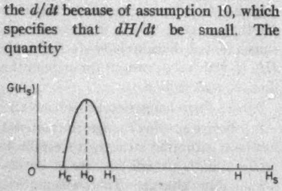

Fig. 5. One type of distribution of starting fields

The integral on the left is taken inside the d/dt because of assumption 10, which specifies that dH/dt be small. The quantity

$$\int_{H_c}^{H}\delta G(H_s)dH_s$$

represents the total distance over which all domain wall elements move. For a complete flux reversal this quantity will proceed from zero to some constant value no matter how the reversal comes about, provided the assumptions are satisfied. Thus an average normalized domain dimension r can be defined as

$$r=K_2\int_{H_c}^{H}\delta G(H_s)dH_s \qquad (4)$$

with the constant K_2 defined to make $r=$ unity, when the flux is completely reversed. Substitution of equation 4 into equation 3 yields

$$\frac{dr}{dt}=K_1K_2\int_{H_c}^{H}(H-H_s)G(H_s)dH_s \qquad (5)$$

This is one equation for the general mathematical model.

When equation 2 is integrated over all domain wall elements that are moving, there results

$$\frac{d\phi}{dt}=2B_s\frac{dA_d}{dt} \qquad (6)$$

where
ϕ=total flux
A_d=total area swept out by moving domain walls

At the start of a flux reversal ($r=0$), $A_d=0$; and at the completion of a flux reversal ($r=1$), $A_d=A_c$.

An additional assumption is that as the area A_d changes it is a function of only the average normalized domain dimension r; consequently, equation 6 can be rewritten as

$$\frac{d\phi}{dt}=2B_sA_cg(r)\frac{dr}{dt} \qquad (7)$$

where $g(r)$ is a function of r which has the property

$$\int_0^1 g(r)dr=1 \qquad (8)$$

The function $g(r)$ can be interpreted as a "shape function." That is, when the applied field H is constant in equation 5, r varies linearly with time; and, from equation 7, $g(r)$ represents the shape of the voltage pulse for constant field switching.

Equations 5 and 7 are the mathematical model for the polycrystalline material. Before this model can be used, the functions $G(H_s)$ and $g(r)$ must be defined. These functions will now be considered.

Switching with Large Constant Field

Consider the case of a material in which the range of starting fields is limited and the distribution function is as shown in Fig. 5. When the applied field is sufficiently large, the integration in equation 5 can be simplified by assuming $G(H_s)$ to be an impulse at $H_s=H_0$, the value of field that divides the area under the curve in half, and having an area equal to the area under $G(H_s)$. Such an approximation yields

$$\frac{dr}{dt}=K_1K_2\int_{H_c}^{H}(H-H_s)G(H_s)dH_s=K_1K_2N_0(H-H_0) \qquad (9)$$

where N_0 is the area under the $G(H_s)$ curve.

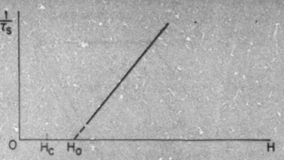

Fig. 6. Switching characteristic at high applied fields

Now consider the time τ_s required to switch the flux in this reactor when the applied field H is constant and $H>>H_1$. Equation 9 can then be easily integrated and rearranged to yield

$$\frac{1}{\tau_s}=K_1K_2N_0(H-H_0) \qquad (10)$$

A sketch of equation 10 is shown in Fig. 6. Experimental results of this type have been reported by Menyuk and Goodenough[18] and later by Menyuk[20] for Permalloy cores made from tapes of 1/8-mil to 1-mil thickness. In these experiments the field H_0 was 1.5 to 2 times H_c and the applied field ranged up to 10 H_c.

Switching with Small Constant Field

Reference to equations 5 and 7 shows that for switching at constant field the shape of the voltage pulse is $g(r)$ with r varying linearly with time. The switching time which is given in general by

$$\frac{1}{\tau_s}=K_1K_2\int_{H_c}^{H}(H-H_s)G(H_s)dH_s \qquad (11)$$

is usually of interest. With the reason-

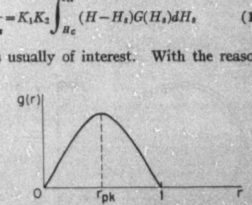

Fig. 7. Shape of voltage pulse for constant applied field

able assumption that the function $g(\tau)$ has only one peak occurring at $\tau=\tau_{pk}$, as shown in Fig. 7, two other quantities may be of interest. They are the peak voltage

$$\left(\frac{d\phi}{dt}\right)_{pk}=2B_sA_cg(\tau_{pk})K_1K_2\int_{H_c}^{H}(H-H_s)G(H_s)dH_s \quad (12)$$

and the time τ_{pk} required from the initiation of the pulse until the peak voltage is reached:

$$\frac{1}{\tau_{pk}}=\frac{K_1K_2}{\tau_{pk}}\int_{H_c}^{H}(H-H_s)G(H_s)dH_s \quad (13)$$

When the applied field has a value in the range where $G(H_s)$ has an appreciable value, no simple linear relation such as equation 10 results. Instead, the function $G(H_s)$ must be known and equations 5 and 7 used without simplification. In the absence of other information from which to obtain $G(H_s)$, it can be inferred from measurements of constant field-switching characteristics.

Any shape of function $G(H_s)$ can be represented to any degree of accuracy over any range of fields by the power series

$$G(H_s)=\sum_{n=0} a_n(H_s-H_c)^{n+p} \quad (14)$$

where

$H_s>H_c$
a_n are constants
$-1<p<0$
n is an integer

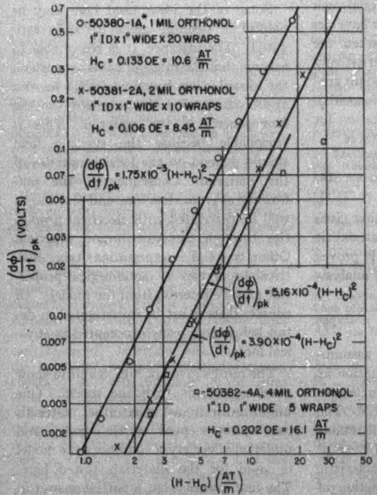

Fig. 8 (left). Plots of $(d\phi/dt)_{pk}$ versus $(H-H_c)$ for three reactors

The peak voltage (equation 12) will be used subsequently, but the process that follows can just as easily be used with τ_s and τ_{pk}.

Substitution of equation 14 into equation 12 and integration of the result yield

$$\left(\frac{d\phi}{dt}\right)_{pk}=2B_sA_cg(\tau_{pk})K_1K_2\sum_{n=0}^{\infty}\frac{a_n}{(n+p+1)(n+p+2)}(H-H_c)^{n+p+2} \quad (15)$$

Constants a_n and p could be chosen to make this expression fit very closely a curve of $(d\phi/dt)_{pk}$ versus $(H-H_c)$; however the resulting model would be difficult to apply in any analytical problems. It proves more practical to obtain an approximate fit with experimental curves in which only one term in the series is retained.

To show that this is so in at least one case, consider the experimental curves of Fig. 8 which were taken with the use of the circuit of Fig. 9. When switch S, which was a set of parallel beam power tubes (*6 L 6*), was closed, the core was strongly saturated. When switch S was opened, the reset source V_r reset the core through the resistance R_r, which was so large that the current i_r remained essentially constant during the resetting process. It is evident from Fig. 8 that these curves are represented to a good degree of accuracy by an $(H-H_c)^2$ term. Consequently, for representing these cores, $(n=p=0)$ can be specified and the constant A defined by

$$A=B_sA_cg(\tau_{pk})K_1K_2a_0 \quad (16)$$

can be determined from the approximate solid curves shown in Fig. 8. The results obtained in Fig. 8 are in good agreement with those reported previously by Huhta.[8]

It is interesting to note that with $n=p=0$ the distribution function $G(H_s)$ is a constant over the range of fields considered. Such an approximation is shown in Fig. 10.

Switching with Slowly Varying Field

To show that the mathematical model is applicable to at least one case in which the applied field varies, and is therefore applicable to some types of actual magnetic-amplifier circuits, consider the resetting of a reactor with the circuit of Fig. 9 in which the reset resistance R_r is small enough that the reset current i_r varies appreciably during the resetting process. To obtain a comparison with experimental results, assume the reactor to have a constant-current switching characteristic that varies with $(H-H_c)^2$, as shown in Fig. 8. Then the mathematical model of equations 5 and 7 reduces to

$$\frac{d\tau}{dt}=K_1K_2\frac{a_0}{2}(H-H_c)^2 \quad (17)$$

$$\frac{d\phi}{dt}=B_sA_cg(\tau)K_1K_2a_0(H-H_c)^2 \quad (18)$$

The voltage equation for the reset circuit is

$$V_r=i_rR_r+N_r\frac{d\phi}{dt} \quad (19)$$

Multiplying this expression by N_1/l_mR_r yields

$$\frac{N_rV_r}{l_mR_r}=H+\frac{N_r^2}{l_mR_r}\frac{d\phi}{dt} \quad (20)$$

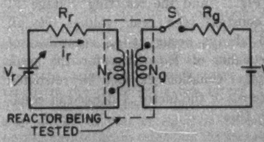

Fig. 9 (right). Circuit for checking model with small constant field and with slowly varying field

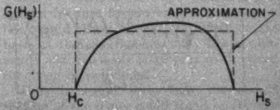

Fig. 10 (right). Approximation for function G(H) to yield switching characteristics that vary as the square of the effective field

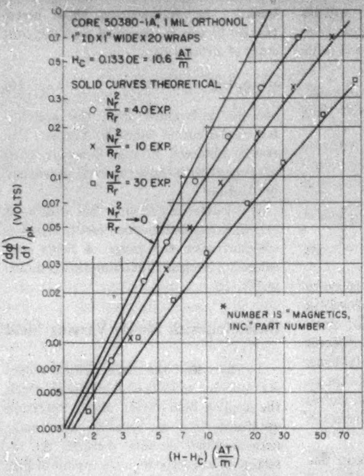

Fig. 11. Same as Fig. 8, for various values of N_r^2/R_r

where

$$H=\frac{N_r i_r}{l_m} \tag{21}$$

is the instantaneous applied field, and l_m is the mean length of the magnetic path.

Assuming that the switch S in Fig. 9 is closed at $t=0$, with $r=0$, simultaneous solution of equations 17, 18, and 20 yields

$$\frac{d\phi}{dt}=B_sA_cq(r)K_1K_2a_0\times \left[\frac{-1+\sqrt{1+4B_sA_cg(r)K_1K_2a_0\frac{N_r^2}{l_mR_r}\times \left(\frac{N_rV_r}{l_mR_r}-H_c\right)}}{2B_sA_cg(r)K_1K_2a_0\frac{N_r^2}{l_mR_r}}\right]^2 \tag{22}$$

Whenever the function $g(r)$ has only one peak occurring at r_{pk}, as shown in Fig. 7, and the resetting voltage V_r is constant, the peak voltage $(d\phi/dt)$ will always occur at r_{pk} regardless of the value of R_r. Thus for the peak voltage, equation 22 can be rewritten in terms of the factor A defined in equation 16 as

$$\left(\frac{d\phi}{dt}\right)_{pk}=A\times \left[\frac{-1+\sqrt{1+4A\frac{N_r^2}{l_mR_r}\left(\frac{N_rV_r}{l_mR_r}-H_c\right)}}{2A\frac{N_r^2}{l_mR_r}}\right]^2 \tag{23}$$

The factor A determined from the constant current switching curves of Fig. 8 for the 1-mil core is used with equation 23 to predict curves for three values of N_r^2/R_r, as shown in Fig. 11. Experimental points are shown for the same conditions, and the agreement is good.

Further Simplifications

So far nothing has been said about the detailed shape of the function $g(r)$. A high-performance magnetic material such as the 50Ni-50Fe material will have an almost rectangular **B-H** loop when the flux is driven sinusoidally. Alternatively when the flux is switched at constant current the voltage pulse is almost sinusoidal. Consequently, a good approximation for so-called rectangular loop material is

$$g(r)=\frac{\pi}{2}\sin \pi r, \text{ for } 0\leq r\leq 1 \tag{24}$$

Although such an approximation gives a good representation of the material, it makes any analysis difficult.[21] It proves more profitable in many cases of analysis to assume that $g(r)$ is a constant:

$$g(r)=1, \text{ for } 0\leq r\leq 1 \tag{25}$$

For instance, such a simplifying assumption allows the application of equation 22 directly to the analysis of a single-core self-saturating magnetic amplifier.[21] The simplification of equation 25 still retains the essential nonlinearity of the $(H-H_c)^2$ variation in the switching characteristic and therefore allows good prediction of single-core self-saturating magnetic-amplifier characteristics over a wide range of operating conditions, e.g., N_r^2/R_r frequency.[21]

A further simplification that can be made for operation at one frequency is to assume a $g(r)$ given by equation 25 and to linearize equation 17 and 18 about some mid-range value of applied field H. Such a simplification results in the representation of the saturable-reactor exciting characteristics as a constant-current source shunted by a constant resistance. This approximation which leads to extremely simple and easily interpretable magnetic-amplifier analyses is illustrated in a compansion paper by Frankenthal.[22] This linear approximation can easily be correlated with the incremental permeability defined by Roberts[4] for constant current resetting. Thus, the results of a Roberts core test can be used with this linear model to predict magnetic-amplifier performance for other than constant-current reset.

Results and Conclusions

In the derivation of the mathematical model, so many speculative assumptions have been made that some readers may doubt that there is any connection between the theory of ferromagnetism and the resulting model. With the present state of knowledge, this point can be argued but not settled. It is the hope of the author that arguments and further experiments will ensue to shed further light on the problem.

Some of the ideas used here may be helpful in defining areas to be investigated. For instance, it is reasonable to assume that the range of fields over which the distribution function $G(H_s)$ has an appreciable value, is governed by the homogeneity of the material. This is reasonable because the starting field should depend on the local properties of the material. Consequently, the uniformity of grain structure and size might well be correlated with electrical properties through this distribution function. Other types of interpretations tying electrical properties to metallurgical properties may be inferred from the model. Of course, these must be investigated in detail before they can be accepted as physical facts.

The results given in Figs. 8 and 11 show good agreement with the model. One might naturally ask what other materials can be represented by the model, and under what variety of conditions the model is valid for the materials tested here. The first question has a partial answer in some indirect evidence published about magnetic-amplifier performance over a supply frequency range.[22]

The answer to the second question is covered in some detail in a companion paper by Lovell.[24] Suffice it to say that a key assumption in the analysis was that the applied field C does not vary appreciably. This assumption was made to allow the assumption of a uniform distribution of domain walls which remains uniform throughout the flux reversal. If, for instance, the field is increased abruptly during the resetting process, new domain walls will, no doubt, be formed and their motion with their resulting $g(r)$ functions must be added, starting at a time $t>0$ in the switching process. It is doubtful that the present model would describe such a process; how well it does is discussed by Lovell.[24]

In spite of all doubts about the model, it can be useful in magnetic-amplifier analysis to improve the quality of a design procedure to one that does not require a cut-and-try process using several breadboard models to arrive at a final design.

◆

Discussion

F. J. Friedlaender (Purdue University, Lafayette, Ind.): Dr. Woodson presents an interesting model for the reversal of flux in certain core materials. A comparison between his model and those suggested by other authors[1-3] would seem worth while. Dr. Woodson assumes that flux reversal initiates as a volume process in his cores, whereas it has been shown previously[1,2,4] that in nickel iron cores flux reversal initiates at the surface.

If flux reversal initiates at the surface, eddy currents introduce a position-dependent damping factor (eddy currents cannot be neglected in the 2-mil tape cores commonly used in magnetic amplifiers at 60 cycles per second, or in thinner tapes at higher frequencies). Dr. Woodson assumes that damping is not a function of the domain wall position and therefore does not express explicitly the resistivity of the core material. How do such factors as the resistivity, the spin relaxation damping constant, and the thickness of the cores enter into the describing functions?

Perhaps the author's model is to be considered merely as an elegant mathematical artifice for the analysis of magnetic amplifiers, in which case it is not clear how the model may be used to handle such questions as the influence of the grain size; this type of question requires a model which is more closely based on the phenomenological processes.

Incidentally, the grain size does not seem to affect the process of flux reversal significantly. This statement is based on recent experiments that we have performed on grain oriented 50% Ni-Fe tape cores with rather uniform grain sizes varying from 10^{-3} mm to larger than 1 mm.

R. C. Barker (Yale University, New Haven, Conn.): In the first sentence of his "Results and Conclusions" the author has made an important statement. This discussion is designed to enlarge on one or two of the points which may be responsible for the author's apprehension.

The paper is divided into two sections: the first consists in some assertions about the magnetization process in metallic tapes; the second has to do with modification and corroboration of the popular inverse-switching-time curves, as summarized in Figs. 6, 8, and 11. The question of the connection between the two may be approached by examining the use made by the author of this analytical description of the ferromagnetic process. He examines flux switching under three conditions in terms of the two functions $G(H_s)$ and $g(r)$, introduced from the first part of the paper. The first switching condition results in equation 10, which uses neither function, and is readily obtained by extending equations 1 and 2. In the second condition of switching, the choice of a power series for $G(H_s)$ results in equation 15, which is a power series in $(H-H_s)$. This amounts to the recognition that the curves of Fig. 8 rectangular paper are not linear. Standard procedure in such cases is to represent the curve by a few terms of a Taylor series expansion. Thus, a relationship similar to that of equation 15 could be obtained by again extending the meaning of equations 1 and 2. This would be entirely equivalent to the author's procedure, because he has chosen the term in the second power of $(H-H_s)$ solely on the basis of the experimental fit. These comments also extend in large part to the third condition of switching.

Thus it would seem that the second portion of the paper could stand on its own merit since it does not depend in any crucial sense upon the existence or the particular form of the functions $G(H_s)$ and $g(r)$. Certainly, to use the experimental corroboration of the equations to "prove" the validity of his assumptions and conjectures on the process of ferromagnetism would be to commit the well-known "fallacy of affirming the consequent."

With regard to the first portion of the paper, the author has been careful to warn that there are many speculative assumptions made. A debate of the validity and consistency of these assumptions would probably be beyond the author's intended scope. But assumptions 2 and 3 deserve comment. With regard to 2, the nucleation field for a domain in a pure crystal is actually larger than the field required for irreversible domain-wall motion. This fact is directly responsible for the tendency toward squareness of the hysteresis loop mentioned in assumption 3. However, as the material is brought out of saturation, the large number of independent domains and the presence of impurities does result in the fact that the field required for the nucleation and initial growth of domains is less than the "starting field" required for further irreversible growth. And the presence of metallurgical irregularities in polycrystalline materials implies further that there is some distribution of these starting fields over the wall elements about the various nucleation sites. This is true whether the domains are nucleated uniformly throughout the volume or only at the surfaces. The result is that the d-c hysteresis loop definitely has rounded coroners in polycrystalline tapes, as the measurement of a d-c hysteresis loop confirms. In this portion of the loop, the domains are changing in size and shape about the nucleating sites, and are combining to form fewer domains of smaller total wall energy. Would the author state his assumptions on the size, shape, and number of domains throughout the flux reversal process? The use of equation 2 carries with it some implications in this regard.

The author's remarks on the limited state of knowledge in this field are sincerely appreciated. Advances in this respect would undoubtedly increase our understanding of the physics of materials and would augment our creative potential as engineers. But when we consider the task of making quantitative calculations of electric circuit performance, it is interesting to contemplate the question of how we would specifically make use of a complete and detailed theory when experimental information such as that contained in Figs. 6, 8, and 11 is available to us.

H. H. Woodson: The interesting and informative discussions by two well-known workers in this field are very much appreciated. Both discussers apparently agree with the first paragraph of the "Results and Conclusions" of the paper.

I cannot fully agree or disagree with Dr. Friedlander that nucleation initiates as a surface process. I am not sure that his references prove this. For instance, his reference 1 states, "An alloy or 50% Ni, or 50% Fe can be made into a tape having a rectangular hysteresis loop by appropriate cold working and heat treating such that a strong texture is developed with the 100 plane in the plane of the tape and the 100 direction along the length of the tape. A sample of the type did not show the simple behavior previously described. Instead it appears that domains are nucleated at many places within the tape." In his reference 2, Fig. 13 is supposed to prove that nucleation is a surface process; however, the percentage spread in his points is a little too great to be completely conclusive. On the other hand, if Dr. Friedlaender has further experimental evidence of surface nucleation, I am sure it would be welcome in the literature.

I should point out that a model of the type described in this paper can equally well be adapted to the assumption of surface nucleation. The essential feature of this model is that all domains are assumed to have identical properties except for the starting field. I agree with Dr. Friedlaender that factors such as resistivity, spin relaxation damping constant, and tape thickness affect the properties of the cores; but my model does not include these effects explicitly. Further study is necessary to determine how the constants of the model are affected by material properties.

With respect to the model being an artifice for the analysis of magnetic amplifiers, Dr. Friedlaender is essentially correct. In the past, models have been so mathematically complex that they could not possibly be applied to any engineering design problem. My object in this work was to devise a model which could be used to design magnetic amplifiers and at the same time had more connection with ferromagnetic theory then previous simplified models. Along this same line, Dr. Barker's final comment indicates that perhaps a model is not really needed. Without any model, experimental information is useful only for the conditions under which it was obtained, thus a vast amount of experimental information may be necessary for a wide variety of conditions. With a reasonable model, the amount of necessary experimental information is reduced.

There were no assumptions made about the sizes, shapes, or number of domains beyond the assumption that the number is sufficiently large (and thus the sizes sufficiently small) that integration instead of summation is valid over the distribution of domains.

Theory of 3-Phase Bridge Magnetic Amplifier

I—Steady State

H. F. STORM
MEMBER AIEE

C. W. FLAIRTY
ASSOCIATE MEMBER AIEE

THE primary object of this paper is to develop a theory for the 3-phase bridge magnetic amplifier. A further object is to describe the utilization of this theory to arrive at design and performance equations which are sufficiently simple and accurate for engineering purposes. Part I deals with the steady-state operation, and Part II (which is planned for future publication) with the transient performance. Because of space limitations, the full description of the circuit components has been relegated to Part II.

With the advent of germanium and silicon rectifiers of large current capabilities, magnetic amplifiers are being used to handle power in increasing blocks. For instance, variable-speed motor drives are now available for motors of 100 horsepower and more, and power supplies for electrochemical and other applications are reaching into the 1,000-kw area.

Although the 3-phase amplifier has more parts than the single-phase version, the 3-phase connection has the following major advantages:

1. Higher utilization of magnetic and rectifier components.
2. Even distribution of load over all three phases of the supply system.
3. Smaller ripple.

For output powers of 1 kw or more, these advantages usually outweigh the drawback of requiring more parts for the 3-phase amplifier. Publications on 3-phase magnetic amplifiers are listed in references 1 through 15.

A. Circuit Connections and Supply System

The circuit under consideration is shown in Fig. 1(A); it is called a 3-phase

bridge magnetic amplifier. The amplifier consists of six identical saturable reactors (A, C', ..., B') and six identical rectifiers (REC A, REC C', ..., REC B'). The load is a pure resistance.

Terminals 1, 2, and 3 are connected to a symmetrical 3-phase supply system, having the star voltages e_{1-0}, e_{2-0}, e_{3-0}.

$$e_{1-0}=\frac{E_m}{\sqrt{3}}\cos\theta \tag{1A}$$

$$e_{2-0}=\frac{E_m}{\sqrt{3}}\cos\left(\theta-\frac{2\pi}{3}\right) \tag{1B}$$

$$e_{3-0}=\frac{E_m}{\sqrt{3}}\cos\left(\theta-\frac{4\pi}{3}\right) \tag{1C}$$

with

$$\theta=\omega t \tag{2}$$

and

$$\omega=2\pi f \tag{3}$$

The line-to-line voltages e_{1-2}, e_{2-3}, e_{3-1} are defined by equations 4

$$e_{1-2}=e_{1-0}-e_{2-0} \tag{4A}$$

$$e_{2-3}=e_{2-0}-e_{3-0} \tag{4B}$$

$$e_{3-1}=e_{3-0}-e_{1-0} \tag{4C}$$

and, when substituted in equations 1, result in

$$e_{1-2}=E_m\sin\left(\theta+\frac{2\pi}{3}\right) \tag{5A}$$

$$e_{2-3}=E_m\sin\theta \tag{5B}$$

$$e_{3-1}=E_m\sin\left(\theta-\frac{2\pi}{3}\right) \tag{5C}$$

The supply voltages are shown in Fig. 1(B) in phasor form and in Fig. 1(C) in sinusoidal form. When using the phasor diagram the instantaneous values of the voltages are obtained by rotating the entire phasor diagram counterclockwise and by taking the projections of the phasors on the stationary base line, indicated by $\theta=0$.

The dots in Fig. 1 signify winding polarities. The voltage across a winding is defined as positive when the terminal with the dot is more positive than the other terminal. A current is called positive when it flows in the direction of the arrow. The magnetomotive force is called positive when derived from a positive current, and the core fluxes are called positive when derived from positive magnetomotive forces.

The symmetries of the circuit configuration and the supply voltages suggest that whatever occurs in one branch will be repeated sequentially in certain other branches. If a period of 360° (degrees) is assumed, and identical waveshapes in all branches, phase-displaced sequentially by 60°, the sequence can be readily visualized from the phasor diagram of Fig. 2. Suppose an occurrence (such as a gate voltage or gate current) in branch A is called $f_A(\theta)$; then corresponding occurrences in the other branches are determined by

$$f_{C'}(\theta)=f_A(\theta-60°) \tag{6A}$$

$$f_B(\theta)=f_A(\theta-120°) \tag{6B}$$

$$f_{A'}(\theta)=f_A(\theta-180°) \tag{6C}$$

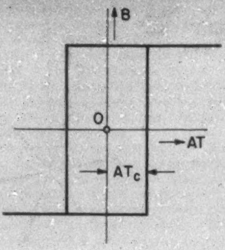

Fig. 3. Simplified B-H loops of cores. Dynamic and d-c loops requiring the same coercive ampere-turns AT_c

$$f_C(\theta)=f_A(\theta-240^\circ) \tag{6D}$$

$$f_B{}'(\theta)=f_A(\theta-300^\circ) \tag{6E}$$

Similarly, if during one and the same interval of 60° the events are known in all branches, the events in any one branch can be synthesized for the full 360° period:

$$f_C{}'(\theta)\Big|_{\theta_1}^{\theta_1+60^\circ}=f_A(\theta-60^\circ)\Big|_{\theta_1}^{\theta_1+60^\circ}=f_A(\theta)\Big|_{\theta_1-60^\circ}^{\theta_1} \tag{7A}$$

$$f_B(\theta)\Big|_{\theta_1}^{\theta_1+60^\circ}=f_A(\theta-120^\circ)\Big|_{\theta_1}^{\theta_1+60^\circ}=f_A(\theta)\Big|_{\theta_1-120^\circ}^{\theta_1-60^\circ} \tag{7B}$$

$$\vdots \qquad\qquad \vdots \qquad\qquad \vdots \qquad\qquad \vdots$$

$$f_B{}'(\theta)\Big|_{\theta_1}^{\theta_1+60^\circ}=f_A(\theta-300^\circ)\Big|_{\theta_1}^{\theta_1+60^\circ}=f_A(\theta)\Big|_{\theta_1-300^\circ}^{\theta_1-240^\circ} \tag{7E}$$

The predominant mode of operation of a 3-phase bridge amplifier has a period of 360°, identical waveshapes in all branches, and phase displaced sequentially by 60°. Other modes are possible, e.g., in underexcitation, where the period can be 720°, and where the waveshapes in saturable reactors A, B, and C are different from the waveshapes in saturable reactors A', B', and C'; a future paper is intended to deal with these modes. In this paper the mode expressed by equations 6 and 7 will be postulated throughout.

B. Operation at Minimum Load

Minimum load (current) is the smallest value to which the current in the load resistance can be reduced by the application of control current. (The minimum load point is designated by M in Figs. 9 and 12.)

1. Control Circuit Open

At the minimum load point, the load current is limited by the unsaturated gate reactance connected in series with the load resistance. That the fundamentals of operation may be seen more clearly, the assumptions in the following paragraphs are made:

The control circuit is open. The dynamic hysteresis loops of the saturable reactor cores are rectangular, Fig. 3, the d-c hysteresis loops have the same widths as the dynamic hysteresis loops, and the saturation branches of the magnetization curves are horizontal. Fluxes due to ferromagnetism only will be considered. The rectifier reverse resistances are infinitely large; all other resistances are negligible during operation at minimum load, including the load resistance. As a result, busses P and N in Fig. 1(A), have identical potential, and hence the two busses can be merged into one single bus, designated by PN.

The phasor diagram of Fig. 4(A) determines the potentials of busses 1, 2, and 3; see Fig. 4(B). The busses are drawn as the extensions of the phasor projections on the time base. Thus, the geometric distances among the busses become proportional to the bus-to-bus voltages. As the phasor diagram turns, the busses change positions accordingly. The question is: What is the potential of bus PN?

Core materials having a strictly rectangular hysteresis loop such as is shown in Fig. 3, convert the entire electric energy supplied for magnetization into heat. No reversible magnetic energy is stored. The reactor becomes a passive element, unable to return energy to the supply system.

With this in mind, consider reactors B, A', and C of Fig. 4(B). Being passive elements, these reactors cannot carry a positive current against the impressed bus-to-bus voltages of Fig. 4(B). Conversely, a negative current cannot be developed by the bus-to-bus voltages because of the blocking action of the rectifiers. With no currents flowing in the three branches B, A', and C, they cannot affect the potential of PN.

Next, examine reactors B', A, and C' of which A, and C' are assumed to be unsaturated. The qualifications placed on the hysteresis loop of Fig. 3 imply that an unsaturated core can develop a voltage, only if the magnetomotive force developed by the winding is at least equal to AT_c, where AT_c signifies the ampere-turns needed to produce the dynamic coercive force H_c:

$$AT_c=\frac{1}{0.4\pi}H_c l_{Fe} \tag{8}$$

In the analysis of magnetic-amplifier circuitry it is often helpful to split a current i into an exciting component i_x and a saturation component i_s:

$$i=i_x+i_s \tag{9}$$

The exciting component i_x is determined by the exciting (magnetizing) properties of the core, whereas the saturation component i_s is determined by the ohmic circuit resistance. Sometimes the current i is made up by only one of the two components.

To return to reactor A, a positive gate voltage will be observed to drive a gate current from bus 1 to bus PN; see Fig. 4(B). The gate current is limited by the width of the hysteresis loop; this fact qualifies the gate current as an exciting component, whose magnitude is determined by

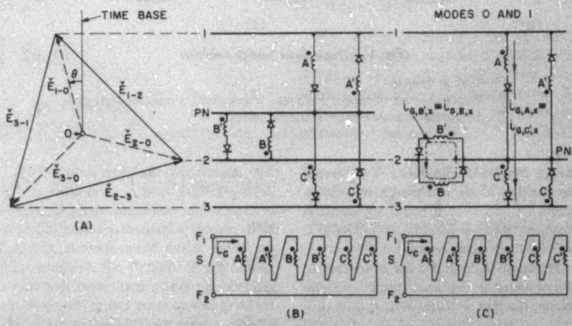

Fig. 4. Voltage and circuit configurations at minimum load

A—Phasor diagram
B—Configurations with bus PN tentative
C—Configurations with bus PN final. Accented E's indicate phasors

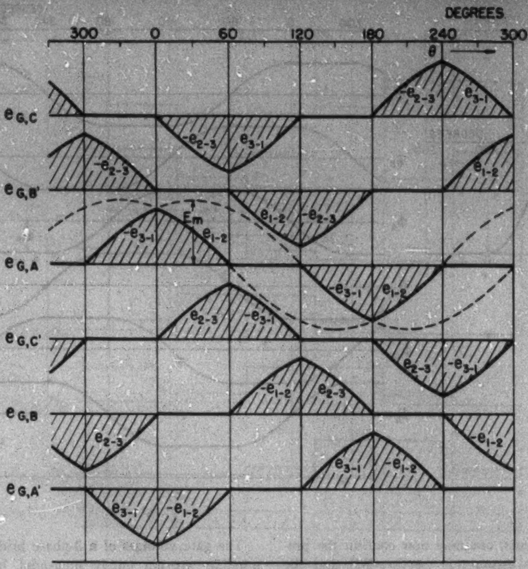

Fig. 5. Gate voltages at minimum load

$$i_{G,A,x}=\frac{AT_c}{N_G} \quad (10A)$$

If this current splits into two parts when flowing out of bus *PN* and into reactors *B'* and *C'*, neither reactor can develop AT_c ampere-turns, and hence neither reactor can develop a voltage. Consequently, the bus *PN* will drop until it becomes equal to bus 2; see Fig. 4(C). When this equality occurs, current flow through *B'* ceases, and the entire exciting current becomes available for reactor *C'*:

$$i_{G,C',x}=i_{G,A,x}=\frac{AT_c}{N_G} \quad (10B)$$

Thus, reactor *C'* can now sustain the voltage between busses *PN* and 3. By the same reasoning, one deduces that the potential of bus *PN* cannot be lower than the potential of bus 2. Hence, the answer to the question posed above is: The potentials of busses *PN* and 2 are identical for an angle *θ* as shown in Fig. 4(A). More generally, the potential of bus *PN* is identical with the smallest of the three star potentials, when measured in terms of absolute magnitudes.

2. Control Circuit Closed

The control circuit, whose resistance is assumed zero ($R_C=0$) is now being closed by means of switch *S*, Figs. 4 (B) and (C), resulting in

$$e_{C,A}+e_{C,C'}+e_{C,B}+e_{C,A'}+e_{C,C}+e_{C,B'}=0 \quad (11)$$

The effect of this circuit closure will be examined in detail by a step-by-step method. It is tentatively assumed that the gate voltages of reactors *A*, *C'*, *B*, and *B'*, as shown in Fig. 4(C) will not be affected by the closure of switch *S*.

(a) CORES A AND C'

Cores *A* and *C'* are assumed unsaturated and therefore the gate voltages will be transformed into the control circuit:

$$e_{C,A}=e_{G,A}\frac{N_C}{N_G} \quad (12A)$$

$$e_{C,C'}=e_{G,C'}\frac{N_C}{N_G} \quad (12B)$$

The voltages, $e_{C,A}$ and $e_{C,C'}$ will attempt to drive a current through the control circuit. The current flowing in the control circuit is called the "control current."

(b). CORES B, B'

Suppose these two cores are in negative saturation prior to the closure of switch *S*. The introduction of a negative control current (by closing switch *S*) cannot drive the cores more negative, and hence no voltages will be induced in cores *B*, *B'* by the control current.

Now, assume that the cores were not in negative saturation prior to the closure of switch *S*. With switch *S* closed, the negative control current may attempt to drive the core fluxes in a negative sense. If this happens, positive gate currents $i_{G,B,x}$ and $i_{G,B',x}$ will flow by transformation. These currents can circulate through the branches *B* and *B'* as shown in Fig. 4(C). Since these branches have no resistance in the forward direction (by previous assumption), the gate voltages $e_{G,B}$ and $e_{G,B'}$ remain at zero; hence the control voltages $e_{C,B}$ and $e_{C,B'}$ also remain at zero:

$$e_{G,B}=0 \quad (13A)$$

$$e_{G,B'}=0 \quad (13B)$$

$$e_{C,B}=0 \quad (13C)$$

$$e_{C,B'}=0 \quad (13D)$$

One concludes that the bus voltages shown in Fig. 4(C) remain undisturbed by the flow of control current, no matter what the state of magnetization of cores *B*, *B'*. If the control current should induce any gate currents in *B*, *B'*, these currents form theoretically a short-circuit loop, and therefore no impedance is encountered by the control current in reactors *B*, *B'*.

(c). CORES A', C

The sum of the control voltages $e_{C,A'}$ and $e_{C,C'}$ can be determined from equations 11, 13(C), and 13(D)

$$e_{C,A'}+e_{C,C}=-(e_{C,A}+e_{C,C'}) \quad (14A)$$

Transforming these voltages to the gate side yields

$$e_{G,A'}+e_{G,C}=-(e_{G,A}+e_{G,C'}) \quad (14B)$$

The forward voltages induced in gate windings *A'* and *C* cannot exceed the voltages on gates *A* and *C'* respectively:

$$-e_{G,A'}\le e_{G,A} \quad (15A)$$

$$-e_{G,C}\le e_{G,C'} \quad (15B)$$

In view of equation 14(B), the solutions are

$$e_{G,A'}=-e_{G,A} \quad (16A)$$

$$e_{G,C}=-e_{G,C'} \quad (16B)$$

and by transformation

$$e_{C,A'}=-e_{C,A} \quad (16C)$$

$$e_{C,C}=-e_{C,C'} \quad (16D)$$

In conjunction with the control current, the voltages $e_{C,A'}$, $e_{C,C}$ reduce the core fluxes in cores *A'* and *C* by the same

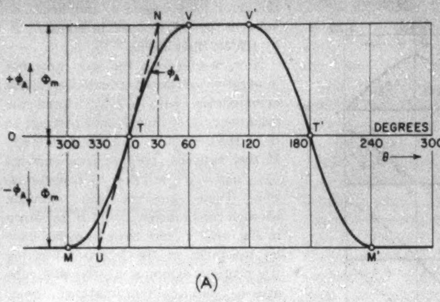

Fig. 6. Core fluxes at minimum load

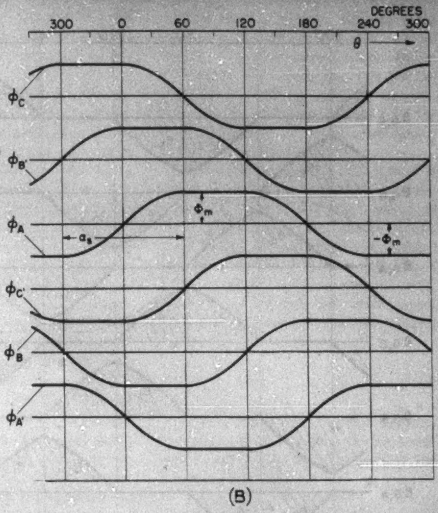
A—Fluxes of core A
B—All core fluxes



amounts by which the core fluxes in cores A and C' are increased (by the supply voltages).

(d). Gate and Control Currents

As stated in section B2(b), no impedance is encountered by the control current passing through the reactors B, B'. The control current, however, will experience a limitation by the resetting cores A', C. These cores are resetting against the line-to-line voltages, shown in equations 16(A), and (B), and thereby hold their excitation $i_C N_C$ to the width of the dynamic hysteresis loop:

$$i_C = -\frac{AT_c}{N_C} \tag{17}$$

Prior to the closing of switch S, the gates A and C' were magnetized by the gate currents only, resulting in AT_c ampere-turns for each core; by closing switch S, negative ampere-turns have been added by the control ampere-turns; see equation 17. The net magnetomotive forces $\mathfrak{F}_A$, $\mathfrak{F}_C$ are

$$\mathfrak{F}_A = i_{G,A,x} N_G + i_C N_C \tag{18A}$$

$$\mathfrak{F}_{C'} = i_{G,C',x} N_G + i_C N_C \tag{18B}$$

To maintain the gate voltages $e_{G,A}$, $e_{G,C'}$, the net magnetomotive forces must produce AT_c ampere-turns:

$$\mathfrak{F}_A = \mathfrak{F}_{C'} = AT_c \tag{19}$$

Substituting equations 17 in equations 18, one obtains for the gate currents

$$i_{G,A,x} = i_{G,C',x} = \frac{2AT_c}{N_G} \tag{20}$$

One recognizes the doubling of gate currents $i_{G,A,x}$, $i_{G,C',x}$ (equations 10) as a result of closing switch S.

Having accounted for all voltages and currents, one may now confirm the previous assumption (section B2) that the closure of switch S will not disturb the gate voltages of A, C', B, B' as shown in Fig. 4(C) for open switch.

(e) Voltages

The foregoing reasoning permits the calculation of all circuit voltages. Consider again the interval $0 \leq \theta \leq 60°$. During this interval the star voltage e_{2-0}, taken absolutely, is the smallest of the three star voltages shown in Figs. 1(C) and 4(A); therefore the potential of bus PN becomes identical with the potential of bus 2; see section B1:

$$e_{G,B} = 0 \tag{13A}$$

$$e_{G,B'} = 0 \tag{13B}$$

From Fig. 4(C)

$$e_{G,A} = e_{1-2} \tag{21A}$$

$$e_{G,C'} = e_{2-3} \tag{21B}$$

and from equations 16(A) and (B), and 21(A) and (B)

$$e_{G,A'} = -e_{1-2} \tag{22A}$$

$$e_{G,C} = -e_{2-3} \tag{22B}$$

Having the voltages established in all cores for one 60° interval (equations 13, 21, and 22), the events in all cores and at all times becomes available from the periodical character of the functions. Equations 7 or the phasor diagram of Fig. 2 lead to the synthesis of all functions. The results are shown in Fig. 5.

The gate voltages of a 3-phase bridge amplifier are not purely sinusoidal, but consist of portions of two sinusoidal line-to-line voltages, each portion lasting for 60°, followed by a 60° interval during which no gate voltage exists. This pattern is repeated with opposite sign. The half-period average of the gate voltage of core A follows from

$$E_{G,A} = \frac{1}{\pi}\int_0^{\pi} e_{G,A}\,d\theta = \frac{2}{\pi}\int_0^{\pi/3} e_{1-2}\,d\theta \tag{23}$$

Substituting for e_{1-2} from equations 5 yields

$$E_{G,A} = \frac{1}{\pi} E_m \tag{24}$$

It will be observed that the half-period average gate voltage, given above, of a 3-phase bridge connected amplifier is precisely one half of the half-period average of a purely sinusoidal waveshape having an amplitude of E_m.

(f). Core Fluxes

The change in core flux $\Delta\phi$ follows from Faraday's law in integral form

$$\Delta\phi = \frac{10^8}{N}\int_{t_1}^{t_2} e\,dt \tag{25}$$

The maximum flux swing $2\Phi_m$ occurs after application of gate voltage for 120° continuously. For instance, for gate A

$$2\Phi_m = \frac{10^8}{\omega N_G}\int_{\omega t=-\pi/3}^{\omega t=\pi/3} e_{G,A}\,d\theta \tag{26}$$

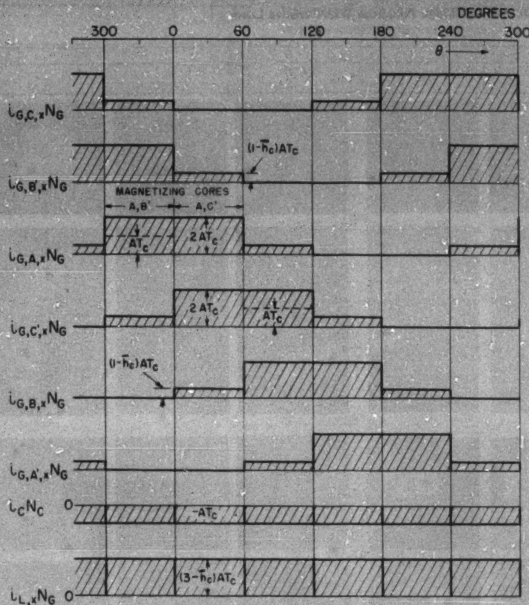


Fig. 7. Gate currents at minimum load

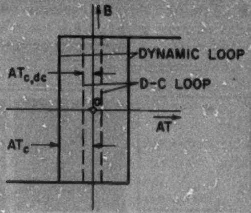

Fig. 8. Dynamic and d-c B-H loops

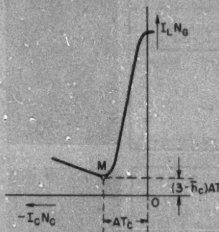

Fig. 9. Position of minimum load point M on control characteristic

From Fig. 5

$$\Phi_m=\frac{10^8}{\omega N_G}\int_{\omega t=-\pi/3}^{\omega t=0}-e_{3-1}d\theta \qquad (27)$$

Substituting for e_{3-1} from equation 5(C) and integrating, yields

$$\Phi_m=\frac{1}{2}\,\frac{10^8}{\omega N_G}\,E_m \qquad (28)$$

Assuming that the flux swings equal amounts in the positive and negative directions, the gate flux of A will be $\phi_A=+\Phi_m$ at $\theta=60°$, and $\phi_A=-\Phi_m$ at $\theta=240°$. Since no gate voltages are applied for $240°\leq\theta\leq300°$ and $60°\leq\theta\leq120°$, the core flux will remain constant:

$$\phi_A=-\Phi_m \qquad 240°\leq\theta\leq300° \qquad (29A)$$

$$\phi_A=+\Phi_m \qquad 60°\leq\theta\leq120° \qquad (29B)$$

In the remaining intervals, gate voltages are present, and the fluxes are computed from equation 25 and recast into the following form:

$$\phi_A=\frac{10^8}{N_G}\int e_{G,A}dt+C \qquad (30)$$

For the interval $300°\leq\theta\leq360°$, $e_{G,A}=-e_{3-1}$. Substituting for e_{3-1}, from equation 5(C), and integrating equation 30, yields, with the aid of equation 28,

$$\phi_A=2\Phi_m\sin(\theta-30°)+C \qquad 300°\leq\theta\leq360° \qquad (31)$$

for $\phi_A=-\Phi_m$ at $\theta=300°$, equation 29(A), yielding the integration constant C:

$$C=\Phi_m \qquad (32)$$

Substituting equation 32 into equation 31, yields for core flux ϕ_A

$$\phi_A=\Phi_m[2\sin(\theta-30°)+1] \qquad 300°\leq\theta\leq360° \qquad (33A)$$

This flux is shown in Fig. 6(A) by MTN; the part TN is merely shown to provide a complete picture of one quarter of a sine function.

For the next 60° interval the core flux ϕ_A is derived in similarity to equation 33(A):

$$\phi_A=\Phi_m[2\sin(\theta+30°)-1] \qquad 0°\leq\theta\leq60° \qquad (33B)$$

and is shown in Fig. 6(A) by UTV. TV relates to the actual core flux and UT merely completes the first portion of the sine function. The two curves MT and TV have a common tangent at point T.

Similarly, one obtains

$$\phi_A=\Phi_m[2\sin(\theta-30°)-1] \qquad 120°\leq\theta\leq180° \qquad (33C)$$

$$\phi_A=\Phi_m[2\sin(\theta+30°)+1] \qquad 180°\leq\theta\leq240° \qquad (33D)$$

as shown by curves $V'T'$ and $T'M'$ in Fig. 6(A).

Having the flux established in one core for the entire period of 360°, the core fluxes in the other cores follow in cyclic order (equations 6) and are shown in Fig. 6(B).

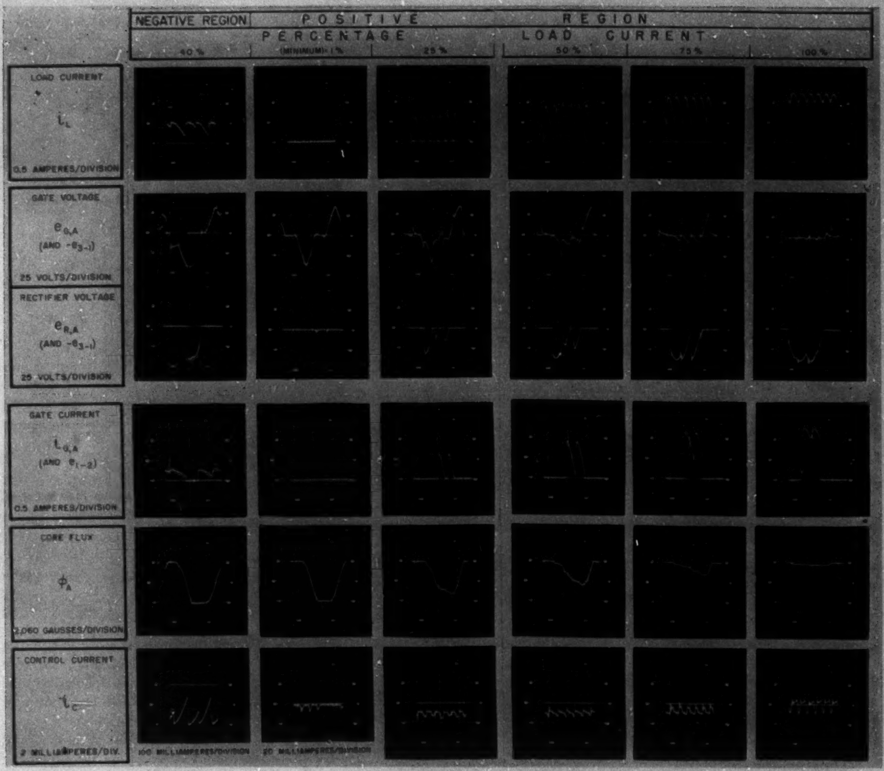
The core behavior may be summarized as follows: Two cores are increasing the flux in the positive direction (called setting), two are increasing the flux in the negative direction (called resetting), and two maintain constant flux level. Cores which are out of phase with each other by 180°, such as A A', B B', and C C', will set and reset at equal rates.

(g). DIFFERENT WIDTHS FOR D-C AND DYNAMIC HYSTERESIS LOOPS

The gate currents $i_{G,A,x}$ and $i_{G,C',x}$ were determined in section B2(d) by equation 20, for $0°\leq\theta\leq60°$, and were plotted for the above interval in the form of ampere-turns in Fig. 7.

The ampere-turns, Fig. 7, were obtained under the assumption of equal widths for the d-c and the dynamic hysteresis loops (section B1), such as in ferrites. If, however, metallic cores are used, e.g., a 50-50 Ni-Fe alloy, the d-c hysteresis loop is narrower than the dynamic hysteresis loop. This is shown

Table I. Three-Phase Bridge Amplistat With Resistive Load



in Fig. 8 where the d-c hysteresis loop is indicated by dashed lines. Of the conclusions reached in section B2, only the subsection B2(b) requires further attention because of the introduction of different widths for dynamic and d-c loops.

As in any transformer, the sum of primary ampere-turns $i_C N_C$ and secondary ampere-turns $i_{G,B',x} N_G$ equal the exciting ampere-turns $(iN)_x$:

$$i_C N_C + i_{G,B',x} N_G = (iN)_x \qquad (34)$$

and

$$i_{G,B',x} N_G = -i_C N_C + (iN)_x \qquad (35)$$

With the core fluxes in B, B' being theoretically constant, $0° \leq \theta \leq 60°$; see Fig. 6(B), the hysteresis loop, representative for zero rate of flux change, is the so-called d-c hysteresis loop; see Fig. 8. It is this loop which becomes pertinent for the transformation described by equation 35:

$$(iN)_x = -AT_{c,dc} \qquad (36)$$

Actually the resistances through which the circulating gate currents are flowing are not zero, and therefore voltage drops develop. However, these voltage drops amount in practical cases to only a small fraction of 1% based on the supply voltage E_m. The resultant flux rates are so low that the hysteresis loops on which the cores are operating are practically identical with the d-c loops.

The control ampere-turns are

$$i_C N_C = -AT_c \qquad (17)$$

By combining equations 17, 35, and 36

$$i_{G,B',x} N_G = AT_c - AT_{c,dc} \qquad (37)$$

The per-unit d-c coercive force $\bar{h}_c$ may be defined as the ratio of the d-c coercive force $H_{c,dc}$ to the dynamic coercive force H_c; then one may express $AT_{c,dc}$ in terms of $\bar{h}_c$, and the coercive ampere-turns AT_c:

$$\bar{h}_c = \frac{H_{c,dc}}{H_c} = \frac{AT_{c,dc}}{AT_c} \qquad (38)$$

One obtains from equations 37 and 38 for the gate exciting ampere-turns in B or B' $(0° \leq \theta \leq 60°)$

$$i_{G,B',x} N_G = i_{G,B,x} N_G = AT_c(1 - \bar{h}_c) \qquad (39)$$

also shown in Figs. 4(C) and 7. In the case of reactors having Deltamax cores of 4-mil thickness, and at 60 cps, $\bar{h}_c = 0.415$.

Having established all gate currents in one 60° interval, the gate currents in all cores and at all times becomes avail-

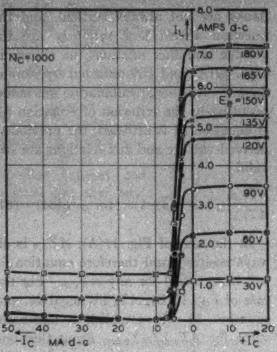


Fig. 10. Control characteristics of amplifier for various supply voltages; E_s=150 volts corresponds to normal excitation

able from the periodic character of the functions. Equations 7 or the phasor diagram of Fig 2 lead to the synthesis of all functions. The results are shown in Fig. 7.

One is now in a position to determine the load current i_L. It will be seen from Fig. 1 that gate curents $i_{G,A,x}$, $i_{G,B,x}$ flow through the load, and return to the supply as gate currents $i_{G,C',x}$, and $i_{G,B',x}$:

$$i_{L,x}=i_{G,A,x}+i_{G,B,x}\equiv i_{G,C',x}+i_{G,B',x} \quad (40)$$

From equations 20, 39, and 40 one obtains the exciting components $i_{L,x}$ of the load ampere-turns. If this analysis is restricted to normal and underexcitation, section B2(i), there is no saturation component $i_{L,s}$ of the load current at minimum load, and therefore the load current i_L consists of the exciting component $i_{L,x}$ only:

$$i_{L,x}N_G=i_LN_G=AT_c(3-\bar{h}_c) \quad (41)$$

Thus the minimum load point M (Fig. 9) which is a cardinal point of the control characteristic, has been determined in terms of the physical properties of the core; see equations 8 and 38.

$$AT_c=\frac{1}{0.4\pi}H_cl_{Fe} \quad (8)$$

As seen from Fig. 7 a direct current flows in the control winding. In the past, all forward circuit resistances were assumed zero and, therefore, once a current has been established in the control winding, no external d-c source is needed to maintain it. In a real magnetic amplifier however, the control circuit has finite resistance, and therefore an external direct voltage source E_C must be connected to terminals F_1, F_2 (Fig. 1) in order to maintain the control current (equation 17):

$$E_C=-\frac{AT_c}{N_C}R_C \quad (42)$$

(h). Reverse Rectifier Voltages

During the interval 0°≤θ≤60°, currents are flowing in rectifiers B', A, C', B (Fig. 7), and therefore no reverse voltages exist on these rectifiers.

$$e_{R,B'}=e_{R,A}=e_{R,C'}=e_{R,B}=0 \quad (43)$$

The voltage $e_{R,C}$ on rectifier C follows from the loop equation Fig. 1(A)

$$e_{R,C}+e_{G,C}+e_{R,C'}+e_{G,C'}+i_LR_L=0 \quad (44)$$

Assuming all circuit resistances as zero, and substituting from equations 16(B) and 43, one obtains

$$e_{R,C}=0 \quad (45A)$$

and, similarly

$$e_{R,A'}=0 \quad (45B)$$

The conclusion is that, with zero resistances in the circuit (except for rectifier reverse resistances), the rectifier reverse voltages are zero at the minimum load point M. This is borne out essentially in the oscillogram in Table I. The residual voltages are due to core asymmetries, also visible in the trace for the control current which should be entirely smooth. Table I also contains oscillograms for load current, gate voltage, gate current, and core flux.

(i). Various States of Excitation

With a given set of reactors, one wishes normally to obtain the smallest possible load current at minimum load, consistent with full utilization of the reactors. This condition is realized by applying a supply voltage of such a magnitude E_m, as to make the flux excursion Φ_m equal to the saturation flux Φ_s. This condition is called normal excitation.

$$\Phi_m=\Phi_s \quad (46)$$

By reducing the supply voltage, E_m, Φ_m is reduced and $\Phi_m<\Phi_s$, a condition called underexcitation. All equations derived thus far are equally applicable to normal or underexcitation. While the minimum load current i_L (equation 41) remains the same theoretically, the output voltage of the amplifier declines proportionally to the supply voltage, and hence the utilization of the reactors declines.

By increasing the supply voltage E_m, one may obtain $\Phi_m>\Phi_s$, a condition called overexcitation. In this mode of operation, the load current is no longer limited by an unsaturated gate reactance during the entire duration of each 60° interval, and therefore the load current rises at minimum load. This is shown in section E, and in Fig. 10, where normal excitation occurs for $E_s=150$ volts.

To return to normal excitation and underexcitation, the pattern of core behavior has been summarized at the end of section B2(f). In anticipation of amplifier analysis between minimum and full load, a distinction will be made for the two cores with constant flux (cores B, B', 0≤θ≤60°). When the core flux is in positive saturation, the core will be called saturated; if not in positive saturation, the core is called idle.

With these definitions in mind, reference is made to Table II. For minimum load and underexcitation, the asterisk indicates mode 0 operation, consisting of no core saturated, and of two cores setting, two resetting, and two idle, at any time. For minimum load and normal excitation, the asterisk indicates mode 1 operation: one saturated core, two setting cores, two resetting, and one idle core at any time. It will be noted that the designation number of the mode signifies the number of saturated cores.

(j). Saturation Angle α_s

As seen from Fig. 6(B), core A saturates at θ=60° when normally excited. Since

- ‡ NORMAL EXCITATION

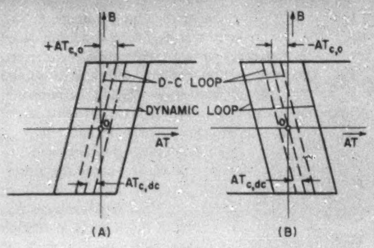

Fig. 11. B-H loops with tilted flanks

there are six cores, but only one time scale, there will be six different values of θ for the six cores. To unify the expressions, a new variable α is introduced. This variable α is counted for each core from the instant at which each core flux starts on its upswing. In this notation, the saturation angle $\alpha_s = 120°$ for the flux configuration of Fig. 6(B), and normal excitation.

(k). NORMAL EXCITATION

In view of its pre-eminence in applications, only normal excitation (equation 46) will subsequently be treated. Substituting equations 28 and 46 yields

$$\frac{1}{2}E_m = \omega N_G \Phi_s 10^{-8} \qquad (47)$$

Designating the effective rms value of the line-to-line voltage by E_s yields

$$E_s = \frac{E_m}{\sqrt{2}} \qquad (48)$$

and one obtains from equations 3, 47, and 48

$$\frac{1}{2}E_s = \pi\sqrt{2} f N_G \Phi_s 10^{-8} \qquad (49)$$

The saturation flux Φ_s is related to the effective area of core iron A_{Fe} and the saturation flux density B_s by

$$\Phi_s = A_{Fe} B_s \qquad (50)$$

Equation 49 is a fundamental design equation relating the line-to-line voltage to the physical properties of the reactor. The right-hand term of equation 49 expresses the effective voltage which can be applied to an ordinary a-c reactor, when energized from a purely sinusoidal voltage source. For the bridge-connected amplifier, however, the left-hand term of equation 49 is only $E_s/2$, and hence the line-to-line voltage of the 3-phase bridge amplifier, can be double the voltage for ordinary, sinusoidal, single-phase a-c reactor operation. For instance, if the single-phase rating of one reactor is 115 volts rms, then the same reactor can be used in a 3-phase bridge amplifier, having a line-to-line voltage of 230 volts rms, assuming the same frequency and normal excitation in both cases.

Up to this point the derivations of voltages and fluxes have been based on a rectangular hysteresis loop as shown in Fig. 3. In actual hysteresis loops, the flanks are not always vertical, and the question arises: how seriously are the voltage and flux relations, as shown in Figs. 11(A) and (B), affected by sloping flanks? A tedious examination was made, resulting in the criterion of equation 51. If equation 51 is satisfied, the previously derived voltage and flux relations are still valid

$$\frac{AT_{c,dc}}{AT_{c,0}} \leq 1-(\sqrt{3}-1)2 \quad (\text{or } -0.464) \qquad (51)$$

In the case of Fig. 11(A), $AT_{c,0}$ is always positive, and therefore equation 51 will be satisfied for any $AT_{c,0}$. For the case of Fig. 11(B), $AT_{c,0}$ is negative, and equation 51 will establish a minimum value for $AT_{c,dc}/AT_{c,0}$. From this, one concludes that the voltage and flux relations are immune to changes of the flank angles (within the limits of equation 51). It will also be observed that the waveshapes of the exciting currents in gate and control windings are sensitive to changes in the flank angles.

C. Minimum to Half-Load, $60° \leq \alpha_s \leq 120°$, Normal Excitation

"Minimum to half-load" refers to the magnitude of the load current, which will be varied in this section from its minimum value (equation 41 and M in Fig. 9) to one half of the maximum load current $I_{L,m}$ for $\alpha_s = 60°$, N in Fig. 12(B); $I_{L,m}$ follows from equation 73. This variation of load current is achieved by varying the control current, thus shifting the saturation angle α_s from 120° to 60°; the load resistance is kept constant.

As in the preceding, the analysis will be carried out within one 60° interval. It will be readily seen in the following that

Vol

A—Phasor diagram. Accented E's indicate phasors

B—Bus voltages and current just before saturation

C—Bus voltages and current just after saturation

two modes of operation occur in one 60° interval. For this reason the 60° interval is subdivided into two subintervals, accommodating one mode of operation for each subinterval.

1. Reactor and Rectifier Voltages

Mode 1 ($60° \leq \alpha \leq \alpha_s$)

In section B2(f), the core fluxes were $-\Phi_m$ at the start of their upswings. One may call the flux at the instant where it starts on its upswing the starting flux point Φ_1; then $\Phi_1 = -\Phi_s$ at the minimum load point.

Now, let all starting fluxes be raised by a value Φ_0, keeping Φ_0 within $-\Phi_s$ and 0. In this subinterval, the mode of excitation is precisely the same as for minimum load, normal excitation (sections B2(f) and (i), and Table II). All gate voltages are given by equations 13, 21, and 22, and are shown in Fig. 4(C). The latter figure has been redrawn in Fig. 13(B) to include the load resistance R_L, which soon will become important.

Mode 2 ($\alpha_s \leq \alpha \leq 120°$)

A new mode will be encountered in the subinterval reaching from α_s to 120°. Of the two setting (climbing) core fluxes ϕ_A, ϕ'_C, flux ϕ_A will reach saturation first. When core A saturates at $\alpha = \alpha_s$, the gate voltage $e_{G,A}$ collapses, as shown in Fig. 14. The bus P is hereby pulled up to the level of bus 1, as illustrated in Fig. 13(C). A heavy load current begins to flow, limited only by the supply voltage and the circuit resistance. The load current permits the much smaller gate exciting current $i_{G,C',x}$ to flow in the reverse direction of rectifier B'. Core C' continues to set as before equation 21(B), and induces a voltage into the control circuit equation 12(B). Since cores A and B' are saturated, $e_{C,A} = e_{C,B'} = 0$, and one obtains from equation 11

$$e_{C,B} + e_{C,A'} + e_{C,C} = -e_{C,C'} \tag{52}$$

In this mode, C' is the only core setting, and this one core is resetting the three cores B, A', and C. For equal reactors, and no currents flowing in the rectifiers B, A', and C ($\theta_s < \theta < \theta_u$ from Fig. 14):

$$e_{C,B} = e_{C,A'} = e_{C,C} = -\frac{1}{3} e_{C,C'} \quad \theta_s \leq \theta \leq \theta_u \tag{53A}$$

and the corresponding gate voltages are

$$e_{G,B} = e_{G,A'} = e_{G,C} = -\frac{1}{3} e_{G,C'} \quad \theta_s \leq \theta \leq \theta_u \tag{53B}$$

with $e_{G,C'}$ known, from equation 21(B). The rectifier voltages $e_{R,B}$, $e_{R,A'}$, and $e_{R,C}$ follow from an inspection of Fig. 13(C):

$$e_{R,B} = -e_{1-2} - e_{G,B} \tag{54A}$$

$$e_{R,A'} = -e_{1-2} - e_{G,A'} \tag{54B}$$

$$e_{R,C} = e_{3-1} - e_{G,C} \tag{54C}$$

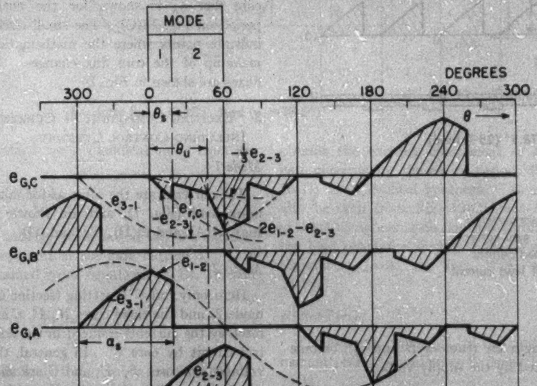

Fig. 14. Gate voltages at 25% load, $\alpha_s = 78.5°$

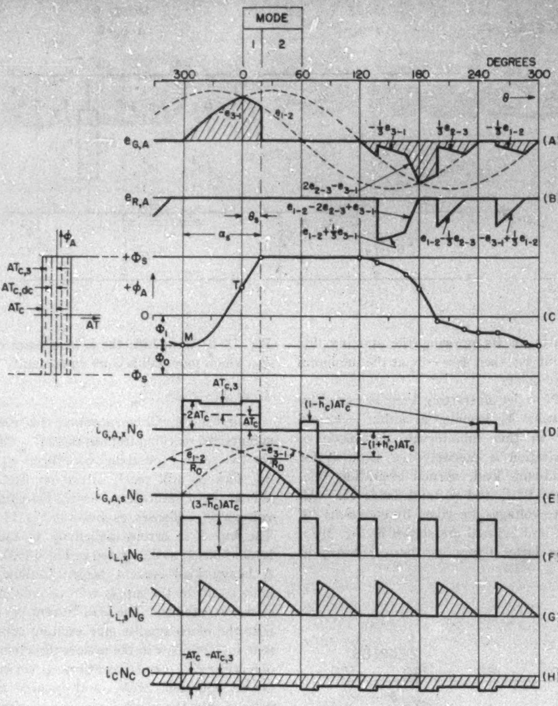

Fig. 15. Saturation angle $\alpha_s=78.5°$ (25% load)

A—Gate voltage
B—Rectifier voltage
C—Core flux
D—Exciting component of gate current
E—Saturation component of gate current
F—Exciting component of load current
G—Saturation component of load current
H—Control current

During the interval $(\theta_s \leq \theta \leq \theta_u)$ the gate voltages are given by equation 53(A). Substituting equation 53(A) into equations 54 results in the negative rectifier voltages. These voltages are called reverse voltages $e_{r,B}$, $e_{r,A'}$, $e_{r,C}$, and are shown in Fig. 14. It may be seen that reverse voltages are present for $\theta \leq \theta_u$, and that therefore no gate currents can flow, as assumed above. In fact, the angle θ_u has been defined as occurring when the rectifier reverse voltages $e_{r,B}$, $e_{r,A'}$ vanish, namely, for $e_{1-2}=1/3e_{2-3}$. This angle $\theta_u=46.1°$ when it is computed from equations 5(A) and (B).

For $\theta_u \leq \theta \leq 60°$ the reverse voltages on rectifiers B and A' vanish, and the voltages on reactors B and A' become limited by the supply voltage

$$e_{G,B}=e_{G,A'}=-e_{1-2} \quad \theta_u \leq \theta \leq 60° \tag{55A}$$

$$e_{C,B}=e_{C,A'}=-e_{1-2}\frac{N_C}{N_G} \quad \theta_u \leq \theta \leq 60° \tag{55B}$$

From equation 52

$$e_{C,C}=-e_{C,C'}-(e_{C,B}+e_{C,A'}) \tag{56}$$

From equation 21(B), 55, and 56 one obtains gate voltage $e_{G,C}$:

$$e_{G,C}=2e_{1-2}-e_{2-3} \quad \theta_u \leq \theta \leq 60° \tag{57}$$

The rectifier voltage $e_{R,C}$ is calculated from equations 54(C) and 57, and shown in Fig. 14.

With all gate and rectifier voltages accounted for during a 60° period, these voltages can be determined for an entire period of 360° by cyclic synthesis, resulting in the waveshapes shown in Figs. 14 and 15(A) and (B).

For mode 2, the core behavior can be summarized as follows, from Table II: two cores are saturated, and one core is setting and thereby resets the remaining three cores.

2. Fluxes

In section C1, the level of the starting flux Φ_1 has been raised from $-\Phi_s$ by the amount of ϕ_0; therefore core flux ϕ_A can be obtained from equation 33(A) by the addition of Φ_0:

$$\phi_A=\Phi_s[2 \sin(\theta-30°)+1]+\Phi_0 \qquad 300° \leq \theta \leq 360° \tag{58A}$$

and, from equation 33(B),

$$\phi_A=\Phi_s[2 \sin(\theta+30°)-1]+\Phi_0 \qquad 0° \leq \theta \leq 300°+\alpha_s \quad 60° \leq \alpha_s \leq 120° \tag{58B}$$

For the remaining part of the period, the flux is obtained by a step-by-step integration of equation 30, with the gate voltage $e_{G,A}$ taken from Fig. 15(A). The core flux ϕ_A is shown for the entire period on Fig. 15(C). The small circles indicate points where the mathematical make-up of the core flux changes. All fluxes are shown in Fig. 16.

3. Exciting Component of Currents Including Control Current

Mode 1

The currents are the same as for minimum load (Fig. 7), and are shown in Figs. 17(A), and 15(D), (F), and (H).

Mode 2

Here, only core C' is setting (section C1 mode 2) and the three cores B, A', C are reset by the currents induced in the control circuit by core C'. In general, the voltages on cores B, A', and C are substantially smaller than the line-to-line voltages (Fig. 14, $\theta_s \leq \theta \leq 60°$) and hence the width of the dynamic hysteresis loops used for resetting these cores will be smaller than AT_c. To appraise the effective widths of the hysteresis loops, the operation of the three resetting cores has been simulated by connecting the windings of three reactors, in series, and applying rated alternating voltage. The width of the hysteresis loop obtained in this manner is called $AT_{c,3}$. In the case of reactors having Deltamax cores of 4-mil thickness, and at 60 cps, $AT_{c,3}$ is about 0.71 AT_c. The control current is now

Fig. 17. Exciting and saturating components of gate currents and load currents at 25% load ($\alpha_s = 78.5°$)

obtained by a modification of equation 17:

$$i_C = -\frac{AT_{c,s}}{N_C} \qquad (59)$$

In analogy to equation 20, the exciting component of the gate current $i_{G,C',x}$ is obtained from equations 18(B), 19, and 59;

$$i_{G,C',x} = \frac{(AT_c + AT_{c,s})}{N_G} \qquad (60A)$$

Similarly to $\bar{h}_c$ in equation 38, $\bar{h}_c'$ is defined by

$$\bar{h}_c' = \frac{H_{c,s}}{H_c} = \frac{AT_{c,s}}{AT_c} \qquad (61)$$

One obtains the exciting component of the gate current C' from equations 60(A) and 61

$$i_{G,C'x}N_G = AT_c(1+\bar{h}_c') \qquad (60B)$$

The current $i_{G,C',x}$ flows through the gate B', Fig. 13(C), and therefore

$$i_{G,B',x} = -i_{G,C'x} \qquad (60C)$$

The exciting currents are plotted in Fig. 17(A). From this illustration one obtains the exciting component of the gate currents for the entire period, Fig. 15(D) by a cyclical synthesis. It will also be seen from Fig. 13(C) that the exciting components do not flow through the load resistance during mode 2, and therefore $i_{L,x}=0$; see Figs. 17(A) and 15(F).

Entire Period

The average value $I_C N_C$ of the control current can be calculated from Fig. 15(H):

$$I_C N_C = -\frac{3}{\pi} AT_c \left(\int_0^{\alpha_s - 60°} d\theta + \bar{h}_c' \int_{\alpha_s - 60°}^{\pi/3} d\theta \right) \qquad (62)$$

$$I_C N_C = -AT_c \left[\bar{h}_c' + \frac{3}{\pi}(1-\bar{h}_c')\left(\alpha_s - \frac{\pi}{3}\right) \right] \qquad (63)$$

Similarly, exciting component $I_{L,x}N_G$ of the load ampere-turns follows from Fig. 15(F):

$$I_{L,x}N_G = AT_c \times \frac{3}{\pi}\,(3-\bar{h}_c)\left(\alpha_s - \frac{\pi}{3}\right) \qquad (64)$$

4. Saturation Component of Currents

Mode 1

None.

Mode 2

The current components $i_{G,A,s}$, $i_{G,B',s}$, $i_{L,s}$ are usually several decades larger than the exciting components $i_{G,A,x}$, $i_{G,B',x}$, $i_{L,x}$. For clearer presentation the saturation and exciting components are shown on different scales in Figs. 17 and 15(D) through (G). According to equation 9, the total currents are obtained by adding the saturation and exciting components after the proper scale factors have been applied.

As seen from Fig. 13(C), the saturation component $i_{L,s}$ of the load current is limited only by the output resistance R_0. The latter consists of load resistances R_L, gate resistances $R_{G,A}$, $R_{,GB'}$ and the rectifier forward resistances $R_{f,A}$, $R_{f,B'}$. Assume that all gate resistances R_G and all rectifier forward resistances R_f are equal:

$$R_0 = R_L + 2R_G + 2R_f \qquad (65)$$

Then

$$i_{G,A,s} \equiv i_{G,B',s} \equiv i_{L,s}$$
$$= \frac{e_{1-2}}{R_0} \qquad \alpha_s - 60^\circ \leq \theta \leq 60^\circ \quad (66)$$

The load current $i_{L,s}$, initiated by the saturation of core A at $\theta_s = \alpha_s - 60^\circ$ returns through reactor B' Figs. 13(C) and 17(B), which had been saturated 60° prior to core A. Similarly, at $\theta = \alpha_s$, core C' will saturate, and the corresponding load current can return through reactor A, which is still saturated. Thus, each gate carries the load current twice: first, when initiating the load current flow, and second, when acting merely as return path; see Fig. 15(E).

The average value $I_{L,s}$ of the saturation component of the load current is

$$I_{L,s} = \frac{3}{\pi} \int_{\alpha_s}^{2\pi/3} i_{L,s} d\alpha \quad (67)$$

Substituting from equation 5(A) and integrating, one obtains

$$I_{L,s} = \frac{3}{\pi} \frac{E_m}{R_0} [1 - \sin(\alpha_s - 30^\circ)] \quad (68)$$

The average value of gate current $I_{G,s}$ follows from Fig. 15(E):

$$I_{G,s} = \frac{1}{3} I_{L,s} \quad (69)$$

5. Control Characteristics

The control characteristic of a magnetic amplifier relates the load current to the control current. By relating the exciting and saturation components of the load current to the control current, and by adding the two components, the total control characteristic is obtained.

First, the saturation angle α_s is determined from equation 63:

$$\alpha_s = -\frac{\dfrac{I_c N_c}{AT_c} + \bar{h}_c'}{\dfrac{3}{\pi}(1 - \bar{h}_c')} + \frac{\pi}{3} \qquad 60^\circ \leq \alpha_s \leq 120^\circ \quad (70)$$

The exciting component of the load current can now be obtained from equations 61 and 64. By relating the exciting load ampere-turns to the exciting gate ampere-turns $2AT_c$ for minimum load, one obtains in nondimensional form

$$\frac{I_{L,x} N_g}{2AT_c} = \left(1 + \frac{1 - \bar{h}_c}{2}\right) \frac{\left(-\dfrac{I_C N_C}{AT_c} - \bar{h}_c'\right)}{1 - \bar{h}_c'} \quad (71)$$

Equation 71 shows a linear relationship between the exciting component of the load current and the control current; see Fig. 12(A).

By substituting for α_s from equation 70 into equation 68, one obtains

$$\frac{I_{L,s}}{\dfrac{3}{\pi} \dfrac{E_m}{R_0}} = 1 - \sin\left(-\frac{\dfrac{I_C N_c}{AT_c} + \bar{h}_c'}{\dfrac{3}{\pi}(1 - \bar{h}_c')} + \frac{\pi}{6}\right) \quad (72)$$

The maximum load current $I_{L,m}$ with fully saturated reactors is

$$I_{L,m} = \frac{3}{\pi} \frac{E_m}{R_0} \quad (73)$$

as will be proved by equation 84 in section *D*. Substituting from equations 72 and 73 one obtains in nondimensional form the control characteristic concerning the saturating components, as shown in Fig. 12(B) by the cosine, from $I_C N_C / AT_c = -1$ to N.

To obtain the total control characteristic the two characteristics in Fig. 12(A) and (B) must be added, after the application of a proper scale factor. Let the per-unit exciting current $\imath_x$ be defined as

$$\imath_x = \frac{2AT_c}{I_{L,m} N_G} \quad (74)$$

Then, the ordinates of Fig. 12(A), when multiplied by $\imath_x$, can be added to the ordinates of Fig. 12(B). In practical cases the per-unit excitation $\imath_x$ is in the vicinity of 1% and therefore the effect of the exciting components is of practical significance only at or near minimum load. Actually, measured points are also shown in Fig. 12(B) by crosses. In the range from minimum load to half load (*MN*) the control circuit resistance can be varied from $R_C = 600$ to 26,000 ohms without noticeable effects.

A fundamental quantity for the evaluation of amplifier performance is the ampere-turn gain K_{AT}

$$K_{AT} = \frac{d(I_L N_G)}{d(I_C N_C)} \quad (75)$$

Since the contribution of the exciting component of the load ampere-turns (equation 71) is so small, only the saturation component will be considered. By differentiating equation 72 with respect to $I_C N_C$, one obtains

$$K_{AT} = \frac{I_{L,m} N_G}{2AT_c} \frac{2\pi}{3} \frac{1}{1 - \bar{h}_c'} \cos(\alpha_s - 30^\circ)$$
$$60^\circ \leq \alpha_s \leq 120^\circ \quad (76A)$$

The highest value for the ampere-turn gain $K_{AT,m}$ is obtained for $\alpha_s = 60^\circ$, resulting in

$$K_{AT,m} = \frac{I_{L,m} N_G}{2AT_c} \frac{\pi}{\sqrt{3}} \frac{1}{1 - \bar{h}_c'} \qquad \alpha_s = 60^\circ \quad (76B)$$

In Figs. 13 through 17 the saturation angle $\alpha_s = 78.5^\circ$. With this angle, $I_{L,s}$ becomes 25% (equations 68 and 73) of $I_{L,m}$. For comparison purposes oscillograms are shown in Table I, for 25% load current. Oscillograms are also shown for the boundary case of 50% load current.

D. Half Load to Full Load, $0^\circ \leq \alpha_s \leq 60^\circ$ Normal Excitation

"Half load to full load" refers to the magnitude of the load current which will be varied in this section from one half to the full value of $I_{L,m}$ (*NP* in Fig. 12(B)). This variation of load current is achieved with constant-load resistance R_L, by varying the saturation angle α_s from 60° to 0°; see equation 86.

It was shown in section C1 that raising the starting flux Φ_1 from $-\Phi_s$ to 0 changes the saturation angle α_s from 120° to 60°, with an attendant decrease in the duration of mode 1 and an increase in the duration of mode 2. For $\alpha_s = 60^\circ$, only mode 2 exists. If the starting flux is raised to become positive, the saturation angle becomes smaller than 60°, and two modes of operation will be encountered: mode 2 for $0^\circ \leq \alpha \leq \alpha_s$ (identical with mode 2 of section C), and a new mode, called mode 3 for $\alpha_s \leq \alpha \leq 60^\circ$.

1. Reactor and Rectifier Voltages

Mode 2 $(0^\circ \leq \alpha \leq \alpha_s)$

The voltage and current configurations are shown for $\alpha_s = 41^\circ$ (75% loading) in Figs. 18(A) and (B): $300^\circ \leq \theta \leq 360^\circ$. Core A is setting and is resetting cores C', B, and A' by equal amounts similar to those shown in section C1 and equation 53(B). The remaining cores C and B' are saturated and therefore produce no voltages.

Mode 3 $(\alpha_s \leq \alpha \leq 60^\circ)$

It will be seen from Fig. 16 (minimum to half load) that cores C and B' were saturated for $(\theta_s - 60^\circ) \leq \theta \leq 0^\circ$. As the saturation angle α_s is reduced below 60°, core A also becomes saturated, which means that there are now three cores which are saturated. The other three cores are idle, as shown in Table II.

Entire Interval

The gate voltages can now be determined for the entire period; see Fig. 19(A).

The rectifier reverse voltages are determined in the same manner as in section C1, and are shown in Fig. 19(B). It will be seen that the maximum rectifier reverse voltage equals the crest value of the line-to-line voltage:

$$E_{r,m} = E_m \quad (77)$$

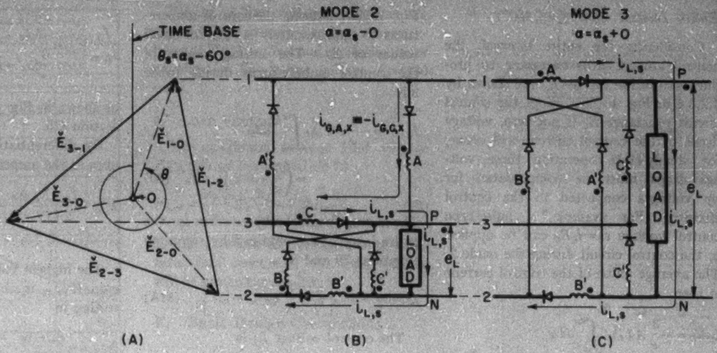
Fig. 18. Bus voltages at 75% load ($\alpha_s=41°$)

A—Phasor diagram. Accented E's indicate phasors

B—Bus voltages and currents just before saturation

C—Bus voltages and currents just after saturation



2. Fluxes

The core flux of A is given again by equation 58(A), as shown in section C2. For the remaining part of the period, core flux ϕ_A is determined by a step-by-step integration of equation 30 with the gate voltage $e_{G,A}$, taken from Fig. 19(A). Core flux ϕ_A is shown for the entire period in Fig. 19(C).

3. Exciting Components of Currents Including Control Current

Mode 2

The gate current $i_{G,A,x}$ in this subinterval $(300° \leq \theta \leq 300°+\alpha_s)$ has the same make-up as gate current $i_{G,C',x}$ had in section C3, $(\theta_s \leq \theta \leq 60$, Fig. 17(A), equation 60(B):

$$i_{G,A,x}N_G=AT_c(1+\bar{h}_c') \tag{78}$$

This current can return as $-i_{G,C,x}$ to bus 3 via the reverse direction of rectifier C because this rectifier is kept open in the forward direction by the flow of load current from bus 3 to bus 2. During $60° \leq \theta \leq 60+\alpha_s$, current $i_{G,C,x}$ becomes identical to $-i_{G,A,x}$, resulting in exciting components of the gate currents, shown in Fig. 19(D). Fig. 18(B) also shows that the exciting components avoid the load circuit and therefore $i_{L,x}=0$; see Fig. 19(F).

The control ampere-turns follow from equation 59 and can be seen in Fig. 19(H).

Mode 3

No cores are being excited, therefore $i_{G,A,x}=0$ Fig. 19(D), and $i_{L,x}=0$; see Fig. 19(F). If no voltages are induced into the control circuit from the gates or applied by a control voltage source, the control ampere-turns area 4,5,6,7, Fig. 19(H), will also be zero.

A—Gate voltage

B—Rectifier voltage

C—Core flux

D—Exciting component of gate current

E—Saturation component of gate current

F—Exciting component of load current

G—Saturation component of load current

H—Control current

Entire Interval ($300° \leq \theta \leq 360°$)

Considering the entire interval, the control ampere-turns necessary to produce saturation for $\alpha = \alpha_s$, are shown by 1,2,3,4 in Fig. 19(H). Since the control circuit resistance R_C is not zero, voltage drops of the control current will occur; for steady-state operation these voltage drops must be compensated for by voltages connected to the control circuitry. For example, a pulse-type control voltage $e_C = i_C R_C$ can be applied to the control circuit during the mode 2. The average value of the control current is then

$$I_C N_C = -\frac{3}{\pi} AT_c \bar{h}_c' \int_0^{\alpha_s} \alpha d\alpha$$
$$= -\frac{3}{\pi} \alpha_s AT_c \bar{h}_c' \quad (79)$$

The control voltage could be modified by attaching to it voltages existing during mode 3. If these added-on voltages are kept below $AT_c\ (R_C/N_C)$, the resulting control currents during mode 3 will not change the saturation angle or power output, yet the average value of $I_C N_C$ (equation 79) may have been changed. One concludes that the output of the amplifier is determined jointly by the average value $I_C N_C$ of control ampere-turns, and by the magnitude and shape of the applied control voltage.

In this paper it has been assumed that no coupling exists between gate and control windings, once the reactor saturates. Actually this is not quite so, as is borne out by the various voltage spikes seen in the oscillograms of Table I. These voltages spikes produce currents, which, if large enough, may operate on the **B-H** loop, and thereby change the average value of control ampere-turns $I_C N_C$ for a given saturation angle even if the voltage spikes are pure alternating current. These voltages spikes become larger for a decreasing saturation angle α_s, because of the concomitant increase of gate current. It will also be seen from Fig. 19(A) that a decreasing saturation angle reduces the duration and the magnitude of the regular, sinusoidal reset voltage derived from the line-to-line voltage. Hence, with decreasing saturation angle α_s, the voltage spikes exert increasing relative influence, and thereby cause deviations from the control characteristic of Fig. 12(B).

In the following, the control characteristic will be calculated under conditions of a constant control voltage E_C, and no induced voltages after saturation.

During mode 3, the constant control voltage produces a control current 4,5,6,7, Fig. 19(H), limiting the control ampere-turns to approximately $AT_{c,dc}$ for small values of E_C. The average value of the control ampere-turns during mode 3 is

$$I_C N_C = -\frac{3}{\pi} AT_c h_c \int_{\alpha_s}^{\pi/3} \alpha d\alpha$$
$$= \left(\frac{3}{\pi} \alpha_s - 1\right) \bar{h}_c AT_c \quad (80)$$

The average control ampere-turns for the entire interval are obtained by summing equations 79 and 80:

$$I_C N_C = -AT_c \left[\bar{h}_c + \frac{3}{\pi} \alpha_s (\bar{h}_c' - \bar{h}_c)\right] \quad (81A)$$

The control voltage E_C is

$$E_C = I_C R_C \quad (81B)$$

and the saturation angle α_s from equation 81(A)

$$\alpha_s = -\frac{\dfrac{I_C N_C}{AT_c} + \bar{h}_c}{\dfrac{3}{\pi}(\bar{h}_c' - \bar{h}_c)} \qquad 0° \leq \alpha_s \leq 60° \quad (81C)$$

4. SATURATION COMPONENTS OF CURRENTS

Mode 2

As shown in Fig. 18(B), the load current $i_{L,s}$ is

$$i_L = -\frac{e_{2-3}}{R_0} \quad (82)$$

Mode 3

From Fig. 18(C)

$$i_L = \frac{e_{1-2}}{R_0} \quad (83)$$

The average load current I_L follows from

$$I_L = \frac{3}{\pi}\left[\int_{300°}^{300°+\alpha_s} -\frac{e_{2-3}}{R_0} d\theta + \int_{300°+\alpha_s}^{360°} \frac{e_{1-2}}{R_0} d\theta\right] = \frac{3}{\pi} \frac{E_m}{R_0} \cos \alpha_s \quad (84)$$

As there is no exciting component, $I_{L,s} = I_L$.

For $\alpha_s = 0$, the load current reaches its maximum value $I_{L,m}$:

$$I_{L,m} = \frac{3}{\pi} \frac{E_m}{R_0} \quad (85)$$

In nondimensional form, the load current is expressed by

$$\frac{I_L}{I_{L,m}} = \cos \alpha_s \quad (86)$$

In terms of core properties, one obtains the control characteristic by substituting from equation 81(C) into 86:

$$\frac{I_L}{I_{L,m}} = \cos \frac{\dfrac{I_C N_C}{AT_c} - \bar{h}_c}{\dfrac{3}{\pi}(\bar{h}_c' - \bar{h}_c)} \quad (87)$$

as shown in Fig. 12(B), and discussed in section C5.

By differentiation of equation 87 one obtains the ampere-turn gain:

$$K_{AT} = \frac{I_{L,m} N_G}{2AT_c} \frac{2\pi}{3} \frac{1}{(\bar{h}_c' - \bar{h}_c)} \sin \alpha_s$$
$$0° \leq \alpha_s \angle 60° \quad (88A)$$

The highest value for the ampere-turn gain $K_{AT,m}$ is obtained for $\alpha_s = 60°$, resulting in

$$K_{AT,m} = \frac{I_{L,m} N_G}{2AT_c} \frac{\pi}{\sqrt{3}} \frac{1}{\bar{h}_c' - \bar{h}_c} \quad (88B)$$

It will be noticed that the maximum ampere-turns, equations 76(B) and 88(B), may be somewhat different from each other at $\alpha_s = 60°$. A typical figure for a 1-kw 60-cps amplifier with Deltamax cores is $K_{AT,m} = 600$.

In Figs. 18 and 19 the saturation angle $\alpha_s = 41°$. With this angle, I_L becomes 75% of $I_{L,m}$; see equation 87. For comparison purposes, oscillograms of the various waveshapes are found in Table I for 75% load. Oscillograms are also shown for the boundary cases of 50% and 100% load.

5. CONTROL CHARACTERISTIC

The results of tests conducted with various values of control circuit resistances R_C are shown in Fig. 12(B). It will be noted that the best agreement with equation 86 is obtained for the highest value of resistance, namely, 26,000 ohms. As previously explained in section D3, the average value of control current may assume various values for the same saturation angle, depending on currents generated in the control circuit by voltage spikes induced after saturation. Voltage spikes $e_{G,p}$ of about 20 volts follow from the oscillogram of Table I for full load. The corresponding voltage spike in the control circuit is 20 $N_C/N_G = 30$ volts ($N_C = 1{,}000$ turns, $N_G = 670$ turns) and an ampere-turn spike of (30 volts/R_C)$N_C = 1.14$ is expected. For the reactors in use, $AT_{c,dc} = 2.8$ ampere turns, and therefore the 1.14 ampere-turn spike cannot produce a significant flux change. Hence, the average control ampere-turns as shown in Fig. 12(B) will be hardly affected. By reducing R_C to 12,000 ohms, the induced spikes become 2.48 ampere-turns, still being less than $AT_{c,dc}$. However, for $R_C = 6{,}000$ ohms, the spikes become 4.96 ampere turns, and

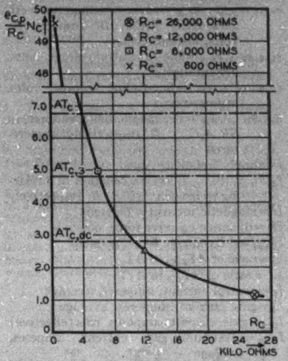

Fig. 20. Magnitudes of ampere-turn spikes $e_{C,P} N_C/R_C$ for various values of control circuit resistance R_C

the deviation of the control characteristic from equation 86 become considerable. This deviation is still more pronounced for $R_C=600$ ohms. Fig. 20 illustrates these relations.

The lower half of the control characteristic in Fig. 12(B) is not affected by the variation of control circuit resistance from 600 to 26,000 ohms, and measured points are shown only for one value ($R_C=600$ ohms).

If the control ampere-turns are made more negative than required for the minimum load point, the control characteristics of Fig. 21 result. The slopes of the characteristics are negative and the ampere-turn gain very small ($K_{AT}=2$ for the lower part of the characteristic). The control characteristic of Fig. 12, when drawn to the scale of Fig. 21 becomes the line coincident with the ordinate axis.

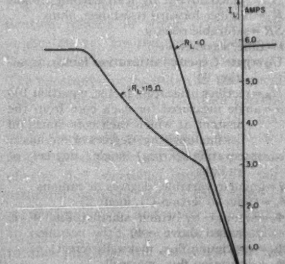

Fig. 21. Control characteristics of amplifier for the negative region

Effects of line voltage variations are shown by the measured control characteristics of Fig. 10. Normal excitation is for an effective line-to-line voltage $E_s=150$ volts.

6. LOAD VOLTAGE

The maximum average load voltage $E_{L,m}$ follows from equation 73:

$$E_{L,m}=\frac{3\sqrt{2}}{\pi}E_s\frac{R_L}{R_0}=1.35E_s\frac{R_L}{R_0} \tag{89}$$

In the presence of overlap due to post-saturation reactance, the load voltage will be somewhat smaller.

E. Basic Design Calculations

Usually the output requirement of an amplifier is given by the maximum load voltage $E_{L,m}$ and the maximum load current $I_{L,m}$.

1. SUPPLY VOLTAGE

The line-to-line supply voltage E_s in rms follows from equation 89:

$$E_s=\frac{\pi}{3\sqrt{2}}E_{L,m}\frac{R_0}{R_L}=0.74E_{L,m}\frac{R_0}{R_L} \tag{90}$$

The ratio R_0/R_L ranges usually from 1.01 to 1.3, if in addition to the circuit resistances, the effects of post-saturation reactance are also included.

2. GATE TURNS AND CORE CROSS SECTION

For normal excitation one obtains from equations 49 and 50

$$A_{Fe}N_G=\frac{10^8}{2\sqrt{2}}\frac{E_s}{fB_s}=0.1125\frac{E_s10^8}{fB_s} \tag{91}$$

3. GATE CURRENT

Gate current and load current are related by equation 69. To determine the copper loss in the gate winding, and provide the proper cross section, the rms value of the gate current must be known. Defining the form factor $k_{f,G}$ as the ratio between rms and average gate current yields

$$k_{f,G}=\frac{I_{G,e}}{I_G} \tag{92}$$

The effective gate current $I_{G,e}$ follows from equations 69 and 92:

$$I_{G,e}=k_{fG}I_G=\frac{1}{3}k_{f,G}I_L \tag{93}$$

Measured values for $k_{f,g}$ are shown in Fig. 22. At full load, the gate current resembles a rectangle; the form factor of a reactangle of one third of a period duration is $\sqrt{3}$.

From equations 91 and 93, the core size and the proper winding can be determined, as shown, for instance, by Anderson.[16,17]

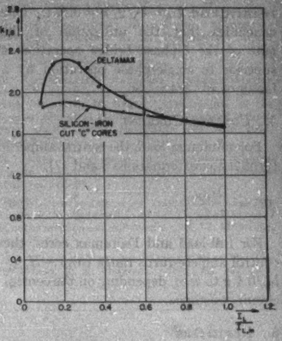

Fig. 22. Form factor for gate currents

4. UTILIZATION OF REACTOR

The reactor utilization may be defined as the share of output of this reactor divided by the volt-amperes of the reactor gate. For the circuit of Fig. 1, this ratio U_G becomes for full load and zero losses

$$U_G=\frac{\frac{1}{6}E_{L,m}I_{L,m}}{\frac{1}{2}E_sI_{G,e}} \tag{94}$$

Substituting for E_s from equation 90 and for $I_{G,e}$ from equation 93, one obtains with $k_{f,G}=\sqrt{3}$

$$U_G=\frac{\sqrt{6}}{\pi}=0.78 \tag{95}$$

For the single-phase amplifier with

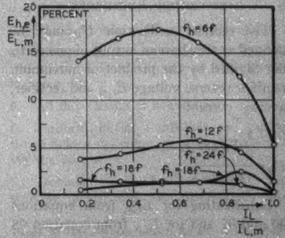

Fig. 23. Measured load voltage ripple of amplifier with Deltamax cores

$E_{h,e}$ = rms value of harmonic voltage
$E_{L,m}$ = rated d-c load voltage
f = supply frequency
fh = harmonic frequency

resistive load, $U_G=4\sqrt{2}/\pi^2=0.574$. One concludes that the utilization of the gate of the 3-phase bridge operation is superior to single-phase operation by a factor of $\pi\sqrt{3}/4=1.36$.

5. CONTROL CURRENT

For minimum load, the control ampere-turns AT_C are (equations 8 and 17)

$$AT_c=-\frac{H_c l_{Fe}}{0.4\pi} \tag{96}$$

For full-load and Deltamax cores, the control ampere-turns range from $-H_{c,dc}l_{Fe}/0.4\pi$ to zero, depending on the control circuit resistance.

6. RECTIFIERS

The maximum rectifier reverse voltage $E_{r,m}$ follows from equations 48 and 77:

$$E_{r,m}=\sqrt{2}E_e \tag{97}$$

The maximum average rectifier current $I_{G,m}$ follows from equation 69:

$$I_{G,m}=\frac{1}{3}I_{L,m} \tag{98}$$

In contrast to mercury arc or gaseous rectifiers, the rating of a semiconductor rectifier is determined not only by the average value, but also by the circuit connection as evidenced in manufacturers' catalogs.

7. LINE CURRENT

The line current i_l consists of one positive current train such that as shown in Fig. 19(E), followed 180° later by the same waveshape, but with reverse polarity. For full load, these currents can be approximated by rectangles, resulting in the simple relation

$$I_{l,e}=\sqrt{\frac{2}{3}}I_{L,m}=0.816I_{L,m} \tag{99}$$

8. UTILIZATION OF RECTIFIERS

The rectifier utilization U_R may be defined as the share of output of one rectifier divided by the product of maximum, rectifier reverse voltage $E_{r,m}$ and rectifier, average current

$$U_R=\frac{\frac{1}{6}E_{L,m}I_{L,m}}{E_{r,m}I_{G,m}} \tag{100}$$

Substituting for $E_{r,m}$ from equations 90 and 97 and for $I_{G,m}$ from equation 98 yields

$$U_R=\frac{3}{2\pi}=0.477 \tag{101}$$

For single-phase operation, $U_R=1/\pi=0.318$. Hence, the rectifier appears to be utilized better in a 3-phase bridge connection by a factor of 3 to 2. Actually, the average current rating of a semiconductor rectifier in a 3-phase bridge connection is about 10% less than in single-phase connection; therefore the superiority of the 3-phase bridge connection becomes $0.9\times3/2=1.35$

9. POWER FACTOR

The power factor (pf) relates the maximum d-c output power $E_{L,m}I_{L,m}$ (assuming no losses) to $E_eI_{l,e}\sqrt{3}$

$$pf=\frac{E_{L,m}I_{L,m}}{E_eI_{l,e}\sqrt{3}} \tag{102}$$

For full load and assuming rectangular gate currents, one obtains from equations 90 and 99

$$pf=\frac{3}{\pi}=0.955 \tag{103}$$

10. LOAD RIPPLE

To enable the designer to calculate load filters, the ripple of the load voltage was measured. Deltamax cores were used; the results are shown in Fig. 23 for the 6th, 12th, 18th, and 24th harmonics. The minimum ripple of the single-phase amplifier is 48%.

The comparisons listed above are intended to point out some of the inherent advantages of the 3-phase bridge amplifier over the single-phase amplifier.

Nomenclature

A_{Fe} = area of active core iron, square centimeters
AT = ampere-turns
AT_C = control ampere-turns
AT_c = ampere-turns to produce coercive force H_c
$AT_{c,dc}$ = ampere-turns to produce static hysteresis loop
$AT_{c,s}$ = (for definition see section C3)
B = flux density, gausses
B_s = saturation flux density, gausses
E_C = control voltage, volts, average
$E_{G,A}, E_{G,C'}, \ldots E_{G,B'}$ = gate voltages on SR $A,C'\ldots B'$ respectively, volts, average
$E_{L,m}$ = maximum load voltage, volts, average
E_e = line-to-line voltage, volts, rms (effective)
E_m = line-to-line voltage, volts, maximum (crest)
$E_{r,m}$ = rectifier reverse voltage, volts, maximum (crest)
$e_{C,A}, e_{C,C'}\ldots e_{C,B'}$ = voltage across control winding of SF $A,C'\ldots B'$ respectively, volts, instantaneous
$e_{C,p}$ = voltage spike induced into control circuit, volts; see (section D.5 and Fig. 20
$e_{G,A}, e_{G,C'}, \ldots e_{G,B'}$ = voltage across gate winding of SR $A,C'\ldots B'$ respectively, volts, instantaneous
$e_{R,A}, e_{R,C'}, \ldots e_{R,B'}$ = rectifier voltage of REC $A,C',\ldots B'$ respectively, volts, instantaneous
$e_{r,A}, e_{r,C'}, \ldots e_{r,B'}$ = reverse voltage on rectifiers REC $A,C'\ldots B'$ respectively, volts, instantaneous
$e_{1-0}, e_{2-0}, e_{3-0}$ = line-to-neutral voltage, volts, instantaneous
$e_{1-2}, e_{2-3}, e_{3-1}$ = line-to-line voltage, volts, instantaneous
$\mathfrak{F}_A, \mathfrak{F}_C'\ldots \mathfrak{F}_B'$ = net magnetomotive force on SR $A,C',\ldots B'$ respectively, ampere-turns
f = supply frequency, cps
$f_A(\theta), f_C'(\theta), \ldots f_B'(\theta)$ = a function of θ relating to branch $A,C'\ldots B'$ respectively
H = magnetic intensity, oersteds
H_c = dynamic coercive force, oersteds
$H_{c,dc}$ = d-c coercive force, oersteds
$\bar{h}_c$ = ratio of $AT_{c,dc}$ to AT_c
$\bar{h}_c'$ = ratio of $AT_{c,s}$ to AT_c
I_C = control current, amperes, average
I_G = gate current, amperes, average
$I_{G,e}$ = gate current, amperes, rms (effective)
$I_{G,m}$ = maximum gate current, amperes, average
$I_{G,s}$ = saturation component of gate current, amperes, average
I_L = load current, amperes, average
$I_{L,m}$ = maximum load current, amperes, average
$I_{L,s}$ = saturation component of load current, amperes, average
$I_{L,x}$ = excitation component of load current, amperes, average
$I_{l,e}$ = line current, amperes, rms (effective)
i_C = control current, amperes, instantaneous
$i_{G,A}, i_{G,C'}, \ldots i_{G,B'}$ = gate current, amperes, instantaneous
$i_{G,A,x}, i_{G,C',x}, \ldots i_{G,B',x}$ = excitation component of gate current, amperes, instantaneous
i_L = load current, amperes, instantaneous
$i_{L,x}$ = excitation component of load current, amperes, instantaneous
$(iN)_x$ = exciting ampere-turns
$\bar{i}_x$ = per-unit exciting current
K_{AT} = ampere-turn gain
$K_{AT,m}$ = ampere-turn gain maximum value
$k_{f,G}$ = form factor relating the rms to average gate current
l_{Fe} = length of magnetic circuit, centimeters
N = number of turns
N_C = number of turns of one control winding
N_G = number of turns of one gate winding
pf = power factor of load
R_C = resistance of entire control circuit, ohms
R_G = resistance of gate winding, ohms
R_L = load resistance, ohms
R_0 = output resistance (total resistance encountered by load current), ohms
R_f = rectifier forward resistance, ohms
SR = saturable reactor
t = time, seconds
U_G = gate (reactor) utilization factor, equation 94
U_R = rectifier utilization factor, equation 100
α = angle measured for each core from the instant at which each core starts on its flux upswing, degrees or radians
α_s = saturation (firing) angle, degrees or radians
θ = angular variable, degrees or radians
θ_u = (refer to section C1, mode 2)
Φ_0 = amount by which starting flux Φ_1 is raised above $-\Phi_s$
Φ_m = maximum flux, maxwells (crest)
Φ_s = saturation flux, maxwells
Φ_1 = starting flux, maxwells
$\phi_A, \phi_C', \ldots \phi_B'$ = core flux in SR $A, C'\ldots B'$ respectively, maxwells, instantaneous
$\Delta\phi$ = incremental change of core flux, maxwell, instantaneous

ω = angular velocity of line veltage, radians per second

Two-Step Switching of Saturable Reactors

B. W. LOVELL
ASSOCIATE MEMBER AIEE

THE FUNDAMENTAL problem in the analysis and design of magnetic amplifiers is the determination of the unsaturated impedance of the reactor by some test less specialized than insertion in the actual circuit. For tape and ferrite cores driven by very large currents, such as are encountered in computer applications, fairly successful approaches have been developed, although they are still incapable of explaining some observed phenomena.[1–3] Unfortunately, cores operating at normal magnetic-amplifier frequencies are not correctly described by these representations, and the designer has been forced to use either extremely idealized models or fairly limited extrapolations from specific measurements.

A core model based upon the magnetization process in single crystals, and applicable to low-frequency operation, has recently been reported by Woodson.[4] The constants incorporated in the model were evaluated from constant-current switching characteristics. For the material Orthonol* this model was shown to give good predictions of the operation of the d-c controlled single-core self-saturating amplifier over a wide range of carrier frequencies and input impedances. In common with most other approaches to this problem, the excitation for the model was assumed to be only slowly varying.[5,6]

This paper investigates the ability of that model and of its simplified forms to handle the more violently fluctuating excitations characteristic of multicore and polyphase magnetic-amplifier circuits. The particular situation considered is flux reversal by a step of magnetic-field intensity which abruptly changes amplitude during the reversal process. The applied fields are as shown in Fig. 1.

Mathematical Model

The behavior of an element of domain wall in a single crystal has been found to be described by equations of the form:

$$f(\delta)\frac{d\delta}{dt}=K_1(H-H_s) \qquad (1)$$

$$\frac{d\phi_1}{dt}=2B_s\frac{dA_1}{d\delta}\frac{d\delta}{dt} \qquad (2)$$

where

δ = distance of domain-wall element from nucleation site
$F(\delta)$ = position dependent damping factor
K_1 = material constant
H = applied field intensity
H_s = starting field for the element of domain wall
$\frac{d\phi_1}{dt}$ = rate of change of flux produced by this domain-wall element
B_s = saturation flux density
$\frac{dA_1}{d\delta}$ = relationship between area perpendicular to domain wall which is swept out by the element of wall and the position of the element

These equations were averaged over all domain walls by Woodson to produce two equations describing the switching process of polycrystalline core:[4]

$$\frac{dr}{dt}=K_1K_2\int_{H_c}^{H}(H-H_s)G(H_s)dH_s \qquad (3)$$

$$\frac{d\phi}{dt}=2B_sA_cg(r)\frac{dr}{dt} \qquad (4)$$

where

r = average normalized domain dimension
K_2 = normalizing constant
$G(H_s)$ = number of elements of domain wall having starting fields between H_s and H_s+dH_s
H_c = coercive force of core, the lowest value of H_s
$\frac{d\phi}{dt}$ = total rate of change of flux
A_c = effective cross-sectional area of core
$g(r)$ = shape function relating rate of change of flux to instantaneous r

In the development, the following assumptions were used or implied:

1. The magnetic field intensity is uniform throughout the material.
2. The nucleating field for each domain is less than its starting field.
3. The d-c hysteresis loop is rectangular.
4. All domains have starting fields $H_s \geq H_c$ which are constant throughout the switching process.
5. All flux change is irreversible.
6. Uniform initial conditions are established before switching by strongly saturating the core.
7. Domains are identical except for starting fields and are distributed uni-

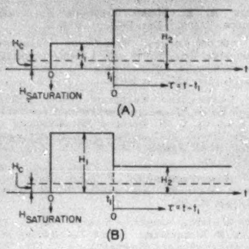

Fig. 1. Applied fields in 2-step switching process

A—Increase in applied field
B—Decrease in applied field

formly. The distribution of starting fields is independent of the applied field.

8. Each domain is described by equations of the form of 1 and 2.

9. $F(\delta)=1$.

10. The rate of change of applied field is small.

11. The rate of change of flux depends only upon the value of r and upon its rate of change.

For constant field switching of Orthonol, it was stated that $g(r)$ could be approximated by a sinusoid,

$$g(r)=\frac{\pi}{2}\sin \pi r \tag{5}$$

and that over a wide range of switching speeds $G(H_s)$ was a constant, a_0.[4] With these simplifications, the describing equation for the core becomes:

$$\frac{d\phi}{dt}=\pi B_s A_c K_1 K_2 \frac{a_0}{2}(H-H_c)^2\times \sin\left[\pi K_1 K_2 \frac{a_0}{2}(H-H_c)^2 t\right] \tag{6}$$

The model was extended to the case of slowly varying applied field by using equation 6 on an instantaneous basis in accordance with assumption 11.[4] This type of assumption is clearly not valid for all cases of discontinuous excitation. The growth of new domains after an increase in excitation cannot be as extensive as it would have been had the large excitation been applied initially, because some of the potential nucleating sites will be included in the region where magnetization has already been reversed at the time of the increase. Because domains of all starting fields are assumed uniformly distributed, the fractional decrease in the number of new domains is that fraction of the core where magnetization has been reversed by the time of the increase. This modification gives a core memory of how it reached a given flux level.

If domains grow from very small nuclei with a velocity dependent only upon the difference between the applied field and the starting field, as assumed, then newly formed domains should not contribute a large switching voltage. To bring the model into line with this consideration while adhering as closely as possible to the original analysis, the sinusoidal shape function which provides initial growth and final collision patterns will be applied to the individual domains. For switching processes during which the excitation is increased, all domains will be considered to grow from the time when their starting field is reached until the core is saturated.

No new domains are formed by a decrease in excitation during the switching process, and the critical assumption is that domain-wall velocity is determined only by the applied field and the starting field of the wall, regardless of the size that the domain may have attained.

The use of the sinusoidal shape function with equation 1 and equation 2 reduces to:

$$\frac{d\phi_1}{dt}=2B_s K_1(H-H_s)K_3 \sin\left(\pi\frac{\bar{\delta}}{\bar{\delta}^*}\right) \tag{7}$$

where

$\bar{\delta}$ = the average distance of all domain-wall elements from their nucleation sites
$\bar{\delta}^*$ = the final value that $\bar{\delta}$ is expected to attain because of present and past excitation
K_3 = a constant to be evaluated so that peak constant-current switching voltage is correct

After the applied field has been changed from one constant value to another, this becomes:

$$\frac{d\phi_1}{dt}=2B_s K_1(H-H_s)K_3\times \sin\left[\pi\left(\frac{\bar{\delta}_1}{\bar{\delta}_1^*}+\frac{\bar{\epsilon}}{\bar{\delta}_2^*}\right)\right](H>H_s) \tag{8}$$

where

$\bar{\delta}_1^*$ = the final value $\bar{\delta}$ was expected to reach before the change in excitation
$\bar{\delta}_1$ = the value $\bar{\delta}$ had reached at the time of the change
$\bar{\delta}_2^*$ = the final value $\bar{\delta}$ does reach at saturation
$\bar{\epsilon}$ = the amount by which $\bar{\delta}$ has changed since the excitation was altered

By equation 1, $\bar{\delta}$ is increasing linearly with time both before and after the change, but with a different coefficient. That is,

$$\frac{\bar{\delta}_1}{\bar{\delta}_1^*}=\frac{t_1}{t_1^*} \tag{9}$$

$$\frac{\bar{\epsilon}}{\bar{\delta}_2^*}=\left(1-\frac{t_1}{t_1^*}\right)\frac{\tau}{t_2^*} \tag{10}$$

where

t_1 = time at which the change in excitation occurs. Time is measured from the start of the flux reversal process
t_1^* = the time when the core would have saturated had the excitation not been changed
t_2^* = the time between the increase in excitation and saturation
τ = time since the change in excitation

Equation 8 applies to already growing domains for both increases and decreases in excitation. The same result may be obtained by replacing the average values in equation 8 with the values pertaining to the particular domain considered and using assumption 11 as applied to that domain only; i.e., utilizing the idea that any two of the quantities

$$\phi_1,\ \frac{d\phi_1}{dt},\ \text{and}\ (H-H_s)$$

determine the other. For domains which start to grow after an increase in excitation, the shape function is taken to be $K_3 \sin(\pi\,\tau/t_2^*)$ so that the initial and final growth patterns correspond to those of the model. Finally, integrating over all domains, the describing equations for a first level of excitation H_1, and a second level H_2, are

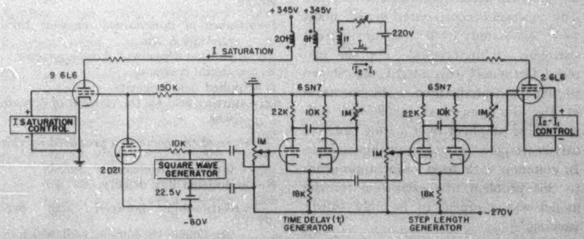

Fig. 2. Excitation circuit

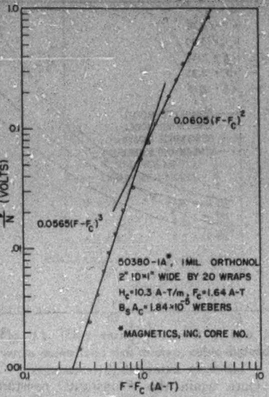

Fig. 3. Peak constant field switching voltage versus excitation

$$\frac{d\phi}{dt}=2B_sK_1K_2\int_{H_c}^{H_1}(H_1-H_s)G(H_s)\times \sin\left(\pi\frac{t}{t_1^*}\right)dH_s \quad (0<t<t_1) \qquad (11)$$

$$\frac{d\phi}{dt}=2B_sK_1K_2\int_{H_c}^{H_1}(H_1-H_s)G(H_s)\times \sin\left[\pi\left(\frac{t_1}{t_1^*}+\frac{t_1^*-t_1}{t_1^*\ t_2^*}\tau\right)\right]dH_s+ \frac{1}{2}\left(1+\cos\pi\frac{t_1}{t_1^*}\right)\int_{H_1}^{H_2}(H_2-H_1)\times G(H_s)\sin\left(\pi\frac{\tau}{t_2^*}\right)dH_s(H_2>H_1;\ 0<t-t_1<t_2^*) \qquad (12)$$

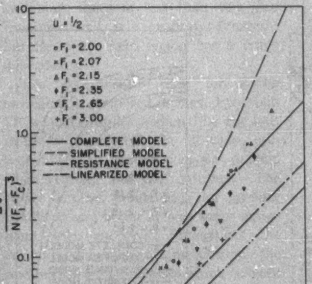

Fig. 4 (left). Discontinuity in voltage at t_1 versus normalized size of step, cubic dependence assumed, increased excitation

$$\frac{d\phi}{dt}=2B_sK_1K_2\int_{H_c}^{H_2}(H_2-H_s)G(H_s)\times \sin\left[\pi\left(\frac{t_1}{t_1^*}+\frac{t_1^*-t_1}{t_1^*\ t_2^*}\tau\right)\right]dH_s(H_2<H_1;\ 0<t-t_1<t_2^*) \qquad (13)$$

$K_1K_2G(H_s)$ is evaluated from constant-current switching data, and t_2^* is determined by requiring that the core saturate at $\tau=t_2^*$. Any other characteristics of this type of switching can then be calculated from these equations.

Linearized Form of Model

The complete model described by equation 6 is very difficult to handle mathematically in any case not involving constant-current excitation, and for this reason several simplifications have been suggested. One eliminates much of the complexity by considering all domains to be identical and thus characterized by the same starting field, the d-c coercive field.[7] For this representation the number of domains is unaffected by changes in excitation. To bring this into agreement with the actual dependence of the number of domains upon the excitation, the "constant" number of domains can be set to be consistent with the normal operating point, in the present case the initial level of excitation. With this compression of the starting field distribution, the equations describing the multidomain core are the same as those for any domain in it.

$$\frac{dr}{dt}=K(H-H_c) \qquad (14)$$

$$\frac{d\phi}{dt}=\pi B_sA_c(\sin\pi r)\frac{dr}{dt} \qquad (15)$$

which reduce to

$$i-i_c=\frac{el_c}{N^2B_sA_c\pi K\sin\pi r}=\frac{el_c}{N^2B_sA_c\pi K}\times \frac{1}{\sqrt{1-(1-2u)^2}}=\frac{e}{R(u)} \qquad (16)$$

where

l_c = mean length of core
N = number of turns in excitation winding
$u=\Delta\phi/\Delta\phi_{\max}=\Delta\phi/2B_sA_c$
K = constant chosen so that peak switching voltage is correct at the excitation level picked as a reference
$R(u)$ = apparent resistance of core
e = voltage across excitation winding

$$\frac{N}{l_c}(i-i_c)=H-H_c$$

This simplification of the model describes the unsaturated core as a current source shunted by a resistor dependent upon the instantaneous flux level, but not upon how that level was reached. The inherent disadvantage of this linearized system is that it only applies for limited deviations from the point where K was evaluated. The constant-current switching characteristics give K as a function of excitation, however, and the problem can be made piecewise linear if a very wide range of excitation is encountered.

Other Simplifications

The difference in waveshape between the induced voltage and the applied field makes analysis difficult for even slowly varying fields. It was suggested in reference 4 that the sinusoidal shape function might be replaced by its average value, and this procedure was shown to

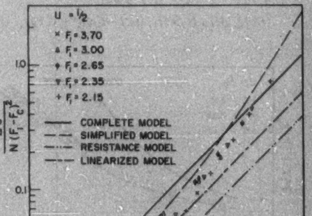

Fig. 5 (right). Discontinuity in voltage at t_1 versus normalized size of step, quadratic dependence assumed, increased excitation

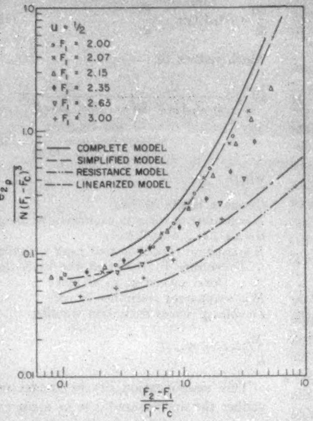

Fig. 6 (left). Peak switching voltage versus normalized size of step, cubic dependence assumed, increased excitation

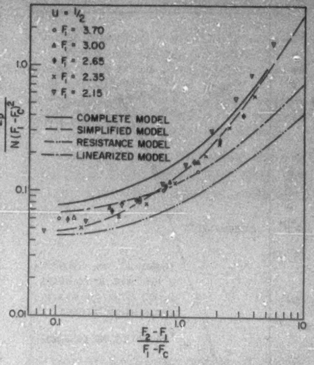
Fig. 7 (right). Peak switching voltage versus normalized size of step, quadratic dependence assumed, increased excitation



give very good results when applied to a single-core magnetic-amplifier circuit. This representation still recognizes the distribution of starting fields, and the same type of correction as before must be applied to account for the reduction of potential nucleation sites by previous flux change. Thus, the describing equations become equation 17 for a single domain and equations 18, 19, and 20 for the entire reactor.

$$\frac{d\phi_1}{dt}=2B_sK_1(H-H_s)K_3\frac{2}{\pi} \qquad (17)$$

$$\frac{d\phi}{dt}=\frac{4}{\pi}B_sK_1K_3\int_{H_c}^{H_1}(H_1-H_s)G(H_s)dH_s \quad (0<t<t_1) \qquad (18)$$

$$\frac{d\phi}{dt}=\frac{4}{\pi}B_sK_1K_3\int_{H_c}^{H_1}(H_2-H_s)G(H_s)dH_s+\frac{4}{\pi}B_sK_1K_3\left(1-\frac{t_1}{t_1^*}\right)\int_{H_1}^{H_2}(H_2-H_s)\times G(H_s)dH_s(H_2>H_1;\ 0<t-t_1<t_2^*) \qquad (19)$$

$$\frac{d\phi}{dt}=\frac{4}{\pi}B_sK_1K_3\int_{H_c}^{H_2}(H_2-H_s)G(H_s)dH_s \quad (H_2<H_1;\ 0<t-t_1<t_2^*) \qquad (20)$$

This type of analysis should be expected to give good results only for predictions of total flux changes and similar noninstantaneous phenomena because the actual waveshape is ignored.

When the shape function in the linearized model is averaged, the result is identical with one of the most widely used models, the model of the core as a constant resistance shunted by a current source to provide the width of the direct-current hysteresis loop.[8-12]

$$i-i_c=\frac{el_c}{\frac{2}{\pi}N^2B_sA_c\pi K}=\frac{e}{\mathcal{R}} \qquad (21)$$

Once again this "constant" resistance must be determined for some nominal level of excitation; and as with the previous simplification, predictions of instantaneous quantities are expected to be in error.

Experimental Evaluation

The major point of interest in the work was the ability of the core models to correctly predict the operation of a reactor under double-step excitation. Accordingly, precautions were taken to eliminate extraneous effects even though they might normally be present in a magnetic-amplifier circuit. The inside-diameter to outside-diameter ratio of the core was chosen as 0.98 so that the excitation would be as uniform as possible. To reduce the capacitance and inductance of windings, very few widely spaced turns were used. When a core is brought

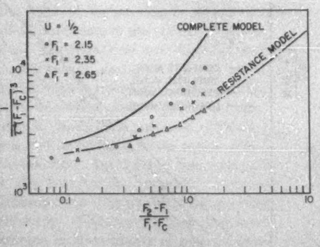


Fig. 8. Switching time after t_1 versus normalized size of step, cubic dependence assumed, increased excitation

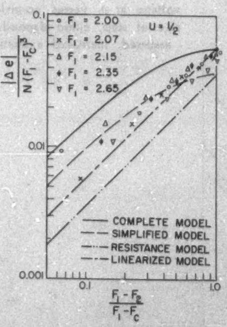

Fig. 9. Discontinuity in voltage at t_1 versus normalized size of step, cubic dependence assumed, decreased excitation

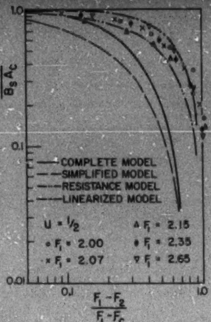

Fig. 11. Flux change between t_1 and t^* versus normalized size of step, cubic dependence assumed, decreased excitation

rapidly out of saturation, a short-duration voltage spike is invariably produced, usually attributed to reversible domain rotation. This spike is not accounted for by any model. While it may not represent useful flux change in the core producing it, it is effective in the control of any other resetting core. For this reason no attempt was made to perform tests in a multicore circuit or to use cores for excitation purposes. The circuit used is shown in Fig. 2. As illustrated, it will produce increases in excitation. The 8-turn winding is reversed for decreases. The constant-current switching characteristic, required to evaluate certain constants of the model, is shown in Fig. 3. This is not the quadratic characteristic reported in reference 4, but rather one with two distinct portions. The higher field portion, applying for switching times of less than 900 μsec (microseconds), is a quadratic function; but the lower field region has a cubic dependence.

The experimental data for 2-step switching is compared in Figs. 4 through 11, with the results predicted by the four methods considered. In all cases presented here the second step was applied when the core was half switched. The choice of other points does not produce results in any better or any worse agreement with theory.[13] Because of the extreme difficulty of performing the mathematics for processes which covered both regions of the constant-current switching characteristic, experimental results are compared with the predictions of the mode for processes restricted to one region. If this limitation is not observed, rather great deviations can be produced, as is shown in several of the illustrations. The features of the switching behavior which are shown are the discontinuity in induced voltage at the time of application of the second step and the peak switching voltage reached. In addition, the time required to reach saturation after the second step is shown for cases of increased excitation; and the change in flux between the beginning of the second step and the originally expected time of saturation is shown for decreases in excitation. For completeness, Figs. 12 and 13 show the type of deviation produced by using the complete experimental constant-current switching characteristic in the complete model. These predicted results cannot be normalized, and therefore, only one magnitude of initial excitation is considered.

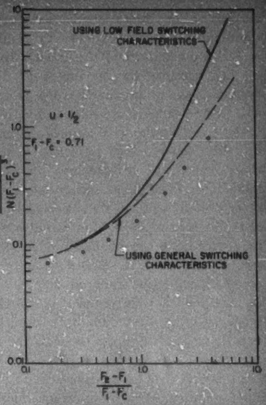

Fig. 12. Peak switching voltage versus normalized size of step, general and low field distribution, increased excitation

Conclusions

As is evident from the illustrations, neither the complex complete model nor the simplified versions give accurate enough predictions of the behavior of a reactor with discontinuously increasing excitation to make their use advisable for quantitative purposes. The errors are large in themselves and the positive feedback inherent in many multicore circuits would be expected to produce still worse agreement.

Certain qualitative features do appear that are worth mention as a guide to future work. The induced-voltage waveshapes, predicted for excitation increases by the complete model and by one not considering a modified shape function, are shown in Fig. 14. The observed waveshape was of the first type, the late-occurring peak produced by the modified shape function being apparent even when the core was three-quarters switched at the time of the second step. Models attempting to relate flux, rate of change of flux, and magnetomotive force without a knowledge of the past excitation history of the core cannot take this into

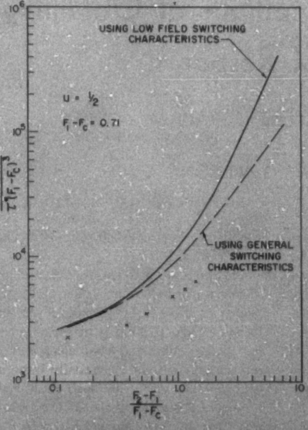

Fig. 13. Switching time after t_1 versus normalized size of step, general and low field distribution, increased excitation

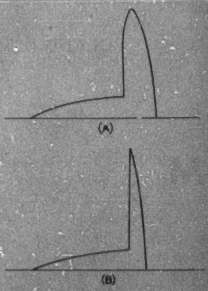

Fig. 14. Predicted switching voltage waveforms

A—Shape function and number of domains dependent on past
B—Only number of domains dependent on past

account. For excitation increases the discrepancy between experimental results and the predictions of the models that do not consider the starting field distribution gets progressively worse as the size of the step is increased. Further, if the complete model is applied neglecting the domain nuclei reduction factor, the disagreement is increased. Thus, a model to handle excitation increases must probably utilize these two features of the present model. The discontinuity in induced voltage at the time of the second step should, according to the complete model, be produced only by the domains which were growing under the influence of the first step, and should be linearly dependent upon the increase in excitation. While this is the case for large initial excitations, it is not so for smaller initial excitations, which would indicate that the effective starting field is a function of domain size or excitation. The other alternative, that the discontinuity is dependent to a considerable extent upon domains which have just started to grow, would require a similar explanation.

For cases of discontinuously decreased excitation, it is possible to predict the core behavior fairly accurately, but not by using the complete model. That is very inaccurate. The best results are obtained with the linearized model, and the next best with the resistive model. These models do not consider the starting field distribution and therefore do not alter the number of growing domains when excitation is decreased. These two models also have the property that flux, rate of change of flux, and magnetomotive force are uniquely related, or at least do not depend upon past-excitation, so that extensions of experimental data using only these three quantities is justified for decreases in excitation.[5] This behavior again supports the idea that the effective domain starting field must vary with domain size or with excitation. A similar behavior has been reported for *65* permalloy but the explanation presented in that case involved surface phenomena.[14] These could not be incorporated in the present model without extensive revision. Here domain nuclei were assumed distributed throughout the volume of the material, and no special significance was attached to those at the surface.

Some Practical Methods of Obtaining Time of Response

ROLAND L. VAN ALLEN

THOMAS G. WILSON
ASSOCIATE MEMBER AIEE

MEASUREMENTS of response time of magnetic amplifiers and similar carrier-modulated control devices have always presented problems to the design engineer. A number of methods have been described in the literature. Some of these have been proved to be reliable and accurate. Nevertheless, practical considerations often have limited their widespread usage.

This paper presents a brief description of three methods of measuring time of response to a step function. They have been found to be particularly useful because of their simplicity and convenience.

The first method entails the use of a "firing angle indicator." The indicating device itself is simply a small pulse transformer. The technique involved is similar to that employed when using a cyclic integrator. Instead of actually integrating the output over each half-cycle, however, a simple phase-shift circuit is used to produce an output which is equivalent to that which would be obtained from a magnetic amplifier having certain ideal characteristics. The time from initiation of the step-function transient until the output reaches a fixed percentage of its excursion is recorded and is the response time of the amplifier.

The second method, referred to as the "core integration" method, utilizes a toroidal core with a square-hysteresis-loop characteristic. The number of turns on this core establishes a fixed volt-second reference. The core is excited by the output voltage from the magnetic amplifier. Saturation of the core indicates when the volt-second integral of the output exceeds the reference level established by the wound core. A record is made of the time from the initiation of a transient

until the average output of the amplifier reaches the preset value of the reference.

The third method describes a "comparison" in which an auxiliary magnetic amplifier is used to establish a reference at some known output level. An indication is made during a transient when the magnetic amplifier under test delivers an output equal to that established by the reference amplifier. Measurements of time of response are made by recording the time from initiation of a step function until the output of the amplifier under test equals that of the reference.

Considering just the variety and number of different approaches that have been made in solving this problem in measurements, there is evidence that the single ideal solution applicable to all situations has not been fully resolved. The particular areas of usefulness for each of the three methods along with their advantages and disadvantages are discussed.

Background

The AIEE Magnetic Amplifier Committee has given consideration to the problem of measuring the response time of magnetic amplifiers and has proposed test codes for the express purpose. Section V.B.1 of the proposed Standard Test Codes[1] states the following concerning the measurement of response time. "Determine the time (preferably in seconds; may also be measured in cycles of the power frequency) required after application of the step-function signal for the output quantity to change by an amount equal to 63% (unless otherwise specified) of the final change in output." For nonreversible magnetic amplifiers, the final change in output has been proposed as being from 20% to 80% of the value between minimum and rated output.

With regard to the nature of the output quantity itself, the proposed standard recognizes that the intended use of the amplifier often dictates that characteristic which will be of greatest interest. This may be either the half-cycle average output voltage,[2] the rms output, or the fundamental component of the output. Whatever it is, a conversion chart may be made by steady-state measurements to permit translation to and from the parameter actually sensed or detected by the measuring device.

It should be noted that the AIEE Magnetic Amplifier Committee has only indicated what is to be measured and has not specified how the measurement is to be made. Most of the techniques or methods indicating how to measure response time depend upon either performing the half-cycle by half-cycle integration of the output voltage or else singling out and identifying the particular half-cycle when the output passes through the reference 63% point.

The use of a cyclic integrator[3,4] is no doubt one of the best methods to display the dynamic behavior of a magnetic amplifier since it can measure the average output each half-cycle. From a practical viewpoint, however, it requires special electronic circuits. This fact probably has retarded its general acceptance by industry. A different method which has found wide usage measures the variation in firing angle using an oscilloscope.[5] This latter method, while convenient and simple for relatively high-speed magnetic amplifiers, is not suitable for measuring long response times. For these and other reasons, need has arisen for methods which, from a purely practical standpoint, could be used without requiring elaborate preparation.

Time of Response With Firing Angle Indicator

THEORY

With reference to Fig. 1, (b) is a sketch of the output load voltage $e_L(wt)$ of a magnetic amplifier which might occur

in response to a transient initiated by a step change in control-circuit voltage. The latter is shown by the sketch (a). For the present, focusing attention only on (a) and (b), the average output during each half-cycle of the transient is obtained by integration. Calling E_{a+} the output of the plus half-cycles and E_{a-} that of the negative half-cycles, the expressions are

$$E_{a+} = \frac{1}{\pi}\int_0^{\pi} e_L(wt)d(wt) \qquad (1)$$

$$E_{a-} = \frac{1}{\pi}\int_{\pi}^{2\pi} e_L(wt)d(wt) \qquad (2)$$

The true cyclic integrator performs these computations each half-cycle and usually produces an output pulse at the end of each half-cycle which has an amplitude proportional to E_{a+} and E_{a-}.

If the load on the amplifier is resistive and if magnetizing current can be neglected, then the assumption that the load voltage approximates a portion of a sinusoid permits some simplification. Considering just the positive half-cycle and calling the firing angle during this period α_+, equation 1 reduces as follows:

$$E_{a+} = \frac{1}{\pi}\int_{\alpha_+}^{\pi} \hat{E}_L \sin(wt)d(wt) = \frac{\hat{E}_L}{\pi}(1+\cos\alpha_+) \qquad (3)$$

This expression indicates that even during a transient when the angle α_+ is changing from cycle to cycle, the half-cycle average of the output can be expressed as a function of the cosine of the angle at which firing took place. This fact is central to the first method of measurement.

METHOD OF MEASUREMENT

Fig. 2 shows symbolically a magnetic amplifier with an a-c load. An R-C (resistance-capacitance) phase shifting network to generate a cosine wave is located across the a-c voltage supplying the amplifier. The primary of a small pulse transformer is in series with the load. This transformer employs a square-loop core material and is designed to support a voltage which is small with respect to the gate circuit supply. It saturates in a few millivolt-seconds and its output is used to modulate the intensity of the beam of the oscilloscope. The design is such that it will intensify the beam for only a few microseconds at the instant the magnetic amplifier fires. The silicon diode placed across the secondary of the transformer permits only a unidirectional pulse to the Z-axis of the oscilloscope and eliminates ringing in the circuit.

With this configuration, there will be a dot appearing on the face of the oscilloscope once each positive half-cycle. Its vertical position will be equal to the instantaneous value of the cosine wave at the moment the magnetic amplifier fires, or proportional to cos α_+.

To obtain transient response, a step-function change in the control-circuit voltage supplying the amplifier is made. This signal is used to trigger the sweep circuit of the oscilloscope. The sweep of the oscilloscope serves as the time base for measuring response time.

Fig. 1(c) shows, as a dashed curve the cosine wave impressed on the Y-axis. The intensity of the beam, however, is adjusted so that nothing is visible unless a d-c potential exists at the Z-axis terminals. This occurs only at the instant of firing and is indicated by the heavy

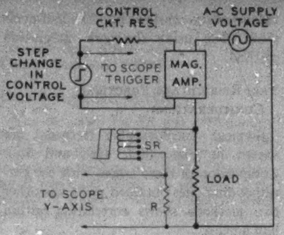

Fig. 6. Circuit for core integration method

dots. A dot at the negative peak of the cosine wave ideally would indicate zero output and one at the positive peak would indicate the theoretical maximum.

Results of measurements of time of response using the firing angle indicator are shown in Figs. 3(a), 4(a), and 5(a) along with comparative results obtained using the other two methods. These figures show the effect of a decreasing N_c^2/R_c on a test amplifier. Details of the experimental circuits used in obtaining these data are given in the Appendix. All oscillograms are the result of "rise-time" measurements. The traces labeled (a) in these figures show, on the left, a reference dot at a level corresponding to a 63% change in output. The time of response in seconds obtained by this method is measured from the calibrated sweep of the oscilloscope from time t_0 until the output reaches the 63%-reference level. Time of response in cycles may be obtained by simply counting the dots, since one dot occurs each cycle.

When fall-times are measured, the appropriate 63% change in output is recorded for reference. It should be recognized that the rise-time indicated using this method will always be slightly shorter than the fall-time. This is caused by the propagation of the firing angle which advances toward the beginning of the half-cycle when rise-time measurements are made and toward the end of the half-cycle when fall-time measurements are made. For most practical measurements, this small error may be neglected as accuracy of ±1/2 cycle is satisfactory.

This characteristic inherent in this method of measurement brings out a basic difference between the "firing angle indicator" and the cyclic integrator. The cyclic integrator indicates the output at the end of each half-cycle, whereas the firing angle indicator indicates the level of output at the instant the amplifier fires. Further, with the firing angle indicator, measurements are made only once each cycle which is a disadvantage with 2 cycles or less response time.

Time of Response by Core Integration

CIRCUIT DESCRIPTION

The same sudden saturation characteristic utilized in the design of the saturable reactors for high-performance magnetic amplifiers also can be employed to measure their response time. This is illustrated by the circuit of Fig. 6. Here, an auxiliary circuit, consisting of a saturable reactor *SR* and a resistor *R*, is connected in parallel with the a-c load on the amplifier. The voltage across *R* is fed to the *Y*-axis of an oscilloscope.

In the design of this auxiliary circuit, *R* is chosen to be large enough so that even if *SR* were short-circuited, the current drain would not exceed a few per cent of the amplifier load current. The other component, saturable reactor *SR*, is constructed from a highly rectangular-loop core material, such as Orthonol, and has numerous taps.

The circuit functions in the following way. Immediately after the firing of the magnetic amplifier, a voltage essentially equal to the entire load voltage $e_L(wt)$ appears across *SR* and causes its flux to change. The only voltage appearing at the *Y*-axis terminals during this period is the *IR* drop due to the magnetizing current for *SR*. If the load voltage becomes high enough, however, *SR* can no longer absorb all of the voltage, and it saturates. Coincident with saturation, the voltage across *R* suddenly increases becoming nearly equal to the load voltage itself.

To measure time of response using the circuit of Fig. 6, the number of turns *N* on *SR* are selected so that the reactor is just on the verge of saturating when the output load voltage of the amplifier is at the 63%- point described earlier. With *N* so selected, the load voltage is set to the "minimum test output voltage"[1] and a step-function of control is applied to take the output to the "maximum test output voltage." A sketch of the wave-shape occurring across *R* is shown in Fig. 2(d). The response time is that period of time from t_0 until the first spike of voltage occurs across *R* indicating saturation of *SR* and showing that the amplifier has completed 63% of its excursion.

In comparing Fig. 1(c) and 1(d), it should be noticed that in the core integration method, indication that the amplifier has reached the prescribed reference value occurs near the end of the half-cycle. On the other hand, in the firing angle indicator method, indication is given near the beginning of the half-cycle in which the output will first exceed the reference value. This difference should be borne in mind when comparing results from the two methods.

MEASUREMENT RESULTS

Figs. 3(b), 4(b), and 5(b) show oscillograms of the voltage appearing across the resistor *R* of Fig. 6 during increasing transients of load voltage. The pictures show unidirectional pulses of output occurring during the first few cycles of the transient. They are produced because the flux level in *SR* at the instant the transient is initiated is arbitrary and may

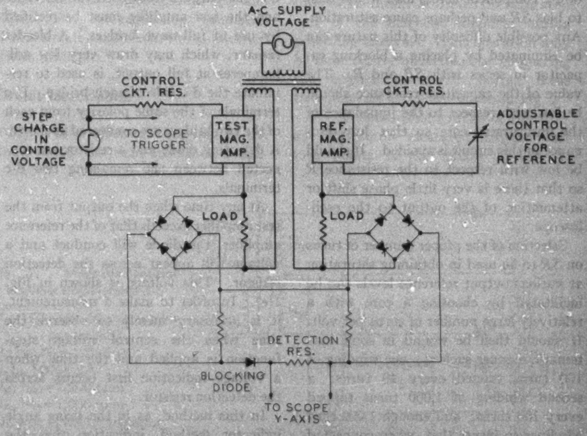

Fig. 7. Circuit for comparison method

Table I. Recommended Use of the Three Methods for Measuring Time of Response

	Firing Angle Indicator Method	Core Integration Method	Comparison Method
Use on slow transients	Good	Good	Good
Use on fast transients	Over 2 cycles	Over 2 cycles	Good
Usable with high-frequency a-c supplies	Requires core with fast switching time	Yes	Yes
Usable for a-c resistive loads	All except high *R* values	All values	All values
Usable for d-c inductive loads	No	Yes	Yes
Usable for d-c loads	Only with modifications	Series capacitor required	Yes
Usable for reversible output	Not practical	Series capacitor required	Yes

be at any point between $+B_r$ and $-B_r$. If the flux should have been left near one of the residual points, then the core probably would saturate in this direction if the load voltage during the first half-cycle of the transient should be of such a polarity to drive it toward this residual point. These pulses disappear within a few cycles, but care should be used in interpreting oscillograms showing fast transients so as not to confuse these pulses with the bi-directional pulse which occurs when the 63%- point is passed. Extrapolation of the envelope of the bi-directional pulses back to zero often helps in locating this point.

PRACTICAL CONSIDERATIONS

This measurement approach is based on the integrating property of square-loop core materials and requires that the voltage impressed upon the *R-SR* circuit be a-c. Sometimes it happens that the amplifier load voltage contains a small d-c component. This might be due to a slight unbalance between the two gate windings or the two rectifier characteristics. Whatever the origin, the existence of d-c component across load would tend to bias *SR* and perhaps cause saturation. Any possible difficulty of this nature can be eliminated by placing a blocking capacitor in series with *SR* and *R*. The value of the capacitive reactance should be low with respect to the impedance of the unsaturated core so that ferroresonance in this circuit is avoided. It should be low with respect to the resistance *R* so that there is very little phase shift or attenuation of the output to the oscilloscope.

Selection of the proper number of turns on *SR* to be used in obtaining saturation at various output reference levels can be facilitated by choosing a core with a relatively large number of turns per volt. It should then be wound in some systematic manner such as: one winding of 100 turns tapped every 10 turns; a second winding of 1,000 turns tapped every 100 turns; and enough 1,000-turn windings to insure that, when connected in series at the highest reference voltage anticipated, the core is saturated. Selection of the proper number of turns to be connected in series then becomes an accurate and rather rapid process.

Time of Response by Comparison Method

MECHANICS OF OPERATION

This technique of measurement is referred to as the comparative method since a reference amplifier, having similar characteristics to the amplifier being measured, is needed to pre-establish an output level against which the output from the test amplifier may be compared.

The mechanics of operation can be understood by considering the circuit of Fig. 7. The reference amplifier is adjusted to some arbitrary output level which normally blocks a simple diode detector. When the output from the test amplifier just exceeds the output from the reference, current flows through the detection branch.

Both amplifiers should have their rated loads connected as in normal operation Unless the outputs are already d-c, the outputs from both the reference and the test amplifier must be rectified by use of full-wave bridges. A bleeder resistor, which may draw very few milliamperes at full output, is used to terminate the d-c side of each bridge. D-c terminals of the same polarity from each of the two bridges are connected as shown. A detecting diode and a resistor are connected between the remaining two d-c terminals.

At any time when the output from the test amplifier exceeds that of the reference amplifier, the diode will conduct and a voltage will appear across the detection resistor. This voltage is shown in Fig. 1(e). In order to make a measurement, it is necessary merely to observe the time when the control voltage step-function is applied and the time when a voltage indication first occurs across the detection resistor.

In this method, as in the firing angle indicator method, indication that the output has arrived at the preset reference value occurs earlier in the half-cycle than when using the core integration method.

TEST RESULTS AND PRACTICAL CONSIDERATIONS

Typical oscillographic records are shown in Figs. 3(c), 4(c), and 5(c). Comparison of these traces with the corresponding ones obtained using the other two methods shows correlation within half a cycle.

A simple modification to the detection branch makes it quite easy to use this scheme to measure response time of reversible-output magnetic amplifiers. This has been employed successfully on a production line where time of response of such amplifiers had to be continually checked and recorded.

The comparison approach is particularly adaptable when measurements are required on amplifiers whose load waveshapes are quite distorted. The only requirement is that the reference amplifier be similarly terminated.

Conclusions

The three methods presented for measuring time of response have certain features in common. None requires special equipment, elaborate preparation time, or a skilled operator. All are accurately reproducible and widely applicable.

Table I shows a comparison of the three methods. It can be used as a guide in selecting the most suitable method to be applied when special measurement problems are encountered.

Appendix

Magnetic Amplifier Circuit

All oscillograms were taken using a doubler-connected magnetic amplifier with a-c output. The amplifier cores were Magnetics, Inc. *50,103-4A* (2 × 3 × 1/2 inch) wound with gate windings of 2,350 turns and a control winding of 900 turns. The self-saturating diodes were silicon, Westinghouse type *3080*. The load resistance was 100 ohms.

All tests were conducted at 120 volts, 60 cps (cycles per second). Under this condition, the "rated output voltage" was taken as 85 volts for the half-cycle average output. The "minimum output voltage" was measured as 0.1 volt. This yields 17 volts for the "minimum test output voltage" and 68 volts for the maximum test output voltage." The 63%- point for a rising transient is thus 49.1 volts on a half-cycle average bias.

Firing Angle Indicator Circuit

The pulse transformer used to record the data presented was made with a Magnetics, Inc., core *50,000-4A* (1/2 × 3/4 × 1/4 inch)

Vol.
Pt. 1
1959

wound with 300 turns on the primary and 100 turns on the secondary. The diode in the secondary circuit was a GE (General Electric Company) *1N538*.

Core Integration Circuit

The core used for *SR* was a Magnetics, Inc., *50,026-2A* (1 × 1½ × 3/8 inch) with various windings. The turns actually used in recording the data were 2,620. The resistor *R* was 5,100 ohms. In all tests, a capacitor of 4 microfarads was used in series with *SR* and *R*.

Comparison Circuit

The reference amplifier was identical to the test amplifier. The auxiliary bridge rectifiers paralleling the two 100-ohm loads were made using *GE 1N538* silicon diodes. The bleeder resistors were 10,000 ohms, and the detection resistor 10,000 ohms. The blocking diode was a *GE 1N538*.

Self-Regulation in Magnetic-Transistor Amplifiers

C. E. HARDIES
ASSOCIATE MEMBER AIEE

R. L. VAN ALLEN
ASSOCIATE MEMBER AIEE

MAGNETIC amplifiers incorporating transistors have received considerable emphasis in the literature. Many circuits have been devised using magnetic amplifiers and transistors in combination to achieve many different characteristics. This paper describes a characteristic available with this combination of devices that has not been heretofore described. By utilization of the circuitry to be described, an amplifier can be designed that has a self-regulated output for variations in supply excitation. This characteristic is inherent to the circuitry; not accomplished by the addition of compensating networks. While self-regulation is the primary advantage to be gained by use of the circuitry, no sacrifice is made in gain, temperature stability, or frequency stability from that of a conventional magnetic amplifier. In addition, since the transistor is utilized only as a switch (transistors have very low saturated resistances as compared with magnetic amplifiers) the regulation of the device with load is very good.

The basic method to be discussed for achieving self-regulation for variations in supply excitation used in the present device has been treated in all-magnetic devices called the "transactor"[1] and the "shunt-coupled magnetic amplifier."[2]

In these devices, the output is taken essentially in parallel with the magnetic cores so that output exists during the time interval while the cores are changing flux. This parallel operation requires that current limiting impedances be placed in series with the gate windings to limit the gate current after firing. Actually, the principle of having output occur during the prefiring interval rather than in postfiring intervals, as with conventional magnetic amplifiers, is the only item common to these all-magnetic devices and the magnetic-transistor amplifier. The self-regulating properties of this circuit result from the application of this principle.

Circuit Description

Fig. 1 is a schematic diagram of the single-ended magnetic-transistor amplifier. It contains a basic center-tapped magnetic amplifier and a transistor, together with their associated power and bias supplies.

The polarity of the transistor bias, acting through R_b, is negative to the base of the transistor and sufficient in magnitude to hold the transistor in its "on" or short circuit condition under the most adverse conditions of load, excitation, and temperature. The polarity of the magnetic amplifier is such that its output is positive with respect to the base of the transistor. Thus, output is delivered via the switched transistor during the time intervals before the magnetic amplifier fires (prefiring), and and no output is delivered during the time intervals either core is saturated (postfiring). The transistor is held "off" or open circuited during postfiring intervals because of the positive voltage established at the base by the magnetic amplifier. The bias current which passed through the base during the prefiring intervals is shunted through the saturated core of the magnetic amplifier during postfiring intervals. This operation may be more clearly understood by comparing the voltage waveforms during these two intervals which are shown in Fig. 2.

Fig. 2 shows photographs of the voltage waveforms measured between various points in the circuit of Fig. 1.

A—Voltage a to b
B—Voltage across R_b
C—Voltage a to c
D—Voltage across R_1

The signal level is such that the magnetic amplifier fires at approximately 90 degrees. Each of the photographs show one full cycle of the circuit operation. Fig. 2 (A) shows the power supply voltage to the transistor and load. This voltage was measured across points *a* and *b* of Fig 1. Fig. 2 (B) shows the bias current to the transistor measured as the voltage across R_b. From this waveform, it can be seen that during post-firing intervals the drop across R_b is increased by the output voltage of the magnetic amplifier, indicating that the bias current is shunted by the gating core.

Fig. 2 (C) is the output of the magnetic amplifier as measured across the base to emitter terminals. During the prefiring intervals, the base is a few tenths of a volt negative indicating that the transistor is saturated or short circuited. During the postfiring intervals this voltage is positive, effectively biasing the transistor off.

Fig. 2 (D) is the waveform of the voltage measured across load resistor R_L. As has been described, the output occurs during the prefiring intervals. This output has a constant volt-second value, determined by the reset of the magnetic cores. The output of the transistor occurs in the prefiring interval determined by the firing angle of the magnetic amplifier. Then, like the transactor and shunt-coupled amplifier, the output is self-regulating with variations in supply voltage. When the supply voltage is increased the instantaneous value of the output will increase, but the firing angle will occur earlier in time maintaining constant volt-seconds and thus regulating the output. Likewise, when the supply voltage is decreased, the firing angle will occur later in time with lower instantaneous values also regulating the output.

Fig. 3, curve A shows a typical transfer characteristic for the amplifier shown schematically in Fig. 1. The magnetic-transistor device has zero output at zero control signal, because with the self-saturating magnetic amplifier full on, the transistor is biased off. This transfer characteristic was taken from a unit containing 50-50 nickel-iron magnetic cores having a high squareness ratio.

Design Considerations

The magnetic amplifier in the magnetic-transistor amplifier shown in Fig. 1 operates in the conventional manner with the base circuit of the transistor as its load. The base diode conducts bias current in its forward direction during prefiring intervals. During this time, the magnetic amplifier's load can can be considered as being made up of a resistor and battery in series. The battery voltage being the forward drop across the base diode. In post-firing intervals, the current which will flow in each of the gate windings will be essentially equal to the bias current. The gate windings current capacity can be determined directly from the required load current since the bias and load (collector) currents are related in the transistor by its gain. The following expression yields the current rating required in the gate windings as a function of the load current of the entire magnetic-transistor device.

$$I_g = \frac{I_b}{2} = \frac{I_c}{2\beta}$$

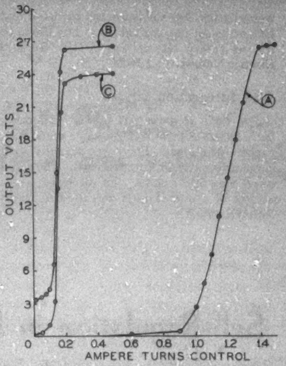

Fig. 3. **Transfer characteristic for single-ended d-c magnetic transistor amplifier**

A—With L_1, L_2 made from Orthonol
B—With L_1, L_2 made from HyMu80
C—With L_1, L_2 made from HyMu80 and with circuit off

where

I_g = average current in the gate windings of the magnetic amplifier
I_b = average bias current
I_c = collector and average current through the load R_L
β = current gain of the transistor, grounded emitter

The voltage output of the magnetic amplifier is dictated by the transistor base diode. The output voltage from the magnetic amplifier must be kept below the ratings for maximum reverse voltage on the base to emitter junction.

With these current and voltage requirements for the magnetic amplifier's load circuit, one can design a magnetic amplifier to suit the other requirements of the particular application such as gain, sensitivity, and response time according to conventional magnetic amplifier techniques.

The transistor used in the magnetic-transistor amplifier is selected so as to be able to withstand the required supply voltage when it is open-circuited and pass the load current when fully turned on. In cases where the maximum collector current is not specified by the manufacturer, this can be determined from the saturated resistance of the device and the allowed junction dissipation. In determining collector current, the transistor must be derated for the highest ambient temperature in which the device is to be used.

The value of the bias resistor is selected

so that the bias current equals the maximum average load current divided by the gain of the transistor.

$$R_b = \frac{E_c}{I_b} = \frac{E_c\beta}{I_L}$$

where

E_c = average transistor supply voltage
I_b = average bias current
β = current gain of the transistor
I_L = average load current (maximum)

For cases where high sensitivity is required, the gain of the magnetic amplifier portion of the circuit can be improved using any of the more sensitive core materials. Fig. 3, curve B shows the transfer characteristic of a unit using an 80% nickel-iron core material and the circuit if Fig. 1. Since the squareness ratio of the 80% nickel-iron is lower, there is an appreciable output at zero control current. This is to be expected since the transistor is biased "on" in absence of output from the magnetic amplifier. Self-saturating magnetic amplifiers made with cores having a poor squareness ratio will exhibit reduced output because of the voltage absorbed in changing flux from B_r to B_m. A more desirable transfer characteristic can be obtained as shown by curve C in Fig. 3 by the simple expedient of modifying the waveshape of the transistor supply voltage.

The circuit diagram of Fig. 4 is the same as Fig. 1 except that a small choke has been added in series with the transistor supply source. The size of this choke will be determined by the squareness ratio of the 80% nickel-iron cores in the magnetic amplifier. The choke should be made of a square hysteresis loop material, such as Orthonol, since its function is to absorb a few millivolt-seconds from the first part of each half cycle. The volt-seconds absorbed essentially remove the supply voltage from the transistor during the time that the magnetic amplifier changes the flux in its cores from B_r to B_m. Resistor R_d is used to pass magnetizing current of the choke since the choke functions when the transistor is not operating.

Magnetic-transistor amplifiers can be designed using either germanium or silicon transistors. Since the voltage drop across the base diodes of silicon transistors is higher than that found in germanium transistors, the magnetic amplifier for use with silicon transistors must have a higher output voltage than one designed for use with germanium transistors. Since the maximum reverse voltage for silicon transistors is considerably higher than for germanium, this presents no problem.

Circuit Modifications

There are additional magnetic-transistor circuits using the same scheme of that shown in Fig. 1 which will also exhibit self-regulation. The circuit shown in Fig. 5 may be used to deliver an a-c output. The transistor in this circuit is connected across the d-c terminals of a full-wave rectifier bridge which is in series with the load and a-c supply source. When the transistor switch is open-circuited, the bridge presents a high impedance to the load and when short-circuited offers a low impedance.

The transistor is supplied with a bias to turn it on and the magnetic amplifier is used to gate the transistor switch as was explained previously.

Fig. 6 shows the circuit of a push-pull magnetic-transistor amplifier. This circuit is made up of two single-ended units connected so that a given direction of signal increases the output of one of the single-ended units and decreases the output of the other. This circuit has d-c output and can be taken differentially to obtain reversible polarity d-c output. The circuit also exhibits self-regulation, having the same properties of that shown in Fig. 1.

Experimental Results

Tests were conducted on magnetic-transistor amplifiers using both silicon and germanium transistors with 50% and 80% nickel-alloy core materials. Fig. 7 shows a typical transfer characteristic of the circuit in Fig. 1 as well as the effects on ± 10% variation in supply voltage. It is of interest that regulation can be maintained past the knee in the region of maximum output. This is accomplished by designing the magnetic amplifier such that at full output and minimum supply voltage the core flux is operated from knee to knee. This flux excursion is the maximum volt-seconds of the core and is a constant; hence, supply voltages in excess of this minimum do not adversely affect the output.

The regulation of the circuit with variations in load is excellent when germanium transistors are used since the saturation resistance of these transistors is one ohm or less. The regulation with load using silicon transistors is higher since the saturation resistance of silicon transistors is much higher than germanium. The variation in output was small over temperature ranges from −45 to +52 degrees centigrade. The effect of temperature change was to translate the transfer curve by an amount predicted by the change in hysteresis loop width as a function of temperature, approximately 0.07% per degree centigrade.

A check of the speed of response showed that with low N_c^2/R_c ratios, the speed of response was less than 1 cycle. It is interesting that the circuit exhibits essentially the same response for both rise and fall times. This probably can be attributed to the limiting of circulating currents flowing in the postfiring interval.

Fig. 8 (A) shows the output of the magnetic amplifier alone, when terminated into a resistive load. The rise time of the voltage which occurs at the firing angle requires 200 microseconds. Fig. 8 (B) shows the output of the magnetic-transistor amplifier under the same conditions. The switching time of the transistor is 24 microseconds. This is the maximum amount of time the transistor is in its class A region during each half-cycle. The fact that the transistor switches very much faster than the magnetic amplifier output in this combination device permits operation of this circuitry at much higher frequencies than are possible with only the magnetic amplifier.

The transistor functions more nearly as a perfect switch than does the magnetic amplifier, and is less frequency sensitive than are the windings of the saturated cores. Therefore, the output of the magnetic-transistor amplifier is changed

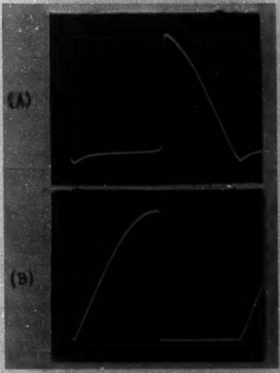

Fig. 8. Comparison of waveforms of magnetic amplifier alone (A); and output of magnetic-transistor amplifier (B)

less by variations in supply frequency than the magnetic amplifier alone.

Conclusions

Magnetic amplifiers and transistors can be combined in a hybrid amplifier to produce a variety of advantages, foremost of which is self-regulation for variations in supply voltage.

In addition to this self-regulation for variations in supply voltage, the circuitry provides high gain, frequency and temperature stability, and excellent load characteristics.

The design of the magnetic-transistor amplifier is simple since the magnetic amplifier of the circuit is a conventional self-saturating circuit.

The use of this circuitry has the additional advantage of being suitable for use at higher supply frequencies since the transistor is switched at approximately 10 times the speed the magnetic amplifier output normally is switched.

Magnetic Amplifier Binary-to-Analog Conversion

I. DANYLCHUK
ASSOCIATE MEMBER AIEE

D. KATZ
ASSOCIATE MEMBER AIEE

THE PROBLEM of digital to analog conversion occurs frequently in systems using digital computers. Where power gain is needed, where a high degree of accuracy must be maintained, and where speed of response is not a limiting factor, magnetic amplifiers have special utility in decoding of digital information. Based on the saturable reactor with multiple control windings proportioned in a binary scale, a magnetic amplifier circuit has been devised to convert a 10-digit parallel binary-coded input to an analog voltage ranging from 0 to 102.3 volts average with an accuracy of better than one part in a thousand. With the 10-digit input, three saturable reactors are used for the basic conversion to analog and a subsequent stage of self-balancing magnetic amplifier provides additional gain to drive a servomagnetic amplifier. In the over-all conversion circuit, the inherent feedback, signal mixing, and power gain capabilities of magnetic amplifiers appear to result in a simpler and more reliable circuit than could be achieved with other techniques.[1] This paper discusses the application of magnetic amplifiers in a digital to analog conversion.

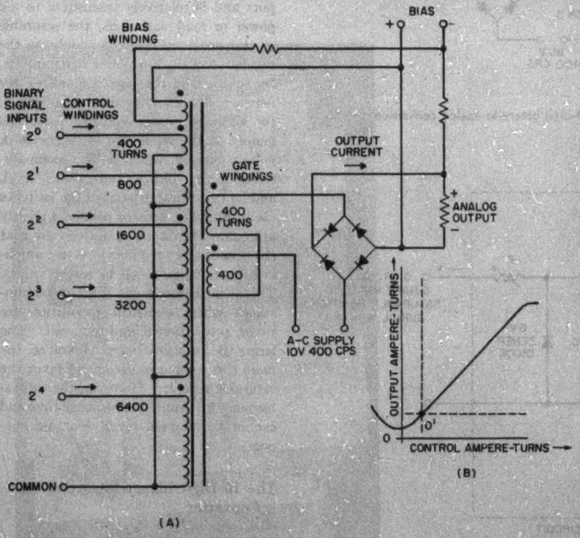

Fig. 1(A). Saturable reactor for 5-digit binary-to-analog conversion. (B). Shift of coordinate axes of transfer characteristic

The Saturable Reactor as a Basic Converter

Binary to analog conversion can be considered as a problem in signal weighting and addition. In the binary system only two symbols are used, 0 and 1. These symbols represent the coefficients of integral powers of the base 2. For example, the binary number 01011 represents $0\times 2^4+1\times 2^3+0\times 2^2+1\times 2^1+1\times 2^1$, or the decimal number 11. To convert a binary number to its analog equivalent, each coefficient is multiplied by the base 2 raised to the power associated with the digit and the quantities so obtained are summed. The conversion factors of the five binary digits in the example, going from the least significant digit (2^0) to the most significant digit (2^4), would be 1, 2, 4, 8, and 16. In an electrical system, the signals representing the binary "ones" are weighted, or multiplied by factors, in accord with these conversion factors and summed to obtain the analog equivalent.

Five binary digits can be converted to analog by a saturable reactor with five signal windings. With the simple saturable reactor, good linearity is obtained

I. DANYLCHUK and D. KATZ are with Bell Telephone Laboratories, Inc., Whippany, N. J.

and the effects of power supply and load variations are minimized.[3] Fig. 1(A) shows a saturable reactor circuit with design values used in the conversion of 5 binary digits. It is a series-connected saturable reactor with gate windings on 4-79 permalloy tape wound cores. The binary input signals are represented by the presence of a 1-milliampere current in the control winding for a binary "1" and the absence of current for a binary "0." As indicated in the figure, the number of turns in each control winding is weighted according to the significance of the binary digit with which it is associated. Since the average gate or output current is directly proportional to the sum of the control ampere-turns in the saturable reactor, the output current is the analog equivalent of the binary input. To maintain high conversion accuracy in the 10-digit converter described later, the bias arrangement shown in Fig. 1 is used. It biases the saturable reactor beyond the exciting current portion of its transfer characteristic into the linear range of operation. The bias shifts the co-ordinate axes as shown by the dashed lines in Fig. 1(B).

The basic feature of the saturable reactor as a converter is that it proportions and adds the several binary inputs at a low voltage and power level and gives the result at a higher output power. Since its output is a direct function of the inputs and is relatively insensitive to a-c power or load variations, the saturable reactor accuracy depends mainly on the regulation of the low-power signal inputs. By contrast, in the conventional resistor networks for binary to analog conversion, the accuracy of the conversion depends mainly on the regulation of the network voltage supply, which is at a comparatively high voltage and power level, and on the characteristics of the switches used. Further, resistor networks greatly attenuate the input quantities so that the output often requires large d-c amplification to bring it up to useful values. This comparison holds for any circumstance where electrical quantities are to be proportioned and summed. The larger the number of signals involved, the more this comparison seems to favor the saturable reactor. However, the saturable reactor is limited in response time and cannot be adapted readily for a-c outputs.

a computer to an analog voltage which must have enough power to drive a servomagnetic amplifier. The 5-digit saturable reactor of Fig. 1 is supplemented by two other saturable reactors to make a 10-digit converter. As is shown in Fig. 2, the three saturable reactors are arranged so that their output voltages are added to obtain the analog of the 10-digit binary input. Additional saturable reactors are used because in this case it is not practical to put all ten control windings on one unit. Continuing the signal weighting in control windings for the more significant digits would require as much as 2^9 times 400 or 204,800 turns for the most significant digit. For this reason, partial signal weighting in *SR2* and *SR3* is accomplished by their respective load resistors, *R2* and *R3*. In the circuit of Fig. 2, *R2* is eight times the resistance of *R1*, so that the output voltage of *SR2* per ampere-turn of input is eight times that of *SR1*. Therefore, the control turns required on *SR2* to continue the binary scale are reduced by a factor of eight. In *SR3*, there is a change in gate winding turns and output resistance so that the control turns are reduced by a factor of 16. The a-c voltages supplied to the saturable reactors increase with output resistance to operate each one in the linear region.

For the accurate performance of this converter it is necessary that the signal inputs be invariant. In this application the 10-digit binary information comes from a computer register. The output of the register across a transistor switch is +0.2 volts for the logical "0" and +20 volts in series with a 3,000-ohm resistor for logical "1." The 20-volt supply to the transistor switches varies ±0.25%. This variation would result in an analog conversion error greater than a desired maximum of 0.1%. The input circuit of Fig. 3 uses a 6-volt Zener diode to provide a constant voltage signal. The two rectifier diodes and a capacitor eliminate errors due to the +0.2 volt for logical "0" and rectification of induced second harmonic voltages from the saturable reactors. A variable resistor (*R*) adjusts the nominal 1-milliampere signal current to compensate for variations in winding turns and Zener voltage from unit to unit.

The analog output of the saturable reactors shown in Fig. 2 is 0 to 25.575 volts average. A final stage of the converter, a self-balancing magnetic amplifier[3], acts as a buffer stage with very high input impedance, large power gain, and good linearity. This magnetic amplifier, having a voltage gain of four, brings the analog output up to 102.3 volts average which is needed to drive to servomagnetic amplifier. The servoloop positions a stylus which plots the analog value of the computer information. A block diagram of the circuit from computer input to servomotor is shown in Fig. 4.

Operation of the magnetic amplifier converter, consisting of the three saturable reactors and the self-balancing magnetic amplifier in Fig. 4, has been satisfactory over the full range of output voltage (0 to 102.3 volts d-c). Data taken with models under actual operating conditions show that the accuracy requirement of 0.1% of full converter output has been met. Fig. 5 gives the measured errors of a typical converter over the full output range. The general electrical characteristics of the magnetic amplifier converter can be summarized as follows:

1. The d-c signal power from the input circuit to the converting magnetic amplifiers for 1 digit is about 10 milliwatts.
2. The converter is capable of delivering 2 watts at 102.3 volts without any loss in accuracy.
3. The a-c power input to the converter is less than 20 watts.
4. The frequency and the voltage variation of ±5% have negligible effect on the required accuracy of 0.1% of full output.
5. The over-all response of the converter is about 0.025 second with a 400-cps (cycles per second) power input.
6. Ambient temperature variations of more than 5 degrees centigrade would cause a noticeable error due to the change in the d-c resistance value of the control circuit in the two most significant digit outputs. If required, this could be compensated for by using a fixed resistor with a negative temperature coefficient in the control circuit.

A chassis with the input circuits on printed boards and final models of the three saturable reactors, the self-balancing amplifier and a-c supply transformer which make up the converter, is shown in Fig. 6. The magnetic amplifiers are cast in an epoxy-resin with the largest (*SR3*) measuring $2\frac{5}{8} \times 2\frac{5}{8} \times 2\frac{3}{4}$ inches. The black casting contains precision resistors for the electrical feedback in the self-balancing magnetic amplifier (*4X*).

Conclusions

A binary-to-analog converter has been described using magnetic amplifiers capable of converting ten binary inputs of low power level to a floating d-c analog voltage. The accuracy of conversion is better than 0.1% of the full output range of 102.3 volts.

From the experimental results it is apparent that conversion of the binary coded information to analog voltages by means of magnetic amplifiers offers certain advantages over the conventional resistive network method. The magnetic amplifier circuits in this converter are inherently stable d-c amplifiers which sum and weigh magnetically up to ten binary input signals. Low-power input signals can be readily and accurately converted without the stringent requirements of many precision resistive components and ideal voltage or current sources and switches. This again emphasizes the capabilities of magnetic amplifiers to proportion and sum electrical quantities in multiple control windings.

An evident limitation of this type of converter is its relatively slow response time (0.025 second with 400-cps input power). However, where the response time is not limiting, the magnetic amplifier can often permit over-all circuit simplification and is an attractive component in military systems because of its ruggedness and reliability.

The A-C Resistance of Solid Magnetic Wires

M. KAMAL GOHAR
NONMEMBER AIEE

WITH THE development of new types of ferromagnetic materials, magnetic conductors are increasingly used in connection with automatic control and electric power, and for industrial and scientific purposes. Here, the a-c resistance varies not only with the frequency but also with the current, as the permeability is not constant over the cross section of the wire. Previous authors[1–3] have given experimental results, and have used qualitative solutions. To make the solution possible, the theoretical analysis has been mainly based on assuming average constant permeability over the cross section of the conductor; this, however, is not actually the case, as the permeability varies from the axis to the circumference; see Figs. 1 through 3. As a consequence, previous authors have not found it possible to obtain numerical correlation between the magnetic properties of such wire deduced from its impedance measurement and those measured by direct magnetic methods. There is still less possibility of predicting the a-c resistance or inductance of these wires from their measured magnetic properties.

To overcome this difficulty, a solution is presented here based, on the new representation of the **B-H** curve previously suggested by the writer,[4] and which can be applied with advantage. It will be used to obtain the a-c resistance of solid magnetic wires from their measured magnetic properties. The theoretical results, verified experimentally, are found to be in accordance with the experimental results obtained from previous authors.

In this case the **B-H** curves as shown in Fig. 4 can be represented by the three straight lines *oa*, *ab*, and *bc*, in which *oa* and *bc* are parallel, and *ab* is perpendicular to the **H**-axis. The simplicity of this method is clearly seen as the incremental permeability in the two regions *oa*; and *bc* is constant and equal, which is not the case for other kinds of **B-H** curve representations. Following the same analysis, it can be deduced that if the magnetic field in Fig. 4 is an alternating one and is in the form **H** sin ωt where $|\mathbf{H}|<|\mathbf{H}_0|$,

the corresponding flux density **B** will be

$$\mathbf{B}=\mu\mathbf{H}\sin\omega t \tag{1}$$

where μ is the slope of oa or bc. While, if the equation of the straight line bc in Fig. 4 is

$$\mathbf{B}=\mu\mathbf{H}+C_0 \tag{2}$$

and the alternating field in equation 1 has its maximum value $|\mathbf{H}|>|\mathbf{H}_0|$, then the corresponding flux density will be

$$\mathbf{B}=\mu\mathbf{H}\sin\omega t+C_0(\omega t) \tag{3}$$

where $C_0\ (\omega t)$ is a Fourier series in the form of

$$a_0+\Sigma a_n\cos n\omega t+\Sigma b_n\sin n\ \omega t \tag{4}$$

representing the constant value C_0 when the magnitude of the field is greater than $|\mathbf{H}_0|$.

According to Fig. 4, $C_0(\omega t)$ will contain odd harmonics only and will take the form

$$C_0(\omega t)=\frac{2C_0}{\pi}\sum\frac{\cos n\,\theta_1-\cos n\,\theta_2}{n}\times \sin n\,wt\quad n\text{ odd}$$

$$=\frac{4C}{\pi}\sum\frac{\cos n\theta_1}{n}\sin n\ \omega t\quad n\text{ odd} \tag{5}$$

In this case $a_0=a_n=0$, $\theta_2=\pi-\theta_1$, and $\mathbf{H}\sin\theta_1=C_0$

It should be noted that the problem here deals only with the value of the a-c resistance and that hence there is no need to consider the harmonic terms in the calculations (other than the fundamental one) if the values of θ_1 and θ_2 are satisfactorily determined. For example, if the current is in the form

$$i_1\sin\omega t \tag{6}$$

and the applied voltage becomes

$$V_1\sin(\omega t+\phi_1)+v_3\sin(3\omega t+\phi_3)+\ldots \tag{7}$$

the power, and hence the effective resistance, will depend only on the magnitudes of the current and voltage of the fundamental frequency only, since the average power will be

$$(v_1 i_1/2)\cos\phi_1 \tag{8}$$

As may be deduced from the following analysis, the harmonic terms are not of value except when it is required to determine the values of θ_1 and θ_2 after the second approximation.

Note that in the theoretical analysis the asymptotic expansion series for the high values of Bessel functions will be adopted; for example when $z>8$,

$$\text{ber}\ z+j\ \text{bei}=\frac{0.399}{\sqrt{z}}\epsilon^{\frac{z}{\sqrt{2}}}\epsilon^{j\frac{z}{\sqrt{2}}+\frac{\pi}{8}}$$

$$=|M(z)|\epsilon^{j\alpha_z}=M_0(z) \tag{9}$$

$$\text{bei}'\ z-j\ \text{ber}'\ z=\frac{0.399}{\sqrt{z}}\epsilon^{\frac{z}{\sqrt{2}}}\epsilon^{j\frac{z}{\sqrt{2}}-\frac{3\pi}{8}}$$

$$=|M(z)|\epsilon^{j\alpha_z'}=M'(z) \tag{10}$$

For smaller values of z, the other forms of Bessel functions are to be similarly treated but they will be of less importance.[5]

Theoretical Analysis

If an alternating current in the form

$$I\sin\omega t \tag{11}$$

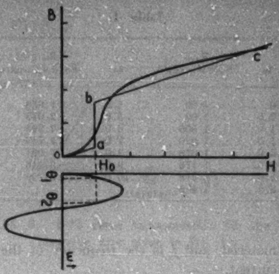

Fig. 4. B-H curve representation

passes in a magnetic conductor of radius a and whose **B-H** curve is represented by $oabc$ as shown in Fig. 4, the maximum magnetic field

$$|\mathbf{H}_a|=\left|\frac{2I}{a}\right| \tag{12}$$

will be at the circumference of the wire. Two cases must now be considered:

Case 1

In case 1, if $|\mathbf{H}_a|<|\mathbf{H}_0|$, the permeability μ can satisfactorily be considered constant over the cross section of the wire. The current density i is given in equation 13 which has been proved by many physicists and electrical engineers.[6]

$$i=A_0(\text{ber}\ mr+j\ \text{bei}\ mr)+\mathbf{B}_0(\text{ker}\ mr+j\ \text{kei}\ mr)$$

$$=A_0M_0(mr)+\mathbf{B}_0Y_0(mr) \tag{13}$$

where, for a solid wire $\mathbf{B}_0=0$

$$A_0=\left(\frac{Im}{2\pi a}\right)/M'(ma),\ m^2=\frac{8\pi^2 f\mu}{\rho}$$

where ρ is the resistivity of the magnetic

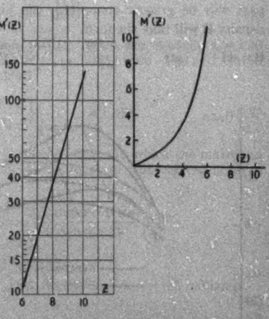

Fig. 5. M′(z)–z chart

Table I

z_a	$\frac{R_{a\text{-}c}}{R_{d\text{-}c}}$ μ constant	z_a	$\frac{R_{a\text{-}c}}{R_{d\text{-}c}}$ μ constant
0	1.00	4.0	1.678
0.5	1.00	5.0	2.043
1.0	1.005	6.0	2.394
1.5	1.026	7.0	2.743
2.0	1.078	8.0	3.094
2.5	1.175	9.0	3.446
3.0	1.318	10.0	3.799
3.5	1.492		

material, and f is the frequency of the current.

The magnetic field **H** at any radius r will be

$$H=\frac{2\int_0^r 2\pi r i dr}{r}=\frac{2I}{a}\,\frac{M'(z)}{M'(z_a)} \tag{14}$$

where $z=mr$ and $z_a=ma$.

Fig. 5 represents the values of $M'(z)$ for different values of z, from $z=0$ to $z=10$. The ratio of the a-c resistance to the d-c one, in this case $(R_{a\text{-}c}/R_{d\text{-}c})_{\mu\text{constant}}$, was found by previous authors[6] to be equal to the real part of

$$\frac{z_a}{2}\,\frac{M_0(z_a)}{M'(z_a)}$$

$$=\frac{\text{ber}\, z_a\, \text{bei}'\, z_a-\text{bei}\, z_a\, \text{ber}'\, z_a}{\text{ber}'^2\, z_a+\text{bei}'^2\, z_a} \tag{15}$$

These values are shown in Table I from $z=0$ to $z=10$.

Case 2

In case 2, the cross section of the wire will be divided into two parts: the first one is from $r=0$ to $r=r_0$ at which the maximum magnetic field will be equal to $\mathbf{H}_0$. The current density distribution will take its original ordinary form as given in equation 13:

$$i=A_0'M_0(z) \tag{16}$$

The second part will be from $r=r_0$ to $r=a$. As the maximum magnetic field in this part will be greater than $|\mathbf{H}_0|$, the flux density **B** will take the form

$$\mathbf{B}=\mu\mathbf{H}+C_0'(\omega t) \tag{17}$$

where $C_0'(\omega t)$ is the Fourier series representing the constant value C_0 of the flux density **B** in equation 2. $C_0'(\omega t)$ is a function of $\cos\theta_1$, r, or z. According to Fig. 4 and equation 5, it should have a zero value when $r=r_0$ or $z=z_0$.

As illustrated in Appendix I, a convenient representation for the coefficient of the fundamental frequency term in $C_0'(\omega t)$ is

$$\left(\frac{4C_0}{\pi\mu}\right)\tanh\alpha\,(z-z_0)\epsilon^{j\frac{z-z_a}{\sqrt{2}}} \tag{18}$$

where $\alpha=0.7+\epsilon^{-z_0}$

and the differential equation for the magnetic field distribution **H** is found to be

$$\frac{d^2\mathbf{H}}{dz^2}+\frac{1}{z}\,\frac{d\mathbf{H}}{dz}=\frac{\mathbf{H}}{z^2}-j\mathbf{H}$$
$$=j\left(\frac{4C_0}{\pi\mu}\right)\tanh\alpha(z-z_0)\epsilon^{j\frac{z-z_a}{\sqrt{2}}} \tag{19}$$

Considering large values of z and neglecting the coefficients of small terms, equation 20 is a satisfactory solution for differential equation 19.

$$\mathbf{H}=\frac{4\pi}{m}A_0'M'(z)+\frac{4\pi}{m}\,\mathbf{B}_0'Y'(z)-$$
$$(0.8+j0.4)\frac{4C_0}{\pi\mu}\tanh\alpha(z-z_0)\epsilon^{j\frac{z-z_a}{\sqrt{2}}} \tag{20}$$

Using the relation between i and **H**, which is

$$\frac{d(r\mathbf{H})}{dr}=4\pi r i \tag{21}$$

the current density distribution i can be deduced from equation 20, which gives

$$i=A_0'M_0(z)+B_0'Y_0(z)-\frac{(0.8+j0.4)C_0m}{\pi^2\mu}\times$$
$$\left[\alpha\,\text{sech}^2\,\alpha(z-z_0)+\frac{j}{\sqrt{2}}\tanh\alpha(z-z_0)+\right.$$
$$\left.\frac{1}{z}\tanh\alpha(z-z_0)\right]\epsilon^{j\frac{z-z_a}{\sqrt{2}}} \tag{22}$$

when $z=z_0$, equations 16 and 22 must be equal; hence

$$\mathbf{B}_0'=\frac{(0.8+j0.4)C_0m}{Y_0(z_0)\pi^2\mu}\,\alpha\epsilon^{j\frac{z_0-z_a}{\sqrt{2}}} \tag{23}$$

From equations 16 and 22 the total current in the wire I is as follows:

$$I=\int_0^a 2\pi r i dr$$

$$I=\frac{2\pi a}{M}\,A_0'M'(z_a)+\frac{2\pi a}{m}\,\mathbf{B}_0'Y'(z_a)-$$
$$\frac{2\pi r_0}{m}\,\mathbf{B}_0'y'(z_0)-\frac{4C_0}{\pi\mu}\,\frac{(04+j0.2)}{m}\times$$
$$z_a\tanh\alpha(z_a-z_0) \tag{24}$$

If the values of A_0' and $\mathbf{B}_0'$ from equations 24 and 23 are substituted in equation 22, the current density distribution i in the second part can be deduced.

It is well known that if $R_{a\text{-}c}$ and L_i are the a-c resistance and the internal inductance of the wire respectively, then

$$R_{a\text{-}c}+j\omega L_i=\frac{i_a\rho}{I} \tag{25}$$

i.e., $R_{a\text{-}c}$ is the real part in $(i_a\rho)/I$ from which

$$\frac{(R_{a\text{-}c})}{R_{d\text{-}c}}=\frac{(R_{a\text{-}c})}{R_{d\text{-}c\,\mu\,\text{constant}}}+\frac{\phi(z_a,\, z_0)}{I}+$$
$$\frac{\Psi(z_a,\, z_0)}{I} \tag{26}$$

where $\phi(z_a,z_0)=[(0.178\; C_0)/\mu]\; az_a[\tanh\alpha(z_a-z_0)-1.43\;\alpha\;\text{sech}^2\,\alpha(z_a-z_0)+1.43\alpha\sqrt{\frac{Z_0}{Z_a}}\epsilon^{\frac{z_0-z_a}{\sqrt{2}}}\cos\sqrt{2}(z_0-z_a)-0.715\alpha\sqrt{\frac{Z_0}{Z_a}}\epsilon^{\frac{z_0-z_a}{\sqrt{2}}}\sin\sqrt{2}(z_0-z_a)\Bigg]$ and $\Psi(z_a,z_0)=-0.286\frac{c_0\alpha a z_a}{\mu}\Bigg[\sqrt{\frac{Z_0}{Z_a}}\epsilon^{\frac{z_0-z_a}{\sqrt{2}}}\cos(\sqrt{2}z_0+1.256)-z_0/z_a\;\cos(3z_0/\sqrt{2}-z_a/\sqrt{2}+1.256)]$ neglecting the coefficient of the term $1/z\tanh\alpha(z_a-z_0)$ with respect to the other terms.

It should be noted that the term $\Psi(z_a,z_0)$ in equation 26 gives damped oscillating values with the current I. (When I increases, z_0 decreases.)

When the damped oscillatory values of $\Psi(z_a,z_0)$ are neglected, equation 26 will reduce to

$$\frac{R_{a\text{-}c}}{R_{d\text{-}c}}=\left(\frac{R_{a\text{-}c}}{R_{d\text{-}c}}\right)_{\mu\text{ constant}}+\frac{\phi(z_a,\, z_0)}{\sqrt{2}I_{\text{rms}}} \tag{27}$$

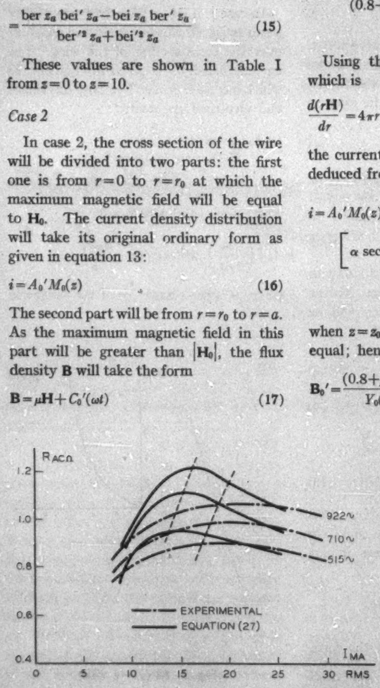

Fig. 6 (left). Comparison between experimental and theoretical results

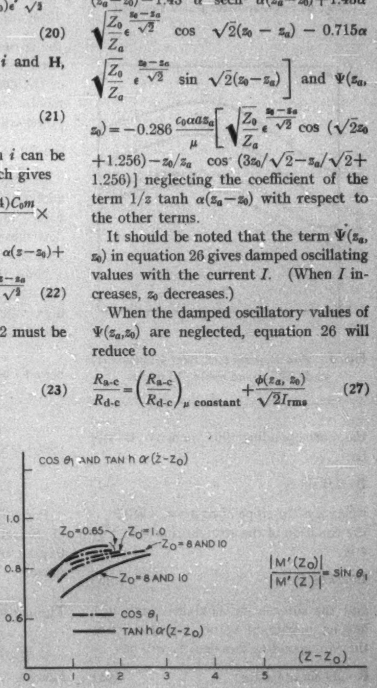

Fig. 7 (right). Comparison between $\cos\theta_1$ and $\tanh\alpha(z-z_0)$

where $I=\sqrt{2}\,I_{rms}$

The first term in equation 27 can be taken from Table I or from the textbooks.[6] The second term in equation 27 is given in equation 26.

From equation 27 it may be seen that

$$\frac{R_{a\text{-}c}}{R_{d\text{-}c}}=\left(\frac{R_{a\text{-}c}}{R_{d\text{-}c}}\right)_{\mu\ \text{constant}}$$

when $z_a=z_0$; and if $z_a>z_0$, the resistance ratio given in equation 27, will increase at first with the current until the increase in the current begins to be greater than the increase in $\phi(z_a,z_0)$. The resistance ratio will then begin to decrease with the current I. Fig. 6 shows a comparison between the experimental a-c resistance extracted from Harrison, et al.,[1] and the theoretical values obtained from equation 27. The procedure and method of calculations are illustrated in Appendix II.

The variation of the a-c resistance as obtained from equation 27 and shown in Fig. 6 is found to be in accordance with the experimental results as given in Figs. 1, 2, and 3.

Appendix I

The alternating voltage drop must be constant at any point in the cross section of the wire. Considering a unit length of the wire, two kinds of voltage drop will be produced. The resistive voltage drop $=i\rho$ and the reactive voltage drop $=j\omega\int_r^a B\,dr+$ the constant external reactive voltage drop.

According to equations 5 and 17, $\mathbf{B}=\mu\mathbf{H}+C_0'(\omega t)$; hence

$$i\rho+j\omega\int_r^a \mu H\,dr+j\omega\int_r^a C_0'(\omega t)\,dr = \text{constant} \tag{28}$$

Differentiating equation 28 with respect to r yields

$$\frac{di}{dr}-j\omega\mu\mathbf{H}-j\omega C_0'(\omega t)=0 \tag{29}$$

The magnetic field **H** at any point in the second part of the wire is given by

$$\mathbf{H}=\frac{r_0\mathbf{H}_0}{r}+\frac{2\int_{r_0}^{r}2\pi ri\,dr}{r} \tag{30}$$

$$\text{i.e.,}\ \frac{d(r\mathbf{H})}{dr}=4\pi ri=r\frac{d\mathbf{H}}{dr}+\mathbf{H} \tag{31}$$

From equation 31

$$\frac{di}{dr}=\frac{1}{4\pi}\left(\frac{d^2\mathbf{H}}{dr^2}+\frac{1}{r}\frac{d\mathbf{H}}{dr}-\frac{\mathbf{H}}{r^2}\right) \tag{32}$$

When the value of di/dr from equation 32 is substituted into equation 29, the differential equation for the magnetic field distribution **H** in the second part of the wire will be

$$\frac{d^2\mathbf{H}}{dr^2}+\frac{1}{r}\frac{d\mathbf{H}}{dr}-\frac{\mathbf{H}}{r^2}-j\frac{4\pi\omega\mu\mathbf{H}}{\rho}=j\frac{4\pi\omega}{\rho}C_0'(\omega t) \tag{33}$$

Letting $4\pi\mu\omega/\rho=m^2$, and $mr=z$, yields for equation 33

$$\frac{d^2\mathbf{H}}{dz^2}+\frac{1}{z}\frac{d\mathbf{H}}{dz}-\frac{\mathbf{H}}{z^2}-jH=j\frac{C_0'(\omega t)}{\mu} \tag{34}$$

considering the fundamental frequency only; then from Fig. 4, and equations 5 and 17, $C_0'(\omega t)$ in equation 34 must have a direction, as that of the magnetic field **H**, and a value $=(2C_0/\pi)(\cos\theta_1-\cos\theta_2)_r$, where $(\cos\theta_1-\cos\theta_2)_r$ is a function of r or z representing the value of $(\cos\theta_1-\cos\theta_2)$ at a point at a distance r from the center of the wire.

As a first approximation, C_0/μ is neglected in equation 34. According to equations 13 and 14, the solution for **H** and i will be

$$i=\frac{(Im)}{2\pi a}\,\frac{\text{ber}\,z+j\,\text{bei}\,z}{\text{bei}'\,z_a-j\,\text{ber}'\,z_a}=\frac{(Im)}{2\pi a}\,\frac{M_0(z)}{M'(z_a)} \tag{35}$$

$$\mathbf{H}=\frac{(2I)}{a}\,\frac{\text{bei}'\,z-j\,\text{ber}'\,z}{\text{bei}'\,z_a-j\,\text{ber}'\,z_a}=\frac{(2I)}{a}\,\frac{M'(z)}{M'(z_a)} \tag{36}$$

Using the asymptotic expansion given in equation 10 for $M'z$

$$\mathbf{H}=\frac{2I}{a}\sqrt{\frac{z_a}{z}}\,\epsilon^{\frac{z-z_a}{\sqrt{2}}}\,\epsilon^{j\frac{z-z_a}{\sqrt{2}}} \tag{37}$$

The direction of **H** with respect to the total current I in this case will be given by

$$\epsilon^{j\frac{z-z_a}{\sqrt{2}}} \tag{38}$$

Knowing z_a, I, a, and $\mathbf{H}_0$, one can determine, from equation 36 and Fig. 5, z_0, which is the value of z at which the maximum magnetic field **H** will be equal to $\mathbf{H}_0$. Hence

$$\mathbf{H}_0=\frac{2I}{a}\,\frac{M'(z_0)}{M'(z_a)} \tag{39}$$

From equation 11, if the total current I varies in the form $I\sin\omega t$, then, according to equation 36 the magnetic field will be

$$\frac{2I}{a}\,\frac{M'(z)}{M'(z_a)}\sin\omega t \tag{40}$$

At any point at a distance $r>r_0$ from the center of the wire, or $z>z_0$, the maximum magnetic field $|\mathbf{H}|$ at this point will be greater than $|\mathbf{H}_0|$.

When $z>z_0$

$$\theta_1=\pi-\theta_2$$

and hence

$$(\cos\theta_1-\cos\theta_2)_r=2(\cos\theta_1)_r \tag{41}$$

The value of $(\cos\theta_1)_r$ begins from zero when $z=z_0$, and reaches unity at relatively large values of $(z-z_0)$. At intermediate values of $(z-z_0)$, and from Fig. 4, equations 36 and 39 yield

$$\left|\frac{\mathbf{H}_0}{\mathbf{H}}\right|=(\sin\theta_1)_r=\left|\frac{M'(z_0)}{M'(z)}\right| \tag{42}$$

$$(\cos\theta_1)_r=\sqrt{1-\left[\frac{M'(z_0)}{M'(z)}\right]^2} \tag{43}$$

is plotted in Fig. 7 against $(z-z_0)$ for different values of z_0. In all the cases $(\cos\theta_1)_r$ begins from zero when $z=z_0$, and increases to unity when $(z-z_0)$ is relatively large. But at intermediate values of $(z-z_0)$, $(\cos\theta_1)_r$ is slightly greater for small values of z_0, e.g., when $(z-z_0)=1.0$, $\cos\theta_1=0.91$; when $z_0=0.65$; and if $z_0=8$ or 10, $(\cos\theta_1)=0.85$.

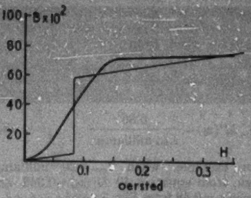

Fig. 8. B-H curve representation for the magnetic wire given in Fig. 1

As seen from Fig. 7, a convenient representation for $(\cos\theta_1)_r$ in this case is found to be

$$(\cos\theta_1)_r=\tanh\alpha(z-z_0) \tag{44}$$

where $\alpha=0.7+\epsilon^{-z_0}$.

From equations 38, 41, and 44 the differential equation will be

$$\frac{d^2\mathbf{H}}{dz^2}+\frac{1}{z}\frac{d\mathbf{H}}{dz}-\frac{\mathbf{H}}{z^2}-j\mathbf{H}=j\frac{4C_0}{\pi\mu}\times \tanh\alpha(z-z_0)\epsilon^{j\frac{z-z_a}{\sqrt{2}}} \tag{45}$$

where $\alpha=0.7+\epsilon^{-z_0}$

Appendix II

The $\mu-\mathbf{H}$ curve at zero frequency for the magnetic material of the wires used by Harrison, et al., may be deduced from Tables III and IV of their paper,[1] from which the corresponding **B-H** curve and its representation are shown in Fig. 8, where $\mathbf{H}_0=0.08$ oersted, $\mu=9{,}000$ and $C_0/\mu=0.55$ ($a=0.02225$ centimeter, the length of wire $=15.25$ centimeters, and its $R_{d\text{-}c}=0.41$ ohm).

From equations 13 and 34

$$z=mr=4.12r\sqrt{f} \tag{46}$$

when $f=515$ cycles per second, $z_a=2.08$ and $M'(z_a)=1.085$ from Fig. 5. From Table I

$$\left(\frac{R_{a\text{-}c}}{R_{d\text{-}c}}\right)_{\mu\text{constant}}=1.078 \tag{47}$$

The value of I_0 rms at which the maximum field will be equal to 0.08 oersted is given by

$$0.08=\frac{2\,I_0\ \text{amperes (rms)}}{10\times0.02225}\sqrt{2}$$

from which

$$I_0\ \text{amp (amperes) (rms)}=6.3\ \text{milliamp} \tag{48}$$

The a-c resistance is a function of the frequency only (a is fixed), and in this case it does not depend on the current until I_0 rms=6.3 milliamp. When I (rms)>6.3 milliamp, then, from equation 39

$$H_0=0.08=\frac{M'(z_0)}{M'(z_a)}\,\frac{0.2\,I\text{ amp (rms)}\sqrt{2}}{0.02225}$$

$$\text{i.e., } M'(z_0)=\frac{6.86}{I_{rms}\text{ milliamp}} \tag{49}$$

For example, when $I_{rms}=20$ milliamp, then, from equation 49 $M'(z_0)=0.343$, and hence $z_0=0.68$ from Fig. 5; and $z_a-z_0=1.4$.

From equation 18

$$\alpha=0.7+0.506=1.206$$

Substituting in equation 27

$$\frac{R_{a\text{-}c}}{R_{d\text{-}c}}=1.078+1.22=2.298$$

$$R_{a\text{-}c}=0.41\times2.298=0.94\text{ ohm}$$

Experimentally, $R_{a\text{-}c}=0.902$ ohm.

An Error-Detection System for 5-Unit-Code Teletypewriter Transmission

P. H. BARRY
NONMEMBER AIEE

A. L. WHITMAN
MEMBER AIEE

FOR MANY YEARS teletypewriter users have operated without automatic means for detecting errors. This was principally because a large part of the transmitted material was ordinary English text with a redundancy so large that for the most part there was no difficulty in reconstructing a misspelled word. For example, recognizing that "enginaer" means "engineer" was simple and obvious. For the correct transmission of numerals various expedients were used, such as sending all numerals twice, spelling out the words, as "one," "two," and "five."

More recently, however, two trends have become more marked. The first is toward the transmission of larger proportions of numeric material, roughly designated by the name "data," in contrast to English text, and the second is toward the direct use of transmitted material in automatic computers without its being read and checked by a human operator. This has brought about an increasing demand for an automatic means of detecting when and where transmission errors have occurred so that their possible bad effects may be guarded against.

In view of the wide extent of telegraph and data transmission by means of the common 5-unit telegraph code, there is a need for means of detecting errors in this transmission. This paper describes one such means. The project in its present stage is a trial in actual field situations to determine the service value of the method chosen.

The present project does not include any means for automatic error correction. When an error is found, it is necessary for the attendant at the receiving end to request retransmission of the portion of the material in which the error was detected. In certain automatic switching systems error correction cannot be readily applied. However, its potential advantages are such that it is not rejected at this time but is set aside for future consideration.

Limitation on Detected Errors

Before describing the system, it may be well to consider a basic limitation. No error-detection system (or error-correction system, for that matter) will give satisfactory service if the communication facility generates frequent errors. For each error detected the user has to send a service message and ask for a rerun. In the absence of experience, the frequency of this operation a user would tolerate is a matter of conjecture. (The price for attaining various degrees of accuracy in transmission may be a major controlling factor but is neglected here.) It is expected that the need for 100 reruns in an 8-hour business day would be cause for major complaint; 10 reruns might be acceptable, especially if it were recognized, as it might be in the particular circumstances, that the cost of substantially improved accuracy would be large.

Assuming operation at 100 words per minute, there would be about 300,000 characters transmitted in an 8-hour day. Ten requests for reruns would mean that there had been one error in each 30,000 characters.

The considerations in the foregoing apply to detected errors only; the efficiency of the system with respect to the detection of errors will be considered later.

Principle of Error Detection

The error-detecting method is based on the addition, at the originating end of the circuit, of a redundant character, known as the check character, after each checking block of text, the checking block being a typed line (about 72 characters) or portion of a line terminated by a carriage-return (CR) signal. While the principle is applicable to keyboard transmission, it will be assumed throughout this paper that transmission is from punched paper tape in a transmitter-distributor. The receiving station has a page printer which may be supplemented by a reperforator if punched tape output is wanted.

When the CR signal in the sending-station tape is sensed by the transmitter, the transmitter stops and waits while a sequence of five error-detection control characters, including the check character, are sent on the line from the error-detection circuit. The transmitter then resumes sending from the tape, the next

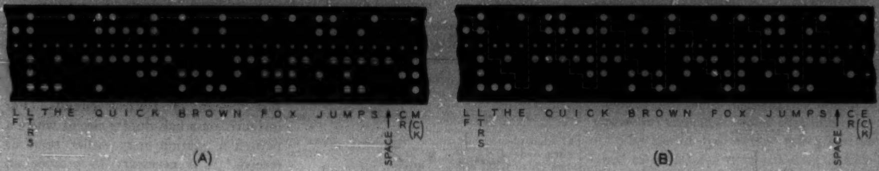

Fig. 1. Check lines

A—Horizontal
B—Spiral

character being the line-feed (LF) character necessary to advance the teletypewriter paper. The check character is a character unique to its checking block, as described in the following.

At the receiving end a new check character is locally generated from the received text by the same process as that used at the sending end. The locally generated check character is compared with the character sent over the line. If the two do not agree, it is an indication that an error has occurred in the preceding line of text. An alarm is sounded, a lamp lights, and an identifying mark is made on the copy of the line in error as described later.

The check character is generated from five odd-even counts of the marking signal elements in five separate lines along the punched tape to be transmitted. Each counting line may be a horizontal line, one of which is illustrated in Fig. 1(A). An alternate form of counting line, shown in Fig. 1(B), shifts one level vertically for each character of horizontal advance. If the tape were formed into a cylinder with level no. *5* brought adjacent to level no. *1*, this form of counting line would be a spiral; hence the term "spiral checking." Obviously, this is the helical type of spiral and not one with varying radius.

Each of the five lines generates from its count a check bit, which is a mark if there is an odd number of marks in the line, or a space if there is an even number. The check bits make five even-parity checks of the five counting lines. The check bits are then used as the five signal elements of the check character, identified as (CK) in Fig. 1(A) and (B). These figures, intended to illustrate the principle of errror detection, do not show the exact format of characters inserted at the end of each block of text. The inserted sequence is explained in detail in a later paragraph.

It will be recognized that while each parity check will detect single errors in its counting line or, in fact, any odd number of errors, it will not detect two or any even number of errors. This is due to the fact that if there is an even number of errors the odd-even count, and hence the check bit, will be the same as if there had been no errors. However, as discussed later, the chance of a double error in the chosen checking block is very much smaller than the chance of a single error so that the chance of an undetected error from double errors is correspondingly small.

The spiral checking method suggested by W. R. Young, Jr., is better than the horizontal check method in detecting errors caused by intermediate teletypewriter apparatus such as transmitters and reperforators. This is because machine errors tend to concentrate in a particular level as, for instance, when a particular transmitter sensing pin tends to stick or a particular contact gets dirty. This tends to increase the chance of double errors in a single horizontal counting line. With the spiral check a double error in one level is less likely to strike the same spiral counting line, which meets that level only once in five characters. Therefore the chance of an undetected error from a double error is reduced as much as five to one depending on the extent of concentration of errors in one level. The benefits of spiral checking may be greater where intermediate relaying is involved, as for example, on *81*-type systems and manual-tape-relay systems. However, it involves more equipment than the horizontal check.

Efficiency of Error Detection

Not enough information on the nature and occurrence of teletypewriter errors is available to permit any satisfactory estimate of the probable efficiency of a detection system. To bring out qualitatively what some of the factors are, rather than as a quantitative estimate, a theoretical calculation has been made based on some limiting assumptions.

It is convenient to express error-detection efficiency in terms of the number of transmitted teletypewriter characters for one undetected error. It is assumed that the teletypewriter circuit for which the efficiency is to be computed causes an error for each 30,000 characters. It is further assumed that a character error is caused by a single bit in error and that these bits in error are distributed at random with respect to time. It is recognized that many character errors are caused by multiple-bit errors and, in fact, that some circuit disturbances, characterized as "bursts," may affect several characters; however, errors of this kind are unlikely to escape detection by the method described and are not considered here.

An undetected error, then, for the purposes of this estimate, will be the occurrence, within a single 72-character line of typing, of two errors in the same counting line. The results of the estimate are reached in two steps: 1. the probability of the occurrence of two errors in the same line of typing, and 2. the probability that they will occur in the same counting line.

To summarize the calculated results for the assumed conditions, the theoretical probability of a double error in a checking block (and hence an undetected error) is about one in 25 million characters. The five-level checking scheme used gives a further advantage of five to one, so that the theoretical probability of an undetected error is one in every 125 million characters. The formula and the method by which these figures were computed are given in the Appendix.

It is necessary to emphasize the theoretical nature of this estimate. The 125 million characters represent operation for more than a year and a half at 100 words a minute, 8 hours a day and 5 days a week. The authors do not expect such results in practice. For one thing, there is evidence that errors do not occur at random but tend to be bunched, thus increasing the probability of double errors in a single line.

It is thought significant, however, to point out that with random occurrence of errors the probability of a double, and hence undetected, error is a function of the square of the probability of a single error. Thus any improvement in transmission quality which reduces errors

gives considerably amplified benefits in the detection of errors.

Application to an Automatic Message Switching System

The error-detection system described was planned for application to an automatic teletypewriter switching system of the *81* type.[1] Various types of data are transmitted from outlying points to a central point where there is a computer. The output information from the computer is then sent back to the originating points or distributed to other points as required. Fig. 2 shows a block diagram of a typical system. Payroll data from a factory is sent to a computer which generates paycheck information. The paychecks are printed at the factory with the information sent from the computer. Error detection is required for both directions of transmission.

There are a number of features of a message switching system which require special treatment of a superposed error-detection system. First, when a message is being transmitted there is no direct line connection between the sending and receiving stations; the message transfer at the switching center is made through two or more stages of punched tape. Thus it is not possible, during transmission, to send control signals directly from the receiving end back to the sending end. Second, no means is provided for control of the switching-center transmitter from the receiving station. Therefore, the flow of transmission is continuous and it is not possible to stop the received message in case an error is detected. This requires some means of marking the received copy so that the location of the error can be determined later For the present, it is not required that the received data go directly into the computer input; there is always a punched-tape link intervening at the receiving station.

Third, the call-directing codes (CDCs) used to direct a message through the switching system are, in general, absorbed in the switching processes and do not reach the receiver. Since the error-detection method requires comparison of the received with the transmitted material, it is necessary to exclude CDCs and confine the error-detection process solely to the text of the message. The fact that CDCs are not error-checked is not a disadvantage since the switching system itself has built-in measures to guard against losses caused by incorrect or garbled address codes.

Fourth, since the Blank character is used as a control character in the *81* switching system, the error-detection encoding system must not introduce Blanks.

Fifth, it is necessary to guard against the generation of a false disconnect signal, FIGS H, resulting from the combination of the check character, which may be any character, with adjacent control or text characters. The control-character sequence described herein accomplishes this purpose.

The use of this error-detection system on other kinds of switching systems or on selective calling systems requires further design of control circuits. For instance, on a half-duplex circuit where a particular station may either send or receive,[2] it is necessary to provide an automatic control of the error-detection circuit so that it will be in the send or receive condition, respectively, at the proper time.

Error-Detection Control Characters

Fig. 3 shows the format of the control characters which are inserted by the error-detection circuit at the sending end. At the end of each line of copy the originating tape will have punched in it the usual CR LF LTRS for the purpose of returning the typebox to the left edge of the paper and advancing the paper. When the CR character is read by the sensing pins of the transmitter-distributor, the sensing-pin contacts operate a circuit which opens the start-magnet circuit and so stops the transmitter. The CR character also disables the counting circuit so that the count of marks is temporarily stopped.

The five control characters are then sent over the line from an auxiliary distributor, the contacts of which are coded for the five characters in turn by a stepping selector switch. The sending of the fifth character, LTRS, closes the circuit of the start magnet and restarts the transmitter which sends the LF character in the tape followed by LTRS and the text of the next line. It also turns on the counting circuit so that the error-detection count of marks begins again with the LF character.

Table I lists in detail the things that happen at the sending and receiving ends as the various control characters are sent and received. Whenever the error-detection count of a typed line generates a Blank character as a check character, it

Fig. 3. Error-detection control characters

Table I. Functions of Control-Character Sequence*

Character	Action at Sending Station	Action at Receiving Station†
CR	Stops transmitter. Ends register count. Printer to nonprint.	Blinds reperforator. Ends register count.
LTRS	Sent through stepping selector. Timing for receiver.	Printer to nonprint condition.
Check Character	Read from register contacts and sent through stepping selector.	Check character comparison. If mismatch, printer returns to print condition, alarm lamp lights and bell rings. All registers reset to zero.
FIGS	Sent through stepping selector.	If error was detected, shifts typebox to FIGS. Prepares circuit to resume error-detection counting.
S	Sent through stepping selector.	If error, prints large gothic O over first character in the line. If no error, returns printer to print condition. Unblinds reperforator.
LTRS	Sent through stepping selector. Operates circuits to restart transmitter and to resume error-detection counting on next character. All registers reset to zero. Printer to print condition.	Timing character.

* Functions listed here are only those affecting error-detection operations. In addition, normal printing operations, such as carriage return and case shifting, take place on the appropriate characters.

† Functions are indicated opposite the characters which initiate them; in some cases, particularly those involving stuntbox contacts, operation is completed during the following character.

is converted to a LTRS character to prevent interference with the switching system. This is done at both sending and receiving ends so that the correct match occurs at the receiver. Also, the receiving end "knows" enough to discard, without action, the Blanks introduced in transmission by the transmitter start pattern of the switching system.

Receiving-End Action When Error Is Detected

With the basic premise that in the automatic switching system the flow of traffic into the receiving station cannot be stopped if an error is detected, some means are required, first, to call the attention of the operator to the fact that an error has occurred, and second, to point out where in the copy the error was located. Since the space limitations of the *28*-type printer do not favor the addition of an auxiliary mechanism to stamp a mark on the copy, it was decided to arrange the machine to print a unique teletypewriter character. Upper-case S appeared a natural choice, first, because it is not normally needed as a printing character, and second, because it is frequently used to ring a bell to attract operator attention. The typebox was equipped with a type pallet in the upper-case S position to print a large gothic O, which is large enough to encircle any other character without obliterating it.

The FIGS S signal is inserted at the sending end as a part of the error-detection control-character sequence (see Fig. 3) sent automatically after the CR signal at the end of each line. At the receiving end the printer is normally in the nonprint condition when FIGS S arrives so that no action results. In case of detected error, the printer goes into the print condition, the large gothic O is overprinted on the first character of the line in which the error was detected, the alarm lamp lights and the bell rings once.

It may seem odd that the O is printed in the same line in which the error was detected, since detection does not take place until the whole line has been printed. This results from the fact that FIGS S comes after carriage return and before line feed. Hence the typebox has returned to the left edge of the paper and prints the O before the line feed advances the paper to the next line.

The use of the regular teletypewriter bell to indicate a detected error is independent of, and does not affect, the normal bell operation at any time during transmission. Further, the normal bell signal does not light the error-detection alarm lamp.

After the attendant has noted an error detected and its location on the copy, the alarm lamp is put out by depression of the alarm-release button.

Equipment Features

The error-detection system is built exclusively to work with the *28* line of teletypewriter apparatus. The stuntbox[3] of the *28* typing unit is a basic element of the error-detection counting process and of the recognition of the series of control characters.

At the sending end, the equipment assembly is contained in the *28* automatic send-receive (ASR) set. Fig. 4 shows the laboratory prototype model. In an *81* system the keyboard is never used for sending directly on the line but only for tape punching.

The relay equipment for error detection, together with its rectifier power supply, is mounted in the base of the *28*

Fig. 4. Sending-end error-detection equipment mounted in 28 automatic send-receive set

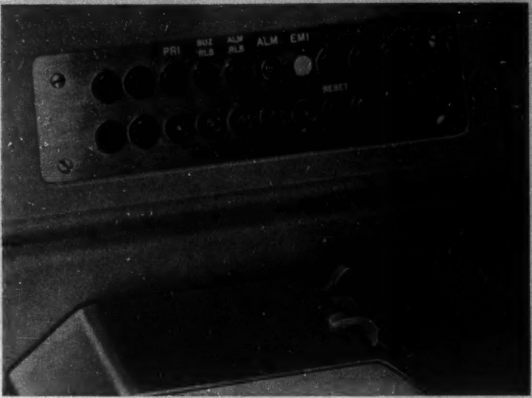

Fig. 5. Key and lamp panel at sending end

ASR. Space is left here for the addition of a relay-rack panel containing a portion of the *81D1*-system station control circuit, the rest of it being in a separate apparatus cabinet.

Installation and maintenance are simplified by making all the connections to and from the panels and the machines with plug-in cords and connectors. Thus any component can be removed, if necessary, for replacement and repair.

The key and lamp control panel, mounted at a convenient place in the *28* ASR cabinet, is shown in greater detail in Fig. 5. The top row of keys and lamps is for *81*-system operation, the bottom row for error detection. The five neon lamps light up to show the operation of the flip-flop relays in the counting circuit and so change with each character during transmission. They give an indication that the error-detection circuit is operating properly and it is expected that they will be useful for maintenance. By the use of a character such as E or T, with a single marking element, the operation of the counter can be readily watched.

The receiving-end equipment is housed in the cabinet of a *28* receiving-only (RO) teletypewriter as shown in Fig. 6. The five counter lamps are shown flanking an alarm-release button which puts out the alarm lamp (yellow plastic insert on the left of the machine) when it is lighted to show a detected error. The connection of the *28* RO to the line to receive messages is controlled by the *81* station-control circuit in an auxiliary cabinet.

ERRORS WHICH THE SYSTEM WILL NOT DETECT AND WAYS TO BEAT THEM

No error-detection system of this type will detect errors made by operators in the original preparation of the tape. Reports indicate that the operator-error rate will generally be of the order of several times the transmission-error rate. A possible way to check for operator errors with this system is to compare the copy printed while the message is being transmitted with the original source of the copy from which the tape was punched.

This sort of comparison check will also detect another possible source of errors, those due to incorrect operation of the transmitter-distributor. Since the error-detection system is actuated by line signals, it gives assurance only that the signals sent on the line are correctly reproduced at the receiving end. If the sending transmitter has either sensing-pin or contact failure, this will not be detected. However, a copy check as suggested will catch errors from this cause.

In the process of planning the design, means of automatically detecting errors caused by the transmitter were considered. One plan required a double reading of the sending-end tape, but such arrangements were felt to be too expensive and too cumbersome for operator use. If experience indicates that detecting machine errors is vitally important, further design work will be needed.

The spiral checking method gives a high degree of protection against errors caused by intermediate machines such as switching-system reperforator-transmitters, or, for manual relay, reperforators and the associated transmitters.

Another source of errors which will not be detected by the system are those caused by machine failure of the reperforator at the receiving end. Again what is checked are the line signals reaching the reperforator. If the punch mechanism, for instance, does not punch the holes called for by the line signals, this is not detected. It is anticipated that with proper maintenance, errors of this kind will be so infrequent as not to be troublesome.

Conclusions

The reduction in undetected errors by the method described in this paper is expected to lead to significant improvement in the quality of teletypewriter transmission. This is particularly needed where the type of material transmitted, as, for example, numerical digits, is such that errors cannot be readily seen by visual inspection.

Appendix. Theoretical Probability of Double and Hence Compensating Bit Errors in a Line of Typing

The probability, P, that an event will happen exactly r times in n trials is given by the formula:[4]

$$P=\frac{n(n-1)\ldots(n-r+1)p^r q^{n-r}}{r!}$$

where

P = probability of r errors in n characters
n = number of characters in a typed line, here taken as 72
r = number of errors in a line of n characters
p = probability of a single error, here taken as one error in 30,000 characters
q = probability that an error does not occur; equal to $(1-p)$

For this particular illustrative example it is assumed that a character error is caused by a single bit in error and that these bits in error are distributed at random with respect to time. An undetected error, then, for the purpose of this estimate, will be the occurrence, with a single 72-character line of typing, of two errors in the same counting line.

When r is 2, the equation reduces to:

$$P=\frac{n(n-1)p^2q^{n-2}}{2}$$

Since p is very small, q is very nearly 1, hence q^{n-2} is nearly 1. Then:

$$P=\frac{(n^2-n)p^2}{2}$$

For

$n=72$ and $p=1/30{,}000$
$P=1/352{,}000$

This means that the probability of occurrence of a double error is once in every 352,000 typed lines, or, with 72 characters in a line, once in about 25,000,000 characters.

The method of error detection here described gives an additional five-to-one advantage because the chances are only one in five that the two errors in a typed line will fall in the same counting line. So, finally, the theoretical probability of an undetected error for the assumed conditions, is one in 125,000,000 characters.

A similar calculation could be made for $r=4$. However, the probability of an undetected error from four errors in one checking line is enormously smaller than the probability from two so that it can be neglected in comparison.

Considerations in SSB and ISB Systems for Long-Distance Radiotelegraph Communications

WALTER LYONS
NONMEMBER AIEE

SINGLE side-band (SSB) and independent side-band (ISB) radiotelegraph systems allow for a high degree of frequency division multiplexing as contrasted to the requirement for time division multiplexing in usual frequency shift keyed carrier systems. This advantage is the principal justification for its use, especially for those circuits requiring high-speed traffic-handling capacities.

For the transmission of bit elements smaller than 10 milliseconds, the multipath delay distortion may be high to a degree that is intolerable for a commercial circuit. To reduce this distortion, it is required that the keyed pulse be "squared up," in other words, that it attain keying harmonics. This, in effect, forces the employment of large bandwidths of emission and reception. Thus, frequency conservation is defeated and power is wasted.

For smaller bit lengths, say, under 5 milliseconds, it may be impossible to improve reception by the method of adding harmonics to the keying pulse. For this reason, it has been proposed to change the code arrangement from sequential bit information to simultaneous frequency-separated bits. Simultaneous code presentation has the additional advantage in error-correcting equipment, where changes in code are usual, to reduce the amount and cost of equipment.

In the application of SSB for multichannel transmission, it is important, because of limited power which is available at this time from linear amplifiers, to limit the peaks of modulation. If the individual tone channels are keyed in an on-off manner, phase locking these tones is sufficient to assure a small peak-to-average amplitude ratio. For frequency-shifted tone channels, other means such as compatible SSB may be employed instead. On the other hand, and for greater simplicity, increasing the number of these channels will reduce the time duration of high amplitude peaks and render them negligible.

Because tone channeling on SSB transmission can be very accurately controlled and spaced because of the low audiofrequencies used, frequency shifting at optimum values can be employed to obtain the highest effective power in the transmission bandwidth. In this way, over 40 teleprinter channels can be accommodated in a voice band at transmitter power levels well within present linear amplifier techniques.

Recent developments in transistorization and semiconductor devices greatly reduce heat dissipation, size, and weight of a great part of the SSB receiver, which would be hardly possible under the older types. Due to these newer tools, maintenance is greatly reduced. The net result is the ability to expand

operational circuits without the usual requirements for increase in personnel, building space, and real estate.

Background

The application of SSB techniques to point-to-point long-distance radiotelegraph communication circuits promises the greatest growth possibilities in this field since its inception. However, in order to realize the benefits to be derived, every advantage offered by SSB must be thoroughly exploited, and all devices which can reduce its shortcomings should be employed.

The advantages accruing to SSB working for point-to-point circuits at high frequency, as compared with ordinary carrier frequency shift (FSK), reside in economy in equipment and antennas, greater simplicity in operation, spectrum conservation, and power gain. The practical realization of economies in equipment depends upon adequate telegraph circuit traffic loading to justify the initial investment and change from the older FSK gear. Transmitted frequency spectrum compression and power gain go hand in hand and are the peculiar attributes of SSB, due to its inherent frequency stability because of carrier reference at audiofrequencies. This is because the frequency-shifted channels being referred to the carrier are low audiofrequencies, and problems in maintaining small shifts and accurate centers are far easier than at carrier shift frequencies.

System Specification

Before further considerations, it is appropriate to set forth the basic requirements for a commercial point-to-point long-distance radiotelegraph circuit. They are that the circuit operate at least 95% of the time for 24 hours daily throughout the sunspot cycle, and that the error rate during operation of the radio path be less than 0.01%. To assure this performance, it has been determined empirically that about a 5-kw input to a 13-decibel rhombic should be provided for each kc emission bandwidth, assuming two and occasionally three frequency changes per day. This does not apply to circuits whose great circle paths go through the high absorption auroral zones.

Implementation

Present practice in loading a 3-kc side band of an SSB transmitter with three time-division 4-channel multiplex aggregates thus will require 15-kw average power and 90-kw instantaneous peak envelope power. For a fixed bandwidth-per-tone channel the average radiated power required increases directly as the number of subcarriers, the peak power rises as the square. Clearly, means for limiting peak power is indicated in order that economic considerations do not lead to a decision against SSB working for this degree of traffic loading. Conventional means for limiting the peak radio-frequency power, however, will result in an increase in spurious signal level with attendant signal degradation. There are two ways to remedy this situation: one would be to limit the modulation peaks, which requires, for minimum spurious output, a compatible SSB generator because the radio-frequency envelope is a replica of the modulation input; the other way is to increase the number of input tone channels so that the duration of each peak is reduced to about 10% of a signal element. Assuming 10-millisecond signal elements, 1-millisecond peak duration is tolerable and indicates a minimum requirement for approximately six tone channels. The assumption is that all channels are not resting on fixed tones and channeling tones are 120 cps (cycles per second) or more apart. This is a fortunate circumstance, since multipath delay distortion effects are not excessive when a bit of at least 10 milliseconds is used. If the three 4-channel multiplex aggregates are split up into six diplex (2-channel) channels (12-teleprinter capacity), peak power will quadruple, but chances are that the duration of any one peak will be short enough nearly to be negligible. The curves for various phasing conditions in Fig. 1 show that, for 120-cps separation, clipping or limiting by the transmitter above the nominal peak level 4, the duration is 1.23 milliseconds. The value decreases as the tone separation increases. Fig. 2 presents the arguments for peak clipping of a large number of tone channels. The equivalent power gain due to clipping increases markedly with the number of tone channels. The percentage time of clipping is a measure of the degree of spurious radiation or distortion. For the 5% and smaller curves, no single peak duration exceeds 1 millisecond for most unfavorable tone phasing. For many subchannels, each being frequency shift keyed, the instantaneous envelope amplitude approaches the probability density of a Rayleigh distribution. The expected distortion therefore will be considerably less than the curves indicate.[1]

A reduction in emission bandwidth and consequent increase in effective power is now feasible, since at the reduced keying speed the transmitted pulse

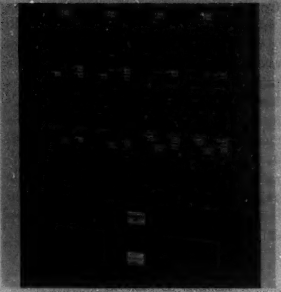

Fig. 3. Section of transmitter FSK subchanneling. Standard 84-inch rack houses 48 channels

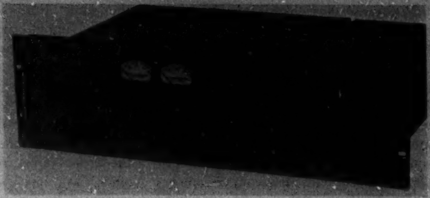

Fig. 4. FSK subchannel diversity receiver and tone transmitter

need not be trapezoidal for protection against multipath delay distortion. The transmission of a sine-wave-shaped signal element will serve to reduce interchannel crosstalk, allowing the use of filters having smooth cutoff characteristics with inherently low phase distortion. In this manner, a system may be devised to provide as many as 23 subcarrier frequency-shifted channels, each operated at diplex speed, accommodating 46 60-words-per-minute teleprinters in a single SSB voice channel. Required parameters are a modulation index of 0.8 and subcarrier channel separation 120 cps, starting at 300 cps and extending to 2,940 cps. A short-term traffic test of a portion of such a system, as compared with the usual 4-channel multiplex (quad) channeling at 340-cps shift and 680-cps channel separation, has shown marked improvement in error rate. For the comparison, four diplexed channels and two quad channels were operated on an SSB voice channel. If, now, a circuit is considered with requirements for only 12 teleprinters, the total bandwidth from carrier need only be about 900 cps and side-band power output roughly a quarter of the power required for full occupancy of the voice band. This is a power level which may be served adequately by linear amplifiers. Heavily loaded circuits and those carrying services such as phone or facsimile in addition might consider using envelope elimination and restoration SSB transmitters not to be limited in power for reasonable levels of spurious radiation.[2]

Frequency-shift keying has been plagued by multipath delay distortion to such an extent that FSK exciters have been built with switches to change transmission to on-off keying. It was possible to overcome the elongation of the "mark" signal by reducing keying weight on transmission. It is an unfortunate circumstance that misconception, due probably to frequency-modulation broadcasting techniques, put the point-to-point radio communications systems on a wide-shift basis. Perhaps also, in an attempt to overcome selective fading effects, the superimposed 200-cps phase modulation dictated the 850-cps shift even for solo channels.

Considerable evidence on long-haul circuits supports the thesis that a reduction in shift reduces jitter. It may be that selective fading is reduced to such an extent that multipath delay tends to act equally on both mark and "space" frequencies. This should facilitate the reduction of distortion in the final signal by simple adjustment of the phase of inspection of the signal element, approaching in this manner an unbiased (equally biased) signal. Thus the reduction in shift conforms to the characteristics of the keying mode, polar and unbiased, with attendant advantages in error reduction.

It is recognized that, in receiving signals with considerable multipath delay, wider filters will reduce the resultant jitter, but the reduction in frequency shift below 100 cps, serving to equalize the delay of both mark and space signals, allows for inspection closer to the trailing edge of the first received element, at the center of the unmutilated resulting bit. Including the increase in power attending the reduction in keying speed permitting sine-wave keying, the case for an FSK modulation index below unity is summarized.[3]

SSB working can enable simplification in terminal equipment by the facility for trading frequency division for time division multiplexing. Most error-correcting systems used in point-to-point radio communications at present employ the 7-unit Moore Code for error detection. This code invariably denotes a character by 3-mark and 4-space elements. Any deviation from this ratio is an error, calling for repetition by the sender. Most land line traffic uses the 5-unit start-stop code, requiring, therefore, a code conversion device for operating into radio circuits protected by error-correcting systems. For this purpose it is required that information for each conversion be changed from serial code to simultaneous presentation of the code elements. By the use of separate tones each to denote an element of the sequential code, each such tone being keyed simultaneously for mark or space, simultaneous code presentation is effected very simply, resulting in equipment reduction and signal element elongation, if desired, without sacrificing traffic handling speed.[4]

Data handling other than regular message should become, very soon, a major service on long-haul circuits. Accommodation of codes peculiar to a specific data-handling system can mean little more complication than adding additional tone channels for simultaneous keying. There is one pitfall, however, that must be avoided and which may be overlooked easily. The time delay in most filters and transfer lines varies with frequency. Steps must be taken, therefore, to assure equal delay for all the filters in a simultaneous code group, as well as the transfer line, over the frequency range of the group. This is an additional item of expense which must be included in an economic analysis of the two code types. Moreover, the need for equipment reliability in each of these tone channels is far greater than in the equipment for sequential keying.

The versatility in point-to-point services of independent side-band working is a great economic argument for this mode. Assuming sufficient power, phone, facsimile, and many telegraph channels may be operated at the same time. These services may be handled at minimum bandwidth occupancy, and should simplify frequency allocation by block assignment. For this type of operation, spurious signal radiation should be kept as low as is practicable, not alone to reduce interference out of band, but also self-interference in band, to which facsimile is especially vulnerable. For this purpose spurious signals should be down 30 decibels or more as measured by the standard 2-tone test.

Multiservice operation naturally is accompanied by equipment complication. Especially is this so when diversity reception techniques are used. The situation breeds, in the designer, a desire to simplify, sometimes at the sacrifice of performance. This tendency is understandable, especially in view of pressure from those who have the responsibility for maintaining the equipment. One design example reduced the problem by divorcing the receiver from the so-called terminal gear (low-frequency equipment), installing the audiofrequency components in the central office. For large commercial carriers, this has two shortcomings: first, the expense of doubling control line facilities for diversity reception, and second, the placing of an electronic maintenance load on an organization having little electronic experience. Diversity at the central office requires that the transfer lines have a very large dynamic range; otherwise, fading signals drop into the noise level suffering serious degradation.

Fortunately, recent developments in transistorization and semiconductor devices allow the possibility of very greatly reducing heat dissipation, the size and weight of receiver units, terminal equipment, and some transmitting units; at the same time effecting considerable circuit simplification. The net result is the ability to expand operational circuits without the usual requirement for expansion in personnel, building space, and real estate. Under such circumstances, it is questionable whether it is economical to consider automation in the form of direct control from the central office. It appears that a minimum personnel requirement at radio stations for maintenance and signal analysis can perform operating tasks as required without intruding on primary responsibilities. Extreme caution is indicated before application of servos and other schemes for automation lest the design result in a requirement for greater human effort in maintenance and service.

Economy in space due transistorization of transmitter channeling equipment is illustrated in Fig. 3. This is an assembly of 32 frequency shift tone keyers (transmitters) and 32 tone signal converters (signal demodulators), making a complete terminal facility for 32 FSK subchannels on SSB-ISB transmission.

Fig. 4 is a complete assembly for tone channel diversity reception, including a tone keyer for transmitting the received signal to the central office. The four separate units comprise two subchannel receivers and the diversity comparator between them, with the tone keyer on the extreme right.

Conclusions

With the upcoming low in the sunspot cycle, frequency conservation will be a prime necessity. The availability of high-power SSB-ISB transmitters, together with techniques outlined above, enables the industry to increase traffic at the same time that frequency occupancy is reduced. Justification for changing over to SSB-ISB might be the establishment of overseas trunk circuits or forked operation to points close to the same azimuth.

The additional complications introduced require greater co-operation between correspondents than heretofore in operating simple carrier FSK. The establishment of standards should help, and efforts in this direction should be made soon to cope with what is expected in propagation in the near future.

Criteria and Tests for Realizability of the Inductance Matrix

YILMAZ TOKAD
NONMEMBER AIEE

MYRIL B. REED
NONMEMBER AIEE

ENERGY considerations and experience have both indicated that measurements of the *R*, *L*, and *C* coefficients of an existing electrical network will lead to the positive semidefinite quadratic forms[1-3]

$$\mathfrak{I}^T(t)\mathfrak{R}\mathfrak{I}(t)\geq 0 \qquad (1)$$

$$\mathfrak{Q}^T(t)\mathfrak{D}\mathfrak{Q}(t)\geq 0 \qquad (2)$$

$$\mathfrak{I}^T(t)\mathfrak{L}\mathfrak{I}(t)\geq 0 \qquad (3)$$

Given a particular numerical set of symmetrical matrices which are to be used as the coefficient matrices $\mathfrak{R}$, $\mathfrak{D}$, $\mathfrak{L}$ of the preceding three inequalities, the positive semidefiniteness of the coefficient matrices is only certain for the first two. This certainty is a consequence of the matrices $\mathfrak{R}$ and $\mathfrak{D}$ being diagonal with nonnegative entries on the diagonal. The inductance (self-and mutual) matrix, $\mathfrak{L}$ of equation 3, on the contrary, may have non-zero off-diagonal entries with positive and negative signs in a variety of patterns. Cauer gave a realization technique for an $\mathfrak{L}$ matrix, satisfying equation 3, by using perfect coupled ($k=1$) transformers.[3] Therefore a particular numerical matrix (symmetric and real) can be realized by a set of coupled coils if it is positive semidefinite. The positive definiteness or semidefiniteness of such a matrix can be tested by checking the nonnegativeness of all the principal subdeterminants of the given matrix. The arithemtic involved in this multiple evaluation of determinants can readily become extensive.

In this paper a different test, in terms of the eigenvalues of the inductance matrix, is formulated. Indications are that this eignevalue test method involves appreciably less arithmetic than the multiple determinant method. Certain necessary and sufficient conditions on the eigenvalues as well as on the coefficient-of-couplings are presented as of interest in their own right as well as incidentals to the eigenvalue test metod.

That $|k_p|\leq 1$ Is Necessary for the Positive Semidefiniteness of the Inductance Matrix

Consider the proposition: If $|k_{pq}|\leq 1$, then $\mathfrak{L}$ is positive semidefinite. This

Paper 59-1090, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted January 29, 1959; made available for printing July 20, 1959.

Yilmaz Tokad and Myril B. Reed are with Michigan State University, East Lansing, Mich.

theorem is actually not true, i.e., not sufficient. The necessary condition for this theorem is proved by showing: If $\mathcal{L}$ is positive semidefinite, then $|k_{pq}|\leq 1$. This necessary condition is proved next.

Let the inductance matrix be reshaped to exhibit the coefficients of coupling. Thus

$$\begin{bmatrix} \sqrt{L_{11}} & 0 & \dots & 0 \\ 0 & \sqrt{L_{22}} & \dots & 0 \\ \vdots & \vdots & & \vdots \\ 0 & 0 & \dots & \sqrt{L_{nn}} \end{bmatrix} \begin{bmatrix} 1 & k_{12} & \dots & k_{1n} \\ k_{21} & 1 & \dots & k_{2n} \\ \vdots & \vdots & & \vdots \\ k_{n1} & k_{n2} & \dots & 1 \end{bmatrix} \times$$

$$\begin{bmatrix} \sqrt{L_{11}} & 0 & \dots & 0 \\ 0 & \sqrt{L_{22}} & \dots & 0 \\ \vdots & \vdots & & \vdots \\ 0 & 0 & \dots & \sqrt{L_{nn}} \end{bmatrix} = \mathcal{L}_d \mathcal{K} \mathcal{L}_d \quad (4)$$

where the coefficients of coupling, $k_{pq}=k_{qp}$, are

$$k_{pq}=\frac{L_{pq}}{\sqrt{L_{pp}L_{qq}}} \quad (5)$$

Since the diagonal matrices, $\mathcal{L}_d$, are nonsingular, the positive semidefiniteness of $\mathcal{K}$ implies the positive semidefiniteness of $\mathcal{L}$ and vice versa.

Assume now that $\mathcal{L}$ is positive semidefinite, i.e., that equation 3 is valid for all $\mathcal{I}(t)$. In particular, then, equation 3 is valid if all entries in $\mathcal{I}(t)$ are zero but any two—$i_p(t)$ and $i_q(t)$. If $p\neq q$, equation 3 is in detail, since $L_{pq}=L_{qp}$,

$$L_{pp}i_p^2(t)+L_{qq}i_q^2(t)+2L_{pq}i_p(t)i_q(t)\geq 0 \quad (6)$$

But the positive semidefiniteness of this quadratic form compels

$$L_{pq}^2\leq L_{pp}L_{qq} \quad (7)$$

Hence, if equation 3 is valid so is equation 7 which requires by equation 5

$$|k_{pq}|=\frac{|L_{pq}|}{\sqrt{L_{pp}L_{qq}}}\leq 1 \quad (8)$$

Therefore, since equation 3 implies equation 8, the relation 8 is necessary.

That $|k_{pq}|\leq 1$ Is Not Sufficient for Positive Semidefiniteness of the Inductance Matrix

That $|k_{pq}|\leq 1$ is not a sufficient condition for positive semidefiniteness of $\mathcal{L}$ is demonstrated next, by showing that equation 8 is not sufficient for equation 3 for the third-order inductance matrix although it is for the second-order case.

First, for a second-order matrix, $\mathcal{K}_2$, where

$$\mathcal{K}_2=\begin{bmatrix} 1 & k_{12} \\ k_{21} & 1 \end{bmatrix} \quad (9)$$

$\det \mathcal{K}_2=1-k_{12}k_{21}\geq 0$ for $|k_{12}|=|k_{21}|\leq 1$
and $\mathcal{K}_2$ is a positive semidefinite matrix and vice versa. Hence for this second-order case the usual condition of the coefficients of couplings, $|k_{pq}|\leq 1$, is necessary and sufficient for positive semidefiniteness of $\mathcal{K}_2$ and so of $\mathcal{L}$.

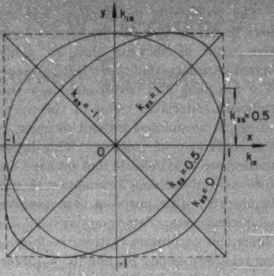

Fig. 1. Loci of k_{pq} for three windings

But consider the third-order matrix,

$$\mathcal{K}_3=\begin{bmatrix} 1 & k_{12} & k_{13} \\ k_{21} & 1 & k_{23} \\ k_{31} & k_{32} & 1 \end{bmatrix} \quad (10)$$

This matrix may or may not be a positive semidefinite matrix with the restrictions, $|k_{pq}|=|k_{qp}|\leq 1$. Indeed, if $k_{12}=k_{21}=0.5$, $k_{13}=k_{31}=-0.5$, and $k_{23}=k_{32}=0.6$, $\det \mathcal{K}_3<0$ and $\mathcal{K}_3$ is neither positive definite nor positive semidefinite. Therefore, the requirement $|k_{pq}|\leq 1$ is not sufficient for the positive definiteness or semidefiniteness of $\mathcal{K}_3$.

The complete pattern of the restrictions on the k_{pq} for the third-order case can be formulated as follows: let $x=k_{12}=k_{21}$, $y=k_{13}=k_{31}$, $z=k_{23}=k_{32}$. The determinant of $\mathcal{K}_3$ is, then,

$$\det \mathcal{K}_3=1+2\times yz-x^2-y^2-z^2 \quad (11)$$

It can be shown that $\mathcal{K}_3$ is positive definite for all points in a volume enclosed by the surface

$$1+2\times yz=x^2+y^2+{}^2z \quad (12)$$

and is positive semidefinite for all points on this surface.

Fig. 1 represents the projection on the $x-y$ plane of the intersection curve of this surface by a horizontal plane $z=k_{23}$. Fixing, say, k_{qr}, restricts the range of values of the other coefficient of coupling, k_{pq} and k_{pr}, for a positive semidefinite $\mathcal{K}_3$. For example, let $p_i(k_{pq}, k_{pr})$ be a point on the $x-y$ plane. If p_i lies inside the ellipse with k_{qr}=constant, then $\mathcal{K}_3$ is positive definite. If p_i is on the ellipse, then $\mathcal{K}_3$ is positive semidefinite, and if p_i is outside the ellipse but inside square of sides 2, then $\mathcal{K}_3$ is neither positive definite nor semidefinite.

If two of the coupling coefficients, k_{pq}, k_{pr}, are fixed, then the third one, k_{qr}, cannot be chosen arbitrarily to maintain the positive semidefiniteness of the matrix $\mathcal{K}_3$. Indeed, in this case it can be seen that k_{qr} must satisfy the relation

$$(k_{qr})_1\leq k_{qr}\leq (k_{qr})_2$$

where

$$(k_{qr})_1, (k_{qr})_2=k_{pq}k_{pr}\pm \sqrt{(1-k_{pq}^2)(1-k_{pr}^2)} \quad (13)$$

Therefore, for the positive definiteness or semidefiniteness of $\mathcal{K}_3$ the following conditions are necessary and sufficient:

$$|k_{pq}|\leq 1 \quad (14A)$$

$$k_{12}^2+k_{13}^2+k_{23}^2-2k_{12}k_{13}k_{23}\leq 1 \quad (14B)$$

In this case, since condition 14(B) contains the condition 14(A), then the necessary and sufficient condition is given by equation 14(B).

The preceding third-order example shows that the positive definiteness or semidefiniteness of the coefficient-of-coupling matrix, and so the inductance matrix, is more complex than simply specifying that all coefficients-of-coupling be less than unity in magnitude. The complexity of the restrictions increases rapidly as the order of the matrix $\mathcal{K}$ increases.

Necessary and Sufficient Requirements on the Inductance Matrix in Terms of Its Eigenvalues

Consider now the eigenvalue formulation. Necessary and sufficient conditions that any inductance matrix of any order is positive definite or semidefinite can be formulated in terms of the characteristic roots, or eigenvalues, of this matrix.[4] These eigenvalues are the roots, λ_i, of the characteristics polynomial of a matrix $\mathcal{L}$, defined by

$$P(\lambda)=\det[\mathcal{L}-\lambda\mathcal{U}]=(-1)^n[\lambda^n-\alpha_1\lambda^{n-1}+\alpha_2\lambda^{n-2}-\dots(-1)^n\alpha_n]$$
$$=(-1)^n(\lambda-\lambda_1)(\lambda-\lambda_2)\dots(\lambda-\lambda_n) \quad (15)$$

where $\mathcal{U}$ is the identity, or unit, matrix of order n and where the coefficients α_i of this characteristic polynomial are

(*a*) α_i=sum of all possible different products of the eigenvalues taken i at a time.

(*b*) α_i=sum of the diagonal minors of order i of $\mathcal{L}$.[5] Particularly $\alpha_n=\det \mathcal{L}$.

Applying Descartes rule of signs[6] to equation 15 leads to

Lemma: If and only if $\alpha_i\geq 0$, then $\lambda_i\geq 0$

and then to

Theorem: If and only if $\mathcal{L}$ is real, symmetric, and positive definite (semidefinite), then the eigenvalues, λ_i are real and $\lambda_i>0$ $(\lambda_i\geq 0)$[7,8]

Also, from the lemma, α_i are real and $\alpha_i > 0$ ($\alpha_i \geq 0$)

This theorem indicates an inspection technique on the coefficients, α_i, or the roots, λ_i, of the characteristic polynomial to detect positive definiteness or lack of it. However, in even the recent past this test would be essentially useless because of the formidable arithmetic barrier to calculating either the α_i or the λ_i. The digital computer has altered this situation to such an extent that it is a matter of minutes or even seconds, to now calculate the eigenvalues of a matrix directly to check for positive definiteness or semidefiniteness; or the multideterminant method is indicated by item *b*.

For example, the matrix

$$\mathcal{L} = 10^{-6}\begin{bmatrix} 0.2240 & 0.2691 & 0.2691 & 0.1724 & 0.1039 & 0.1039 \\ 0.2691 & 0.4713 & 0.3851 & 0.3163 & 0.2333 & 0.08629 \\ 0.2691 & 0.3851 & 0.4713 & 0.3163 & 0.2684 & 0.2333 \\ 0.1724 & 0.3163 & 0.3163 & 0.6188 & 0.4092 & 0.4092 \\ 0.1039 & 0.2333 & 0.2684 & 0.4092 & 1.048 & 0.7814 \\ 0.1039 & 0.08629 & 0.2333 & 0.4092 & 0.7814 & 1.048 \end{bmatrix}$$

recently was calculated from certain approximation formulas, for the calculation of the air-gap inductances, at a particular instant, of all the commutating coils in a d-c machine, and the question arose as to whether this matrix is an inductance matrix, i.e., does it correspond to a possible set of coupled coils, or mathematically is it positive semidifinite?[9] In a matter of about one minute a digital computer (MISTIC) gave the eigenvalues

$\lambda_1 = 0.0312 \times 10^{-6}$
$\lambda_2 = 0.0666 \times 10^{-6}$
$\lambda_3 = 0.2429 \times 10^{-6}$
$\lambda_4 = 0.2960 \times 10^{-6}$
$\lambda_5 = 0.9102 \times 10^{-6}$
$\lambda_6 = 2.3346 \times 10^{-6}$

through use of one of the programs in the computer library. All of these eigenvalues are real and positive, hence the matrix, $\mathcal{L}$, is positive definite and so an allowable inductance matrix.

The coefficients of coupling, k_{pq}, are used in the foregoing largely in the negative sense of showing that an easily stated necessary condition is not sufficient. The foregoing and useful necessary and sufficient criteria in terms of the eigenvalues, is formulated without recourse to the coefficients-of-coupling. This latter pattern seems to indicate that perhaps the coefficient-of-coupling formulation should be used for other purposes than positive semidefiniteness determinations. To clinch this conclusion further the following relations among α'_i and the k_{pq} have been established. Where α'_i are the coefficients of the characteristic equation of the matrix, $\mathcal{K}$, i.e.,

$$\det[\mathcal{K} - \lambda\mathcal{U}] = (-1)^n[\lambda^n - \alpha'_1\lambda^{n-1} + \alpha'_2\lambda^{n-2} - \ldots (-1)^n\alpha'_n] = 0$$

where again α'_i have the same properties as α_i. From characterization (b) following equation 15, the α'_i are

$$\alpha'_1 = \sum_{p=1}^{n} k_{pp} = n > 0 \quad (\text{trace of } \mathcal{K})$$

which is always positive,

$$\alpha'_2 = \sum_{p<q}^{n} (k_{pp}k_{qq} - k_{pq}^2) = \sum_{p<q}^{n} (1 - k_{pq}^2) > 0$$

i.e., the point $P(k_{12}, \ldots, k_{1n}, k_{21}, \ldots, k_{(n-1\ n)})$ must be in the $n(n-1)/2$ dimensional sphere of radius $\sqrt{n(n-1)/2}$

$$\alpha'_3 = \sum_{p<q<r}^{n} [1 + 2(k_{pq}k_{pr}k_{qr}) - (k_{pq}^2 + k_{pr}^2 + k_{qr}^2)] > 0$$

$$\begin{aligned}\alpha'_4 = \sum_{p<q<r<s}^{n} [1 - (&k_{pq}^2 + k_{pr}^2 + k_{ps}^2 + k_{qr}^2 + k_{qs}^2 + k_{rs}^2) \\ &+ 2(k_{pq}k_{pr}k_{qr} + k_{pr}k_{ps}k_{rs} + k_{pq}k_{ps}k_{qs} + k_{qr}k_{qs}k_{rs}) \\ &+ (k_{pq}^2k_{rs}^2 + k_{pr}^2k_{qs}^2 + k_{ps}^2k_{qr}^2) \\ &- 2(k_{pq}k_{pr}k_{qs}k_{rs} + k_{pq}k_{ps}k_{qr}k_{rs} + k_{pr}k_{ps}k_{qr}k_{qs})] > 0\end{aligned}$$

$$\vdots$$

$$\alpha'_n = \det \mathcal{K} > 0$$

The complete detailing of this general set of inequalities is not feasible although these inequalities could be established, of course, for a particular case, or for many cases, the k_{pq} evaluated from the *L*-values, and the whole tested for positiveness. Or it should be possible to set a computer to work locating and evaluating the appropriate minors of $\mathcal{K}$ and then combining them. In contrast with the clearly simple computer eigenvalue pattern, there seems little chance that the coefficient-of-coupling technique can compete.

Design Features of a New Frequency Shift Carrier Telegraph System

M. L. STEPHENS
ASSOCIATE MEMBER AIEE

NARROW-BAND frequency shift carrier telegraphy has found steadily increasing usage throughout the communications industry since such systems were first introduced. Today, the major communication companies of the United States and Canada are rapidly expanding their carrier telegraph networks, and many applications are being found among such industries as the railroad and pipeline companies. A surprising number of data transmission problems may be solved through the use of these modern high-speed telegraph circuits.

This paper describes some of the design features of a new carrier telegraph system designated as type *23A*. The broad design objective was to develop a telegraph system with the rigid performance requirements and flexible application demanded by the user, making use of the latest developments in components and manufacturing technology.

A complete *23A* terminal of 18 channels occupies about 7 feet of space on a standard 19-inch rack; the over-all depth is 10 inches. The circuits are transistorized, and the full terminal dissipates about 55 watts of power exclusive of loop drains. Comparable vacuum-tube equipment dissipates nearly ten times this power. The transistor circuits operate on negative 48-volt office battery, and loops may be operated on the same office battery or on the usual telegraph supplies. Loop facilities are built in, and the channels operate with most existing neutral and polar systems without the use of additional equipment. Both 2-wire and 4-wire carrier lines may be used.

Carrier frequency assignments are chosen to co-ordinate with existing Western Electric Company type *43A* systems:[1] 18 channels spaced at 170 cps (cycles per second) are obtained between 425 and 3,315 cps. A mark-to-space frequency shift of 70 cycles is used. Eight other channel assignments exist at higher frequencies and these use slightly greater frequency shifts and spacings. The maximum signaling speed of each channel is slightly more than 100 wpm (words per minute) or, in data language, 80 bits per second.

Fig. 1 represents a typical 16-channel terminal showing, from top to bottom, terminal block panel, fuse panels, loop equipment panels, meter panel, jackfield, line equipment panel, and channel equipment shelves. The basic equipment module is four channels.

System Considerations

Fig. 2 is a block diagram of the *23A* system. Each block is self-explanatory, but note that the system is divided functionally into three groups indicated as loop equipment, channel equipment, and line equipment. This same division is also present in the physical arrangements of the terminal equipment, as may be seen by reference to Fig. 1. Advantages of such a separation are twofold. First, the transistorized channel equipment is physically separate from the heat-producing loop equipment. Second, flexibility of design and application is obtained in that the basic channel equipment may be used with many different types of loop and line equipments according to the ultimate system usage. At present, two types of d-c equipment units are designed. One is intended for neutral and polar loop options, and the other for voltage-type hub operation. New applications may well stimulate additional designs, such as might be needed for telemetering converters. The same basic channel unit is also used in the type *2340* subscriber set, a miniature, self-contained carrier telegraph terminal which may be installed in a teleprinter console.

RECEIVE RELAY

A great deal of consideration was given to the use of a transistor as a receive loop keyer in place of the traditional polar telegraph relay. The advantages of using a relay are well known, but the difficulty and expense of maintenance on many common telegraph relays usually outweigh their direct advantages. The polar relay used in the *23A* system (known as the type *PTW 204*), was carefully designed with the emphasis on long service life and extreme ruggedness.[2] Laboratory tests indicate, and user reports verify, that a service life in excess of 1 to 2 years is obtained without readjustment even on full-time high-speed circuits.

The outstanding characteristics of the relay are due primarily to the use of relatively large tungsten-carbide contacts which are fixed to a rigid bar-shaped armature. In use, the contacts slowly powder away without the usual pitting or build-up commonly encountered. Contact burnishing is never required. Field adjustment of the contacts is readily accomplished by resetting each gap to make up for the material which has worn away. There are no other adjustments.

With the maintenance problem under control, full advantage is taken of the relay in design of the loop unit circuitry. Use of a silicon junction diode bridge as an oscillator modulator further simplifies the problem. The basic loop unit may be conditioned for some 40 different loop options including most neutral, polar, effective polar, and inverse neutral types of operation. Selection of the desired option is accomplished by installing a 20-pin option plug which is equipped with the appropriate jumper wiring to select and arrange the various circuit elements. In some of the less commonly used options, the plug contains two or three resistors. Automatic selection of the most appropriate relay contact protection network is also accomplished by the option plug.

The loop unit, then, is seen to contribute great versatility to the system; a flexibility not economically possible with purely electronic keyers such as transistors and vacuum tubes.

CARRIER LINE EQUIPMENT

A minimum requirement of the carrier line equipment panel is balancing and matching transformers for 4-wire lines, and hybrid and matching transformers for 2-wire lines. In addition to such basic facilities, the system design of the *23A* places further requirements on the line equipment.

To permit the use of small inductors in the channel band-pass filters, the output power of an individual channel is −15 decibels referred to 1 milliwatt (−15 dbm). Also, such a level is convenient for group attenuation or amplification to produce the entire range of

Paper 59-1111, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted June 10, 1959; made available for printing July 15, 1959.

M. L. STEPHENS is with the Lenkurt Electric Company, Inc., San Carlos, Calif.

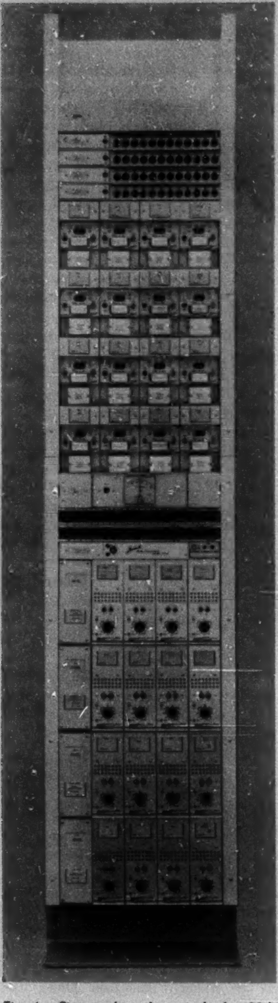

Fig. 1. Sixteen-channel terminal of a 23A system showing channel units, jackfield, meter panel loop equipment units, and fuse panel

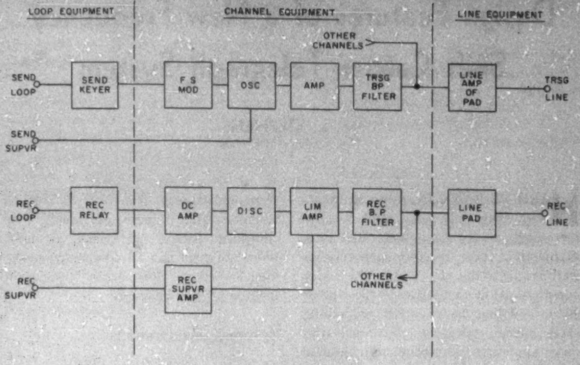

Fig. 2. Block diagram of the 23A system

line power required of the system, which is −40 dbm to +6 dbm. Therefore, the transmit branch of the line equipment panel is provided with an optional adjustable attenuator pad or amplifier as required, and transmit line levels are adjusted on a group or system basis. A similar arrangement is used in the receive branch: an adjustable attenuator pad is provided, and the receiving level is adjusted on a group basis. Such an arrangement has the advantage that all channel units in any system transmit and receive a standard power. Channel units may then be moved from system to system or from spare status to system operation without regard to level adjustments.

Third Function

In addition to mark-and-space functions, the *23A* system provides for low-speed carrier on and off keying. This third function is optional on a channel basis, and is used for certain signaling or supervisory purposes. The channel carrier oscillator is turned on by the application of a ground to the send supervisory lead, and the reception of carrier is indicated by a ground appearance on the receive supervisory lead. Transmission of the third function through a back-to-back channel interconnection is possible without the use of repeating relays.

When equipped, each channel unit is arranged to ground the receive supervisory lead whenever the received channel carrier exceeds a level of approximately −55 dbm. No adjustment of this trip level is necessary and none is provided. Adjustment of the common receive branch attenuator to produce a channel receive level of −40 dbm automatically provides a trip margin of approximately 15 db for every channel in the system. The channel receive filter provides a margin of approximately 8 to 10 db against false operation from noise even if the received carrier to channel noise ratio is as small as 5 to 10 db. Channel noise is defined as that measured in dbm, existing in the band of frequencies from approximately 300 to 3,300 cps.

Circuit Descriptions

Loop Equipment

The function of the loop unit is to modulate the channel carrier oscillator in accordance with the mark-and-space signals generated on the loop by the teleprinter. And, on the receiving side, the unit must key the loop in accordance with the carrier signals received from the distant end. Fig. 3 is a simplified representation of the loop unit arranged for half duplex, using −130-volt telegraph battery, and adjusted for a marking current of 60 ma (milliamperes). With the receive relay contacts closed representing a received mark signal, loop current flows holding the teleprinter selector magnets on mark. The voltage drop through resistor $R1$ is such as to produce a potential of approximately −110 volts at point X. By voltage divider action, the potential at point Y is about −120 volts. The diode quad is therefore held nonconducting by a potential of about 10 volts, and capacitor Cs, the shift capacitor, is isolated from the main oscillator tank circuit by a high impedance and the oscillator produces the high or marking frequency. The diode quad, shift capacitor, and oscillator tank are located with the basic channel unit.

When the teleprinter contacts open to indicate transmission of a space, loop current ceases, point X becomes more negative than point Y, and a current flows through the diode quad. The shift capacitor is therefore coupled into the

tank circuit through the low impedance of the conducting quad, and the oscillator produces the low or spacing frequency.

Now, assume that the teleprinter keyboard contacts are closed, and that the receive relay contacts are open because of the reception of a spacing signal from the distant terminal. Loop current is interrupted by the open relay contacts, point *X* is at ground potential, and point *Y* is still held at about −120 volts by the voltage divider. The diode quad is held nonconducting by a potential of approximately 120 volts, and the oscillator continues to produce the high or marking frequency. Received carrier signals, then, are not transmitted back to the distant terminal.

Different nominal values of loop current are permitted by using a different value of resistance for *R*1, but in all cases *R*1 produces a drop of approximately 20 volts. By changing the value of *R*4, different potentials of telegraph battery may be used. In all cases, the drop across *R*3 is made to be about 10 volts. Positive telegraph battery is accommodated by reversing the connections to the diode quad.

Fig. 4 represents the arrangement used for 2-path polar loops. The voltage developed across *R*1 by the send loop current is used to bias the diode quad. Marking current (from negative battery) biases the quad off: spacing current (from positive battery) biases the quad on. On the receive side, polar signals are developed in the loop directly from the contacts of the receive relay. Selection and arrangement of the proper resistors are done by the jumper wiring of the 20-pin option plug.

The loop unit contains only resistors, capacitors, and the receiving relay; no semiconductors are used (the modulator quad is located within the basic channel unit). The unit is therefore capable of withstanding the temperatures created by the power dissipated by the loop-adjusting rheostats.

Transmission characteristics of the loop unit are similar to those of a system which uses a transmitting relay, in that the oscillator frequency is a function of loop current. Conventional wave-shaping networks may therefore be used whenever indicated.

Hub Equipment

A hub equipment unit is used with the basic channel unit instead of the loop unit when it is desired to operate on a voltage hub basis. In this system, carrier terminals are connected in parallel to a hub lead, and a party-line type of operation results in which transmission received from one channel is transmitted to all other channels. The *23A* hub unit was designed to be compatible with the Western Electric Type *2B* service board where a potential of +60 volts represents marking; −30 volts is spacing; and −60 volts represents a condition known as double space.[3]

Fig. 5 is a simplified schematic diagram of the hub circuitry. The half duplex case is illustrated, in which the

HUB POTENTIOMETER

Fig. 5. Electronic hub circuit

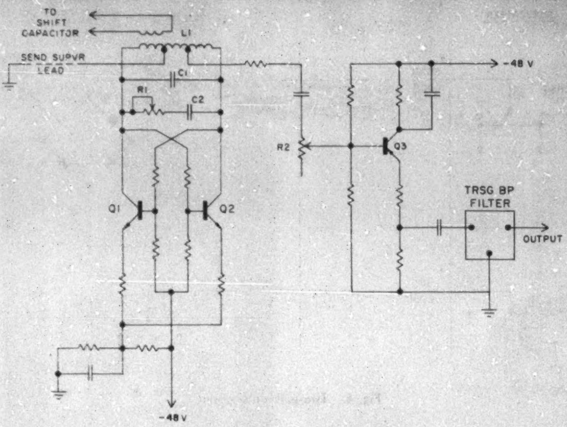

Fig. 6. Oscillator and buffer amplifier

send hub lead and receive hub leads are connected directly together and to a half-duplex hub potentiometer. The hub potentiometer is not a part of the *23A* system, and is located elsewhere. The modulator quad, shift capacitor, and oscillator tank connections are utilized in the same way as in the loop unit, but now the proper voltage and current is supplied by two transistors. *Q*1 and *Q*2 (*2N270*) are connected in tandem in such a way that when *Q*1 is driven to current saturation, *Q*2 is biased to cut off, and vice versa. The base of *Q*1 (input) is subject to bias from two sources: the signals from the hub are applied to the transistor through *R*2 as a current-limiting resistor, and a biasing current which depends upon the position of the receive relay is supplied by means of *R*3, *R*4 and *R*5. When the receive relay is in its marking position, the resistor network produces no net bias upon the base of *Q*1, and when the relay is in its spacing position, the network provides a net positive base bias which drives *Q*1 into current cut-off.

When all of the channels connected to the half duplex hub are on marking, the hub assumes a potential of +60 volts as determined by the hub potentiometer. A small current (about 0.5 ma) flows from the hub into the send hub lead, causing the base of transistor *Q*1 to become positive with respect to the emitter. The collector current is therefore cut off and because of the direct coupling to the collector of *Q*1, the base of *Q*2 becomes negative with respect to its emitter, and its collector current reaches saturation. A portion of the current flows through *R*10 and *CR*2; the resulting voltage drop biases the diode quad into its high impedance condition and the oscillator produces the high (marking) frequency.

When the hub potential is −30 volts, indicating that a spacing signal is to be transmitted, the base of *Q*1 becomes negative with respect to the emitter, and the collector current reaches saturation. Transistor *Q*2 loses its negative base bias, and its collector current becomes cut off. A small reverse bias is provided by *R*12 and *CR*3 to insure full cut-off. A portion of the collector current from *Q*1 is passed through *R*11, and the diode quad biasing the diodes into the low-impedance condition; the oscillator produces the low (spacing) frequency.

Incoming signals are passed to the hub via the receive hub lead and the spacing contact of the receive relay. When the relay spaces, a current of about 30 ma flows through *R*1 and the hub potential becomes −30 volts. Therefore all other hub units connected to the hub transmit a spacing signal. The positive bias produced by the resistor network overcomes the negative signal from the hub and *Q*1 remains cut off. The channel oscillator continues to generate the high (marking) frequency, and the incoming space signal is not transmitted back to the origin. Should a second channel also receive a space signal at the same time, there are two paths from the hub to negative battery, and the hub potential becomes −60 volts. The signal at the base of *Q*1 is now large enough to overcome the positive bias from the resistor network, and a space signal is transmitted back to the origin. In this way, double space signals are always transmitted regardless of the condition of the receive relay. Full duplex hub operation is possible by arranging two hub potentiometers to form an east-west hub and a west-east hub. A jumper connection is made to connect *R*3 to negative battery permanently, and now transmission on the send hub lead is independent of the position of the receive relay, and signals may be passed in both directions at the same time. In either full or half duplex operation, up to ten units may be connected to a single hub.

CHANNEL UNIT

The channel unit contains the frequency-shift transmitting and receiving circuitry required for one channel of a system. For purposes of description, the circuitry is divided into four categories.

1. *Oscillator, Buffer Amplifier, and*

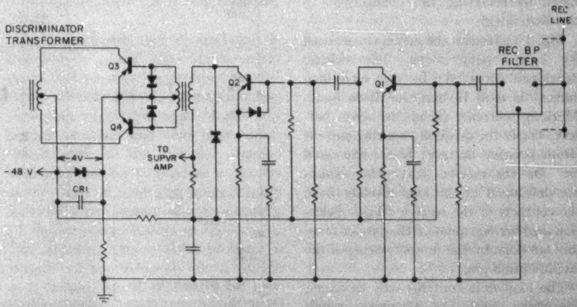

Fig. 7. Limiter amplifier

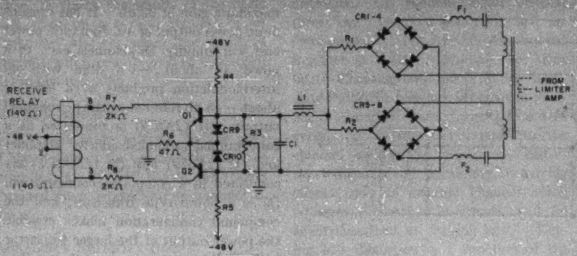

Fig. 8. Discriminator–d-c amplifier

Transmit Filter. Fig. 6 is a schematic diagram of the oscillator, buffer amplifier, and transmit filter. Transistors *Q*1 and *Q*2 (type *2N679*) are the n-p-n type of devices connected in a push-pull oscillator circuit in which the frequency of oscillations is determined by the resonant circuit composed of *L*1, *C*1, and the shift capacitor. *R*1 and *C*2 provide a means of fine frequency adjustment of about ±0.3%. Transistor collector capacitance also appears across the tank circuit, but with the transistors used, capacitance is small compared to the main tank capacitance. Amplitude of oscillations is limited by clipping in the transistors. Oscillations are produced as long as a ground is present on the send supervisory lead; opening of this conductor removes the collector voltage, and oscillations cease.

To obtain good frequency stability as a function of circuit voltage, a ferrite core inductor is used, which is resonated with a polystyrene film capacitor. The combination also gives good stability as a function of temperature because the ferrite core and polystyrene capacitor have nearly equal and opposite temperature coefficients. Any residual coefficient is further reduced by padding of the final tank assembly with capacitors of positive, zero, or negative temperature coefficient as indicated by measurement of the resonant frequency at two ambient temperatures: room temperature and 50 C (degrees centigrade). Coarse frequency adjustment is provided by means of padder capacitors which are brought out to strapping terminals on the outside of the enclosure.

Transistor *Q*3 (type *2N270*) is connected as a common collector amplifier whose primary function is one of impedance transformation from the oscillator to the transmit band-pass filter. Potentiometer *R*2 is provided as a means of precisely adjusting the output to the desired level: a range of approximately 3 db is available, which is just sufficient to take care of variation in transistors and filter insertion loss. Amplifier output power to the filter is approximately −11 dbm.

The transmit band-pass filter provides rejection to the unwanted keying side bands which would otherwise cause adjacent channel interference. The nominal output impedance is 600 ohms, unbalanced, and the out-of-band impedance tends toward open circuit so as to permit flanking (paralleling) of the transmit filters of adjacent channels.

The transmit filter and the oscillator tank are assembled together into a hermetically sealed plug-in case. By changing this one unit, the transmit branch may be operated at any one of the 26-channel frequency assignments.

2. *Limiter Amplifier.* Fig. 7 is a schematic diagram of the limiter amplifier circuits. At the input is shown the receive band-pass filter which serves to select the desired channel frequencies from all those present. The input impedance of the filter is 600 ohms, unbalanced, and it is designed for flanking. Adjacent channel frequencies are rejected by at least 35 db.

The limiter amplifier eliminates amplitude variations which are present in the incoming signals and supplies the discriminator network with a signal of the required power. Transistors *Q*1 and *Q*2 (*2N270*) are connected in grounded emitter configuration; diodes are added to assist in obtaining symmetrical limiting. The final stage is a push-pull transformer-coupled grounded emitter circuit operating with a collector supply voltage of approximately 4 volts as controlled by the Zener diode *CR*1. Collector saturation in this stage is complete for an input power to the filter of about −60 dbm. Output voltage of the stage is a square wave of approximately a 14-volt amplitude, peak to peak, regardless of input level variations between −60 and −15 dbm. The Zener diode maintains the level constant regardless of power supply fluctuations.

A portion of the output voltage from *Q*2 is taken for the input to the supervisory receive amplifier. At the level at which this amplifier must operate, *Q*2 is not in saturation, thus assuring predictable operation of the receive supervisory function.

3. *Discriminator and D-C Amplifier.* The discriminator and d-c amplifier circuits are shown in Fig. 8. The discriminator consists of two series resonant meshes; one mesh is tuned to a resonant frequency *F*1, which is slightly higher than the channel mark frequency, and the other is tuned to a frequency *F*2, which is slightly lower than the channel space frequency. The output of each mesh is individually rectified in full-wave bridge rectifiers and the rectified currents are added in opposition. The resultant difference current flows through the input circuit of the d-c amplifier. Fig. 9 shows the response curve of a typical discriminator network. At the channel mark and space frequencies the output current is approximately ±2 ma respectively. Series resonant circuits are used because they favor the low input impedance (approximately 200 ohms) of the d-c amplifier.

A low-pass filter, *L*1 and *C*1, is included between the discriminator and d-c amplifier. It attenuates carrier frequency energy and other unwanted tones which could cause interference from adjacent channels. Also included, but not shown in Fig. 8, is a reversing switch that permits the proper reception of either the high or low channel frequency for mark.

The d-c amplifier consists of two power-type transistors, *Q*1 and *Q*2 (*2N301A*), connected in a push-pull, grounded emitter configuration. Each transistor drives one coil of the receiving polar relay whose contact position is a function of the difference in current flowing in its two windings. When marking frequency is received, the discriminator mesh tuned

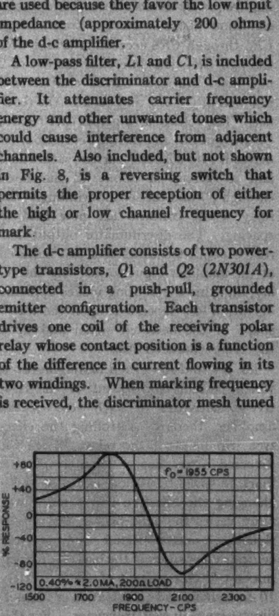

Fig. 9. Typical discriminator response

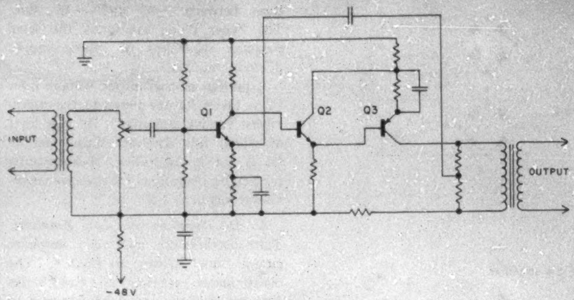

Fig. 10. Group amplifier

to *F*1 has a lower impedance than that tuned to *F*2, and the rectified current from bridge *CR*1 through *CR*4 exceeds that from bridge *CR*5 through *CR*8, and the difference current of 2 ma flows through *L*1, *CR*9, emitter-base junction of *Q*2, and back to the rectifier. The voltage drop across *CR*9 biases *Q*1 into cut-off, and the base current of *Q*2 drives it into collector saturation. A current of approximately 22 ma flows through *R*8 and one winding of the relay and its contacts are held to marking. When spacing frequency is received, the opposite condition obtains: current from bridge *CR*5 through *CR*8 exceeds of bridge *CR*1 through *CR*4, the difference current of 2 ma flows through *CR*10, emitter-base junction of *Q*1, *L*1, and back to the rectifier. The voltage drop across *CR*10 biases *Q*2 into cut-off, and the base current of *Q*1 drives it into collector current saturation, and a current of about 22 ma flows through *R*7 and the second winding of the relay whose contacts are now held to spacing. The discriminator output current is about ten times that just required at the amplifier input to just trip the relay, and this d-c limiting makes dynamic operation less dependent upon the waveshape of the detected signal and upon the relay characteristics.

*R*3, *R*4, and *R*5 form a biasing network which permits adjustment of the relative sensitivities of each side of the amplifier, thereby controlling the effective trip point of the relay. Since the detected signal has a definitely sloping mark to space transition, and vice versa, changing the effective trip point of the relay varies the time bias in the output signals. Under no-signal conditions, the centralized position of the bias control permits a collector current of approximately 10 ma to flow, and a dissipation of 240 milliwatts exists in each transistor. For this reason power-type transistors are used in the amplifier. The small signal transistors used elsewhere in the circuit do not have the necessary dissipation rating.

The entire d-c circuit is truly polar, and variations in relay or transistor parameters which would, in neutral (single-ended) circuits produce bias, are cancelled out.

The receive relay and bias control potentiometer are located in the loop equipment panel along with the other controls and jacks which may be used in day-to-day operation. The discriminator network elements are assembled in the same hermetically sealed plug-in package as the receive band-pass filter. By changing out this one unit, the receive branch may be operated at any of the 26-channel frequency assignments.

4. *Receive Supervisory Circuit.* The received supervisory circuit (not illustrated) consists of a conventional linear grounded emitter a-c amplifier, a voltage doubling detector, a d-c amplifier, and a neutral relay. Gain of the circuit is constant and stabilized with local feedback in such a way that the trip point of the relay is at a receive level of approximately −55 dbm. Stiffness of the circuit is such as to produce an operate-release differential of about 1 db. A time delay capacitor is included to prevent false operation on line hits. The relay contacts are brought out to a terminal block where they may be used for supervisory purposes and, by appropriate strapping, to hold the receive polar relay to mark or space as desired upon loss of carrier.

LINE EQUIPMENT

Of the various elements included within the two basic types of line equipment panels, only the transmit amplifiers will be described in any detail. Fig. 10 is a schematic diagram of the amplifier used for up to 26 channels. The unit is a plug-in, 3-transistor amplifier having a maximum gain of 22 db. It has a maximum power output of +6 dbm total power and will amplify 18 channels each to a power of about −6.5 dbm with all intermodulation products at a level of about −45 db referred to the per-channel output. *Q*1 (*2N679*) is connected as a conventional grounded emitter amplifier and *Q*2 (*2N679*) and *Q*3 (*2N301A*) are connected in a compound configuration. *Q*3 is a power-type transistor, and the compound configuration makes possible the power output of the larger transistor with the linearity and gain of the smaller. Bridge feedback from the output to the input emitter resistor is used to control distortion and output impedance.

When only one channel is to be amplified, as in subscriber set applications, a simpler 2-transistor amplifier is used. The channel amplifier, as it is called, also uses the compound configuration, but the input transistor is omitted, and no overall feedback is provided. Use of the simpler circuit is permissible because, for the same power output an amplifier handling 18 tones must have a peak power output capability of some 12 to 13 db greater than an amplifier for one tone. Single-channel installations, therefore, benefit from the lower cost of the simpler amplifier.

Performance Characteristics

SIGNAL-TO-NOISE CHARACTERISTICS

One of the most important system performance characteristics is its behavior in the presence of randomly distributed (white) noise. For the tests reported here, a method of measurement is used which is rather easily duplicated in the field; signal-to-noise ratio is defined as the ratio of a single-carrier tone power to the rms power of white noise passed through a 3.4-kc low-pass filter. Performance of the system is rated in terms of maximum checkable telegraph distortion in each channel, usually at 100 wpm, and this phrase defines the maximum total distortion (peak distortion) observed over approximately a 5-minute interval.

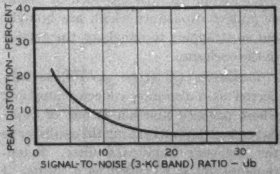

Fig. 11. Peak distortion versus signal-to-noise ratio. Typical channel 100 wpm

Fig. 11 shows the results of the noise tests made on a typical channel of an 18-channel system, using the transmit amplifier and a receive level of −40 dbm at the channel filter.

LIMITING RANGE

Of considerable interest to the user of the system is the permissible range of input levels. Fig. 12 shows the results obtained on a representative channel at 100 wpm.

FREQUENCY STABILITY-BIAS CONSIDERATION

Any frequency shift telegraph system suffers bias distortion from frequency drift in the oscillator, the discriminator, or the transmission facility. If such drifts are small they may be compensated for with the receive bias control, and if they occur slowly with time, they may be ignored between normal line-up intervals. In the *23A* system, a frequency drift of 1 cycle causes a bias distortion of approximately 2% at 100 wpm for the 18 voice-frequency channels. At 60 wpm, the distortion is estimated at about 1.2% per cycle. Slightly less distortion occurs for a given frequency drift for the eight high-frequency channels.

Temperature and voltage fluctions may cause bias distortion in so far as frequency of tuned elements are temperature or voltage dependent. Also, unbalance in the d-c amplifier used to drive the receive relay will cause bias. Through the use of temperature compensation in the tuned networks, a voltage-stabilized limiter circuit, and push-pull d-c amplification, bias distortion is less than 5% at 100 wpm for a 10% change in line voltage or a 15 C change in ambient temperature. Typical channels measure about 2% from either cause.

TOTAL DISTORTION

Other than bias distortion, which may be removed, total channel distortion consists of characteristic and fortuitous distortion. On random traffic signals, these two types of distortion are indistinguishable, and are therefore quoted together as total distortion, other than bias. Characteristic distortion is associated with the response time of the channel to a mark-to-space transition or vice versa, and is therefore related to the channel bandwidth. Fortuitous distortion includes all randomly occurring effects such as internal channel noise, adjacent channel interference, and an effect described as "keying loss." Keying loss distortion is a function of the ratio of channel carrier frequency to the signal or keying frequency; it is minimized by full-wave detection. For a given speed of transmission, keying loss distortion decreases with increasing carrier frequency, and for this reason, the two lowest carrier frequency channels show a greater total distortion than all the others.

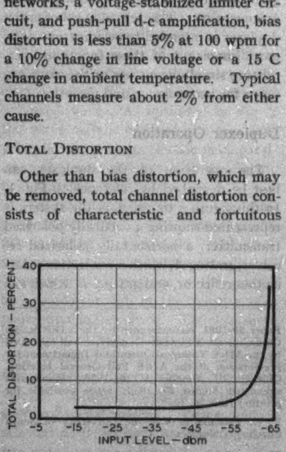

Fig. 12. Typical performance characteristics. Total distortion versus input level at 100 wpm $f_0 = 2{,}805$ cps

For an 18-channel system operating at 100 wpm, the total distortion in any channel is 5% or less, except for the two channels at the low-frequency end of the scale where the distortion is 8% or less. These figures include keying loss and adjacent channel effects.

Equipment Features

TRANSISTOR CONSIDERATIONS

Transistors, as active circuit elements, offer the designer many advantages over vacuum tubes. However, unlike tubes, transistors are quite temperature-sensitive and due care must be taken to prevent the junction temperature from exceeding its rating (usually 85 C) under all operating conditions. In practical terms, power dissipation within the transistor must be derated to account for the equipment temperature rise and ambient temperature expected, and total circuit dissipation must be limited to reduce equipment temperature rise.

The *23A* system is designed for a maximum ambient temperature of 50 C, or 122 F. All transistors are derated for operation to at least 65 C, and temperature measurements on equipment assemblies have indicated a maximum heat rise of about 8 C. Power dissipation within the type *2301A* channel unit is 2.5 watts compared to about 30 watts for comparable vacuum-tube designs. Four different transistor types are used through out the system, and a standardization program currently under way may reduce this number to three.

Fig. 13. The 2301 telegraph channel unit

CHANNEL UNIT

Fig. 13 shows the type *2301A* channel unit. The receive card with the two power transistors is visible. Transmitting, receiving, and supervisory circuits are assembled on separate phenolic cards which are installed in the sheet metal chassis. The unit is plugged into its position in the channel equipment shelf which provides terminal block facilities. The unit face plate provides a card holder for circuit identification, and mounts the switches and test points. An oscillator on-off switch is installed and is used for maintenance purposes, or to turn the oscillator on when the supervisory feature is not used. The second switch

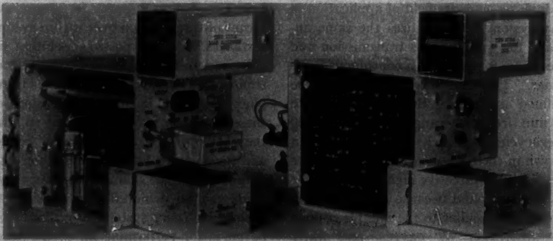

Fig. 14. Type 2332 loop and hub equipment units

is the receive polarity switch. An 11-pin test socket is provided which makes available a number of bridging tests points which are useful in line-up and trouble isolation. The two tuned network assemblies plug into the top of the unit, and can be removed when the channel unit is withdrawn from its mounting. Each circuit card is independently removable from the chassis for servicing, and suitable cable hinges are included to facilitate this operation.

The circuit cards are constructed of phenolic material through which are driven wire staples. Components are installed on the crown side of the board (opposite the legs of the staple), and leads are fed through holes in the board, wrapped around the staple ends, and soldered. Most of the interconnect strapping on the board is done with bare wire, and the number of external cable connections is kept to a minimum.

The mechanical design of the cards is such as to permit much of the assembly to be done by machinery, and automatic fabrication of the cards is gradually being introduced. An adequate description of the process is beyond the scope of this paper.

Other automatic production techniques are being used currently in the production of the filter networks. The process is called "modularized filter construction." Each mesh of the filter consists of a molded plastic module which contains the toroidal inductor and associated capacitor. The modules are tuned (resonated) individually, and then assembled into the final enclosure and connected together to make the complete network. In many cases, padding of the mesh to the required resonant frequency is unnecessary because the toroid has been wound to the precise inductance required on a machine which individually measures the permeability of the core and automatically calculates and winds the correct number of turns.

Loop Equipment Panel

Fig. 14 shows the loop equipment unit (left) and the hub equipment unit. On the back panel of the loop unit is mounted the loop-adjusting rheostats; shaft extensions are used to reach the front panel. The receive relay, option plug, full-duplex half-duplex switch, receive bias control, and closed circuit metering jacks are mounted on the front panel. At the top of the unit is a 24-lug terminal block to which is brought the necessary cabling. Four of the units mount in a shelf, designed to provide sufficient room for cable hinges which permit the units to be withdrawn for inspection without interruption of service.

The card which mounts the transistorized send keyer may be seen on the hub unit in Fig. 13. The front panel of the unit mounts the relay, bias control, and two test points. Hub units mount in the same panel as loop units, but because of the heat generated by the loop unit, the two must not be mounted side by side in a single shelf. Also, hub units must not be mounted directly over loop units. The loop or hub unit is cabled to its associated channel unit with seven conductors.

Conclusions

The *23A* system represents a successful solution to the broad design objectives set forth at the beginning of the paper. Through the use of modern components such as transistors, an improved relay, and modular filters has come a system which is extremely flexible in its application, meets the most rigid performance specifications, and yet is compatible with existing telegraph plant facilities.

A Circular-Polarization Duplexer for Millimeter Waves

R. G. FELLERS
MEMBER AIEE

THIS PAPER describes a circular-polarization duplexer for use in the millimeter (mm) wavelength range. Such a duplexer finds its field of application in any system which utilizes the same antenna for simultaneous transmission and reception, for example, a continuous-wave radar. The mm wavelengths are here defined as covering the range from 1 to 10 mm (frequency range 30,000 to 300,000 megacycles).[1] Much interest has been shown in these frequencies because of the possibility of directive high-gain antennas of small size and because of atmospheric properties peculiar to the mm range such as absorption by oxygen and water vapor.[2–4]

The fact that dominant (TE_{10}) mode rectangular waveguides possess extremely high attenuation in this frequency range has led to a search for alternative means of transmission over within-system distances.[5–8] One possible solution to this intrasystem problem is the use of transmission between two antennas to replace a waveguide run.[9] Dimensions of these antennas may be selected so that they are operating in the Fresnel region and transmission loss much less than that obtainable in the dominant mode waveguide can be achieved. In considering such a free-space system, provision must be made for performing all of the functions which are performed by the waveguide elements in the more conventional arrangement. The circular-polarization duplexer is intended to perform one of the most important of these functions: permitting simultaneous use of the same antenna for transmission and reception.

Duplexer Operation

The operation of the duplexer can best be described by reference to Fig. 1. In this figure a top view of the system is represented showing a vertically polarized transmitter, a horizontally polarized receiver, grating *A*, which is a selective polarization reflector, and grating *B*, which is a

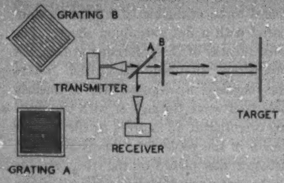

Fig. 1. Duplexer system diagram

device for producing circular polarization. The enlarged views of gratings *A* and *B* at the left of the figure represent the gratings in the normal vertical position as seen from the transmitting side. A vertically polarized wave comes from the transmitter and passes through grating *A* which is so oriented that there is virtually perfect transmission. The wave then passes through grating *B* and emerges circularly polarized. Upon reflection from the target the sense of the circular polarization is reversed and after passing back through grating *B* the wave emerges as a linear horizontally polarized wave which is completely reflected by grating *A* into the receiving horn.

The selective reflector, grating *A*, consists of closely spaced metal slats so oriented that a vertically polarized wave has its electric field normal to the slats and hence passes through with extremely small reflection. The spacing between slats is such that each pair behaves as a waveguide which is well below cutoff at the operating frequency for waves polarized parallel to the slats. As a result it acts as an almost perfect reflector for horizontally polarized waves.

Grating *B* consists of slats which are oriented at 45 degrees with respect to the electric vector of the incoming vertically polarized wave. As indicated in Fig. 2 this wave may be resolved into two components, one with its electric field parallel to the slats and one with its electric field normal to the slats.

The magnitude of each of the components of the wave is 0.707 times the magnitude of the incident field. The component normal to the slats is virtually unchanged by the presence of the grating and passes through at the velocity of a plane wave in free space. The slats serve as a group of parallel waveguides for the field polarized parallel to the slats and this component propagates at the phase velocity for a waveguide of width corresponding to slat spacing. This spacing is selected as 0.280 inch for the operating free-space wavelength of 8.5 mm. The guide wavelength in a guide of this dimension is then 10.61 mm as computed from the well-known relation:

$$\lambda_g=\frac{\lambda}{\sqrt{1-(\lambda/2a)^2}}$$

where

λ = free-space wavelength = 8.5 mm
λ_g = guide wavelength = 10.61 mm
a = slat spacing = 0.280 inch = 7.115 mm

$$\lambda_g=\frac{8.5}{\sqrt{1-(8.5/14.230)^2}}=\frac{8.5}{0.801}$$
$$=10.61 \text{ mm}$$

The dimension of the grating in the direction of propagation, which corresponds to the waveguide length, was selected as 10.61 mm which is exactly one guide wavelength and 10.61/8.5 = 1.25 free-space wavelengths. With these dimensions the component parallel to the slats emerges from the grating advanced in phase by 1/4 free-space wavelength or 90 degrees in phase with respect to the component normal to the slats.

This grating has then produced two components oriented perpendicular to each other and 90 degrees out of time phase which constitutes a circularly polarized wave as described by the equations:

$$E_x=0.707E_0\cos(\omega t-\beta z+90°)$$

$$E_y=0.707E_0\cos(\omega t-\beta z)$$

with reference to the co-ordinate system of Fig. 2, the positive *z*-axis being directed into the paper. The electric vector in this circularly polarized wave may be regarded as rotating in the clockwise direction as viewed looking in the direction of propagation

Upon reflection from the plane, almost perfectly conducting target, the expressions for the field components become:

$$E_x=-0.707E_0\cos(\omega t+\beta z+90°)$$

and

$$E_y=-0.707E_0\cos(\omega t+\beta z)$$

This represents a wave propagating in the negative *z*-direction with the electric vector rotating counter clockwise as viewed looking in the direction of propagation which is now away from the target.

When this wave again reaches the polarizing grating, the component of field along the *x*-axis is still parallel to the grating slats and, on passing through the grating, is advanced by an additional 90 degrees with respect to the component of field along the *y*-axis.

After passing through the grating the components are represented by the equations:

$$E_x=-0.707E_0\cos(\omega t+\beta z+180°)$$
$$=0.707E_0\cos(\omega t+\beta z)$$

and

$$E_y=-0.707E_0\cos(\omega t+\beta z)$$

In these equations β is the propagation constant measured in radians per meter and ω is the angular frequency measured in radians per second.

These components can now be recombined to represent a horizontally polarized wave as indicated in Fig. 2. This wave is then completely reflected from grating *A* into the receiver which is polarized to receive only horizontally polarized waves.

This device accomplishes the duplexing operation with no loss in power due to the action of the duplexer itself. The field components are recombined to yield a horizontally polarized field, equal in strength to the transmitted vertically polarized field, except, of course, for the decrease in amplitude resulting from traveling to the target and back which is inherent in any system of this sort.

Experimental Results

Experimental evaluation of the duplexer system was carried out with the arrangement indicated in Fig. 1 using the apparatus shown in Fig. 3.

All experimental work was done at a frequency of 35,300 megacycles which corresponds to a wavelength of about 8.5 mm. A Raytheon *QK 291* reflex klystron was employed as the radio-frequency oscillator with an appropriate power supply, square-wave-modulated at 1,000 cycles. The detectors used were type *1N53* crystals in properly designed mounts. The square-wave output of these detectors was amplified by low-noise amplifiers tuned to 1,000 cycles and dis-

played on a conventional meter after rectification of the amplified 1,000-cycle signal.

All relative power measurements were made with a Polytechnic Research and Development Company calibrated attenuator type *192F1* with a presumed accuracy of 0.2 db (decibel). In order to eliminate crystal law and amplifier nonlinearity, power levels were adjusted to the same value by adjusting the attenuator and differences in level were obtained from the attenuator calibration. For example, in measuring transmission loss, the crystal detector was connected to the transmitter and the attenuator set at some high value of attenuation to produce a convenient meter reading on the output of the amplifier. The detector was then moved to the receiver and the attenuator readjusted to yield the same meter reading as that obtained when it was connected to the transmitter. The difference in attenuator settings then provides the value of the transmission loss and all system inaccuracies except those in the attenuator are eliminated. Output power from the oscillator was maintained constant by use of a directional coupler power monitor and a second adjustable attenuator.

The reflector grating *A* was approximately 1 foot square and was constructed of brass strips 0.020 inch thick and 0.200 inch wide with a spacing of 0.100 inch. Polarizing grating *B* was constructed of brass strips 0.020 inch thick and 0.418 inch wide with a spacing of 0.280 inch. Fig. 4 shows the gratings. The horns used for transmission and reception had aperture dimensions of 2.925 by 2.132 inches and were 25.6 inches long. A sheet of aluminum sufficiently large to intercept virtually all of the antenna beam was used as a target. Reflections from floor and surrounding objects were eliminated by properly disposed absorptive material.

As a prelude to evaluating the performance of the duplexer system as a whole, essential characteristics of various components were measured.

Transmission loss through the reflector grating *A* was measured with the electric field polarized normal to the grating slats and was found to be negligible (<0.1 db). Loss on reflection from this grating was measured with the electric field polarized parallel to the grating slats and was found to be negligible (<0.1 db) as compared with a flat aluminum sheet. The effectiveness of the polarizing grating for producing circularly polarized waves was checked by transmitting a linearly polarized wave through it with the grating oriented at 45 degrees to the electric vector in the wave. A linearly polarized detector was placed on the receiving side of the grating and relative received power level was measured as function of angle between the polarization of the detector and the vertical. For full 360-degree rotation of the detector, the variation in received signal was less than 0.3 db from maximum to minimum, indicating very good achievement of circular polarization.

The duplexing system was then arranged in operating position as shown in Fig. 1 and the target was replaced by absorptive material to permit measurement of transmitter power which reaches the receiver due to imperfections in the duplexer. Isolation in the original setup was found to be about 30 db. A matching device which was designed and attached to the grating increased this figure to about 50 db.

Experimental operation of the duplexer system was then carried out. In view of the characteristics of the component parts no difficulty was expected and none was encountered. The duplexer operated as predicted with the aluminum plate as a target and very little loss (≤ 0.5 db) due to the duplexer was detected. This was ascertained by comparison with measurements taken using transmitter and receiver horns side by side at the same distance from the target as that used in the duplexer operation and by direct transmission measurements between transmitter and receiver horns at twice this distance.

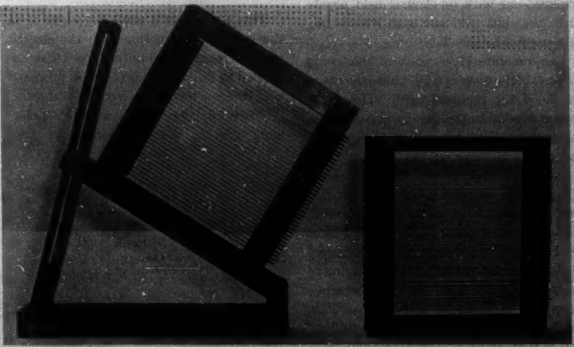

Fig. 4. Reflector and polarizing gratings

Conclusions

From the foregoing results it is clear that a circular-polarization duplexer designed according to the principles of this paper functions as predicted with very small duplexer loss. This is an advantage as compared with the magic-T or hybrid-junction continuous-wave duplexer which has an inherent 6-db loss.

It might be contended that a plane target is very improbable and that the return signal would not be circularly polarized and that this would result in some loss. This is a valid criticism but one which is also applicable to linearly polarized systems. Any target may have characteristics which yield reflected signals of different polarization than those incident upon it. To explore this question fully, it would be necessary to accumulate extensive data on the reflection properties of typical targets for incident radiation of various polarizations.

A free-space mm wave transmission system including a duplexer as described is most likely to find application in the use of extremely short wavelengths (1 to 3 mm) where the physical size of the components is small. It can be used in a radar system as described here or in a communications system in which both transmitting and receiving antennas produce circular polarization.

Conducting Sphere in Alternating Magnetic Fields

H. PORITSKY
MEMBER AIEE

THE FIELD DISTURBANCE produced by a conducting metallic body in an alternating magnetic field is of interest from several points of view, for instance in connection with eddy-current losses, induction heating, and in high-speed rotation of a sphere induced by a revolving field. Again, the location of a hidden metallic body, a problem met in a number of industries, is often carried out by producing an alternating magnetic field and detecting the presence of the body from the field distrubance produced by it.

In this paper an analysis is carried out of the field disturbance produced by a conducting sphere placed in a uniform alternating magnetic field. The electromagnetic oscillations of a dielectric sphere have been discussed by J. J. Thompson.[1] The following solution was obtained by the author in an unpublished paper in 1948, and has since appeared in the literature.[2] For this reason, its derivation will be reviewed very briefly.

By using a complex permeability, $\mu=\mu_0\epsilon^{-j\delta}$, one may take approximate account of magnetic hysteresis.

The disturbance produced by an oblong body of rotational symmetry is also briefly discussed.

Field Solution

The conducting sphere of radius a, permeability μ, and resistivity ρ in ohm-cm (centimeter), is placed so that its center is at the origin, and axes chosen so that the z-axis is parallel to the applied, uniform alternative field, of frequency f. In addition to the rectangular co-ordinates and their unit vectors $\mathbf{i}$, $\mathbf{j}$, $\mathbf{k}$, also introduced are cylindrical co-ordinates r, φ, z with unit vectors $\mathbf{i}$, $\mathbf{i}_\varphi$, $\mathbf{k}$ in directions of increasing r, φ, z, and spherical co-ordinates R, θ, φ, and vectors $\mathbf{i}_R$, $\mathbf{i}_\theta$, $\mathbf{i}_\varphi$, where

$$x=r\cos\varphi,\quad y=r\sin\varphi \tag{1}$$

$$\cos\theta=z/R,\quad R^2=r^2+z^2 \tag{2}$$

Time is assumed to enter as a factor

$$\epsilon^{j\omega t},\ \omega=2\pi f,\ j=\sqrt{-1} \tag{3}$$

where f is the frequency, but generally this factor is omitted.

Upon neglecting displacement currents, Maxwell's equations become, in practical centimeter-gram-second units

$$\nabla\times\mathbf{H}=0.4\pi\mathbf{I}=0.4\pi\sigma\mathbf{E}$$

$$\nabla\times\mathbf{E}=-10^{-8}j\omega\mu\mathbf{H}$$

$$\nabla\cdot(\mu\mathbf{H})=0,\ \Delta\cdot(\mathbf{E})=0 \tag{4}$$

where $\mathbf{E}$ is in volts/cm, $\mathbf{I}$ the current density vector, and $\sigma(=1/\rho)$ the conductivity. Elimination shows that the $\mathbf{E}$, $\mathbf{H}$ vectors, as well as their scalar Cartesian components, satisfy the differential equation

$$\nabla^2u=\alpha^2u \tag{5}$$

where

$$\alpha^2=4\pi\omega\sigma\mu\,10^{-9}j,\ \alpha=(1+j)\beta,\qquad \beta=2\pi\sqrt{f\sigma\mu\,10^{-9}} \tag{6}$$

From equation 5, it is evident that α (and hence also β) are of dimensions 1/length; $1/\beta$ is called the "depth of penetration" of the material at the frequency in question, since the solution of equation 5

$$u=\epsilon^{-\alpha y}=\epsilon^{-j\beta y}\,\epsilon^{-\beta y} \tag{7}$$

shows that a uniform plane parallel (magnetic) field penetrating a semi-infinite solid $y>0$, decays as $\epsilon^{-\beta y}$.

In free space $\mu=1$, $\sigma=0$. The first Maxwell equation 4 yields

$$\nabla\times\mathbf{H}=0 \tag{8}$$

while equation 5 reduced to the Laplace equation

$$\nabla^2u=0 \tag{9}$$

Solutions of equation 9 in spherical co-ordinates are given by

$$R^nY_n(\theta,\varphi),\ Y_n(\theta,\varphi)/R^{n+1} \tag{10}$$

Paper 59-1102, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted November 5, 1958; made available for printing July 3, 1959.

H. Poritsky is with the General Electric Company, Schenectady, N. Y.

where R^nY_n is a homogeneous polynomial of degree n in x, y, z, and Y_n is a "surface spherical harmonic" of degree n; it can be represented as a linear combination of

$$(\cos m\varphi,\ \sin m\varphi)P_n^{(m)}(\cos\theta),\quad m\leqq n \tag{11}$$

where $P_n^{(m)}$ are the "associated" Legendre functions.

Inside the conducting sphere, similar pertinent solutions of equation 5 are given by

$$Y_nS_n(\rho),\quad \rho=\alpha R \tag{12}$$

where S_n satisfy the differential equation

$$\frac{d^2S_n}{dR^2}+\frac{R}{2}\frac{dS_n}{dR}-\frac{n(n+1)}{R^2}S_n+\alpha^2S_n=0 \tag{13}$$

Solutions of equation 13 for $n=0, 1, \ldots, n$, which are analytic at $R=0$ are given by[1]

$$\left.\begin{aligned} S_0&=\frac{\sinh\rho}{\rho}\\ &\vdots\\ S_n&=\rho^n\left(\frac{1}{\rho}\frac{d}{d\rho}\right)^n\left(\frac{\sinh\rho}{\rho}\right)\end{aligned}\right\}\rho=\alpha R \tag{14}$$

and S_n may be also expressed in the form

$$R^{-1/2}J_{n+(1/2)}(\rho) \tag{15}$$

since equation 13 may be converted to a Bessel differential equation of order $n+(1/2)$ for the function $R^{1/2}S_n$.

Field Solution for Sphere

Let the applied alternating uniform magnetic field pointing in the z-direction be

$$\mathbf{H}=H_0\mathbf{k} \tag{16}$$

(The exponential factor in equation 3 is implied.) It is evident that the complete field will be symmetric about the z-axis. Indeed, integration of the second Maxwell equation 4 for this $\mathbf{H}$ yields as a possible electric field

$$E=(Cy\mathbf{i}-Cx\mathbf{j})=-Cr\mathbf{i}_\varphi,\quad C=j\omega10^{-8}H_0/2 \tag{17}$$

with the electric lines of force running in circles about the z-axis.

The scalar x, y components in equation 17 are of the form R^nY_n with $n=1$, and

$$Y_1=\left(\frac{y}{R},\frac{-x}{R}\right)=(\sin\theta\sin\varphi,\ -\sin\theta\cos\varphi) \tag{18}$$

It turns out possible to complete the field solution including the eddy currents, with the same Y_1 by putting

$$\mathbf{E}=C\left(\frac{y}{R},\frac{-x}{R},0\right)\left(R+\frac{A}{R^2}\right),\quad R\geqq a \tag{19}$$

outside the sphere, and

$$\mathbf{E}=C\left(\frac{y}{R},\frac{-x}{R},0\right)BS_1(\rho),\quad R\leqq a \tag{20}$$

inside the sphere.

These equations imply that in cylindrical components $\mathbf{E}$ reduces to $E_\varphi\mathbf{i}_\varphi$ where E_φ is independent of φ

$$\mathbf{E}=E_\varphi\mathbf{i}_\varphi=-C\sin\theta\left(R+\frac{A}{R^2}\right)\mathbf{i}_\varphi,\quad R\geqq a \tag{21}$$

$$\mathbf{E}=\mathbf{E}_\varphi\mathbf{i}_\varphi=-C\sin\theta\,BS_1(\alpha R)\mathbf{i}_\varphi,\quad R\leqq a \tag{22}$$

The constants A and B are now to be determined so that the tangential components of $\mathbf{H}$ and $\mathbf{E}$ are continuous at the spherical boundary $R=a$.

Making the magnitude E_φ continuous at $R=a$, one obtains

$$a+\frac{A}{a^2}=BS_1(\alpha a) \tag{23}$$

Upon making H_θ along $R=a$ continuous, one is led to

$$\frac{d}{dR}\left(R^2+\frac{A}{R}\right)=\frac{1}{\mu}\frac{d}{dR}BRS_1(\alpha R)\quad\text{for } R=a \tag{24}$$

Solving for A there results

$$A=a^3\frac{(2\mu-1)-F(\alpha a)}{(\mu+1)+F(\alpha a)} \tag{25}$$

where

$$F(\alpha a)=\frac{(\alpha a)S_1'(\alpha a)}{S_1(\alpha a)}=\frac{-2(\alpha a)+[(\alpha a)^2+2]\tanh(\alpha a)}{(\alpha a)-\tanh(\alpha a)} \tag{26}$$

From the second Maxwell equation 4 and equation 19, one may solve for $\mathbf{H}$. For $R>a$ it turns out that the resulting magnetic field is derivable from a scalar potential V

$$\mathbf{H}=\Delta V,\quad R\geqq a \tag{27}$$

where

$$V=H_0\left(z-\frac{Az}{2R^3}\right)=H_0P_1(\cos\theta)\left(R-\frac{A}{2R^2}\right) \tag{28}$$

Indeed, the existence of a scalar potential for $\mathbf{H}$ for $R>a$ follows from equation 8.

It can be verified that for all R, the magnetic field $\mathbf{H}$ also possesses a flux function f which is axially symmetric and such that

$$\mu\mathbf{H}r=\nabla'f \tag{29}$$

where

$$\nabla'=\mathbf{i}_r\frac{\partial}{\partial z}-\mathbf{k}\frac{\partial}{\partial r}=\mathbf{i}_\theta\frac{\partial}{\partial R}-\mathbf{i}_R\frac{\partial}{R\partial\theta}$$

and f is given by

$$f=j(10^8/\omega)rE_\varphi \tag{30}$$

This can also be inferred from the emf (electromotive-force) law, applied to the circles of constant r and z, since

$$\psi=2\pi f \tag{31}$$

is the magnetic flux linking them.

The potential

$\gamma=1$, $\mu=10\ (1-3j)$, $\Delta\psi/\psi_0=1.51530-0.196443j$.

$$-2H_0A\ \frac{z}{R^3} \tag{32}$$

which is added to H_0z, the potential of the initial applied field, will be recognized as the potential of a magnetic dipole of moment

$$M=-2AH_0 \tag{33}$$

placed at the origin, with its axis in the z-direction. It is easy to verify that the same net external field results if the sphere is replaced by a (nonconducting) sphere of radius a, magnetized in the z-direction, to a uniform flux density

$$B_z=H_0\left(1+\frac{4A}{a^3}\right) \tag{34}$$

Flux Increase Over Equatorial Plane

The increase in flux $\Delta\psi$ over the equatorial plane $r=a$, $z=0$ of the sphere, as a fraction of the initial flux ψ_0 passing through the equator in absence of the sphere will now be calculated.

Equations 21, 25, 30, 31 yield

$$\frac{\Delta\psi}{\psi_0}=\frac{\Delta E}{E_0}=\frac{A}{a^3}=\frac{2\mu-1-F(\alpha a)}{\mu+1+F(\alpha a)}=\xi+j\eta \tag{35}$$

where ξ is the real part, η the imaginary part of $\Delta\psi/\psi_0$.

As a limiting case consider $\omega\rightarrow\infty$. Now $|\alpha a|$ is large numerically, tanh $(\alpha a)=1$, thus reducing $F(\alpha a)$ to $|\alpha a|$ and $\Delta\psi/\psi_0$ to -1. This means that the increase in flux is -100%, corresponding to zero net flux crossing the region occupied by the sphere. This is due to the pronounced skin effect which keeps the flux away from the interior of the sphere.

It will be noted that large μ keeps the limit -1 from being reached even when $|\alpha a|$ is large, until $|\alpha a|$ is larger than μ. Apparently, even with a pronounced skin effect and thin penetration, a fair amount of flux may crowd into the skin layer if its permeability is large.

As a further limiting case, consider the other extreme of very complete flux penetration, or small $|\alpha a|$. We now obtain from equations 26 and 35, on expanding the hyperbolic functions in powers of $\alpha a=\rho$,

$$F(\alpha a)=\frac{\rho^2\left(\frac{1}{3}\right)+\dots}{\rho^2\left(\frac{1}{3}\right)+\dots}=1+\dots \tag{36}$$

and equation 35 yields

$$\frac{\Delta\psi}{\psi_0}=\frac{2\mu-2}{\mu+2} \tag{37}$$

This agrees with the flux increase for the d-c field case. In particular, for $\mu=\infty$ there results $\Delta\psi/\psi_0=2$, leading to the well-known result that the net flux through the sphere is three times the flux crossing the space occupied by the sphere previous to its introduction.

As a numerical example consider

$$\mu=1$$

$$1/\sigma=60\ 10^{-6}\ \text{ohm-cm}$$

$$a=1\ \text{cm}$$

$$\alpha a=(1+j)$$

Since $a=1$, $\alpha=1+j$, $\alpha^2=2j$ there follows

$$\alpha^2=j4\pi\mu\omega\sigma10^{-9}=2j$$

$$\omega=\frac{2}{4\pi\sigma10^{-9}}$$

$$=\frac{2(60)10^{-6}}{12.6\ 10^{-9}}=9{,}530$$

this corresponds to a frequency of 1,516.

The calculation of the disturbance in the field proceeds as follows

$$\tanh\,(\alpha a)=\tanh\,(1+j)$$

$$=\frac{\tanh 1.0+j\tan 1.0}{1+j\tanh 1.0\tan 1.0}$$

$$=\frac{0.7616+j1.5574}{1+j0.7616(1.5574)}$$

$$=\frac{0.7616+j1.5574)(1-j1.187)}{1+1.408}$$

$$=1.084+j0.271$$

$$F(\alpha a)=\frac{(a\alpha)S_1'}{S_1}=\frac{((\alpha a)^2+2)\tan(\alpha a)-2(\alpha)a}{\alpha a-\tanh\,(\alpha a)}$$

$$=\frac{(2j+2)(1.084+j0.271)-2(1+j)}{(1+j)-(1.084+j0.271)}$$

$$=\frac{2(1+j)(0.084+j0.271)}{-0.084+j0.729}=1.018+j0.396$$

Substitution in equation 35 yields

$$\frac{\Delta\psi}{\psi_0}=\frac{(2-1)-F(\alpha a)}{1+1+F(\alpha a)}=\frac{1-1.018-j0.396}{2+1.018+j0.396}$$

$$=\frac{0.018+j0.396}{3.018+j0.396}$$

$$=-\frac{(0.018+j0.396)(3.018-j0.396)}{9.12+0.1568}$$

$$=-0.0227-j0.128$$

Calculations of $\xi+j\eta=\Delta\psi/\psi_0$ were carried out for various values of γ in

$$(\alpha a)=(1+j)\gamma,\ \gamma=\beta a \tag{38}$$

and various values of μ. The results are shown on Fig. 1 in the complex $(\xi+j\eta)$-plane. As will be noted, the points are plotted for fixed values of μ and varying values of γ, and for fixed values of γ and varying values of μ. It will be noted from equation 35 that for fixed γ, and hence fixed αa, the variable $\xi+j\eta$ is linear rational in μ. Hence for fixed γ, as μ varies, the locus of $\xi+j\eta$ may be shown to describe an arc of a circle passing through the points $\xi+j\eta=-1$ (for $\mu=0$) and $\xi+j\eta=2$ (for $\mu=\infty$).

The values of $\Delta\psi/\psi_0$ are also displayed in Table I.

Detection of Sphere by Means of Circular Coils

Consider a circular coil of radius b, placed as in Fig. 2, in the plane $z=d$, so that its center is $(0, 0, d)$. The fractional change in the induced emf in the coil, due to the introduction of the sphere, may be found from the fractional increase in the flux linkage of the coil, $\Delta\psi_1/\psi_1$. Equations 21, 30, 31, 35 yield

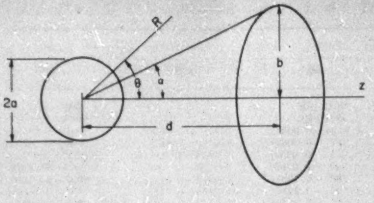

Fig. 2 (left). Sphere and detecting coil

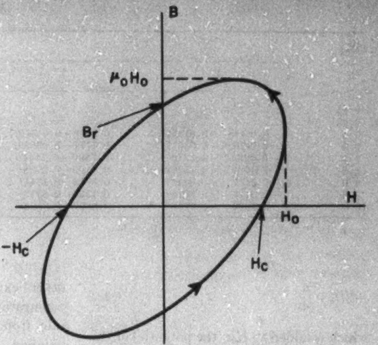

Fig. 3 (right). Elliptic hysteresis loop

$$\Delta\psi_l=\pi H_0\frac{a^3b^2(\xi+j\eta)}{(b^2+d^2)^{3/2}} \tag{39}$$

and hence

$$\frac{\Delta\psi_l}{\psi_l}=\frac{a^3(\xi+j\eta)}{(d^2+b^2)^{3/2}} \tag{40}$$

Suppose next that the coil axis, while passing through the sphere center, makes an angle ζ with the initial field direction. The initial flux linked by the coil is evidently reduced by a factor cos ζ. It may be shown that the change in the flux (linkage) due to the sphere is reduced in the same ratio. Hence equation 40 still applies.

The magnetic field of the dipole of the moment M given by equation 33 can also be produced by a current I' flowing in c', a circular coil $r=\epsilon$, $z=0$ where ϵ is small and

$$M=(0.4)\pi I'\pi\epsilon^2 \tag{41}$$

Hence the calculation of the flux $\Delta\psi$ for any coil C' can be reduced to the calculation of the mutual inductance of C', c'. This applies to any shape and orientation of C'. By a well-known reciprocity relation, this calculation may be reduced to the calculation of the field component H_z at the origin, due to a current flowing in C'.

If the initial field is itself caused by NI ampere turns in a coil of radius a' at a large distance d' from the center of the conductor sphere, then if a'/d' is small, the initial field is very nearly constant over the area of the sphere, and is given by

$$H_0=\frac{2NI\pi a'^2}{10d'^3} \tag{42}$$

Calculation of Losses

The losses caused by the eddy currents in the sphere may be found by integration of $|E_\varphi^2|/2\rho$ over the volume of the sphere, or by integration of the normal component of the Poynting vector over a surface enclosing the sphere. They may also be obtained from the induced emf in a "primary" coil which is used to generate the "initial" or "applied" field $H_0\mathbf{k}$. The last method is considered.

Assume that the initial field is generated by a "primary" current J in a very long solenoid S of radius $b>a$, with axis along the z-axis, and with N turns per unit z, where

$$(0.4)\pi NJ=H_0 \tag{43}$$

The additional linkage in the primary coil turn at z, due to the introduction of the sphere, may be found from equation 39, and is given by

$$\frac{\pi H_0a^3b^2(\xi+j\eta)}{(b^2+z^2)^{3/2}} \tag{44}$$

yielding for the whole solenoid

$$\Delta\psi_s=N\pi H_0a^3b^2(\xi+j\eta)\int_{-\infty}^{+\infty}\frac{dz}{(b^2+z^2)^{3/2}}$$

$$=N\pi H_02a^3(\xi+j\eta) \tag{45}$$

This leads to a net (added) induced emf

$$\Delta(\text{emf})=-j\omega10^{-8}\Delta\psi_S \tag{46}$$

From point of view of the primary circuit, the sphere is equivalent to a series impedance

$$Z=-\frac{\Delta(\text{emf})}{J}=j8\pi^2N^2\omega10^{-9}a^3(\xi+j\eta) \tag{47}$$

as if an added inductance

$$\Delta L=8\pi^2N^210^{-9}a^3\xi \text{ henry} \tag{48}$$

and a resistance

$$R=-8\pi^2N^210^{-9}\omega a^3\eta \text{ ohm} \tag{49}$$

were inserted in series with the solenoid coil. The net losses are

$$W=J^2R/2=25H_0^2a^3\omega(-\eta)10^{-7} \text{ watts} \tag{50}$$

Rotating Magnetic Field

Replacing the steady (pulsating) applied or initial field, equation 16 by a field rotating in the y-, z-plane.

The rotating field may be resolved into two pulsating stationary fields, 90 degrees out of phase, as described by

$$H=H_0(\mathbf{k}+j\mathbf{j}) \tag{51}$$

Applying superposition, the field for a stationary sphere is calculated, as a result of the added component $jH_0\mathbf{j}$, from equations 19, 20, 32–35 by proper permutation of the x, y, z co-ordinates and field components, and multiplication by j.

In particular it will be found that the losses are $2W$ where W is given by equation 50.

The torque exerted on the sphere may be obtained by integrating the moments of the interaction forces of **H** and the currents in proper solenoids, or from stresses $H^2/8\pi$ along and across tubes of force. Consideration of the latter shows that one may replace the sphere by proper dipoles and calculate the reactions on them. Noting equation 33 and replacing A by $a^3(\xi+j\eta)$ one has a dipole of moment

$$\mathbf{M}=-2AH_0(\mathbf{k}+j\mathbf{j})=2a^3H_0(\xi+j\eta)(\mathbf{k}+j\mathbf{j}) \tag{52}$$

Recalling the factor $\epsilon^{j\omega t}$ and taking real parts

$$M_x=0$$

$$M_z=2a^3H_0(-\xi\cos\omega t+\eta\sin\omega t)$$

$$M_y=2a^3H_0(\eta\cos\omega t+\xi\sin\omega t) \tag{53}$$

Equation 51 yields for the "real" initial field

$$H_x=0,\ H_y=-H_0\sin\omega t,\ H_z=H_0\cos\omega t \tag{54}$$

At the time $t=0$, the dipole of moment $2a^3H_0\sqrt{\xi^2+\eta^2}$ makes an angle $\tan^{-1}\eta/\xi$ with the negative z-axis. The field $H_z=H_0$ produces on it a torque

$$T=2H_0a^3\eta \text{ dynes} \tag{55}$$

about the positive x-axis. The same torque results for any t.

Sphere in Field of a Circular Coil

As a more complex example utilizing the solutions 10–15 for all n, the field described in the title is considered.

First consider in free space the "primary" field of a current I flowing in a circular coil. Let the coil be placed so that its axis is the z-axis and its center at $z=d$. Let (see Fig. 2)

$$\alpha=\tan^{-1}(b/d),\quad c=\sqrt{b^2+d^2} \tag{56}$$

be the semivertical angle of the cone subtended by the coil at the origin, and c its distance from the origin. This field of a circular coil in free space, when displacement currents are negligible, as well-known, can be expressed in a finite form involving elliptic integrals. The electric field $\mathbf{E}$ is axially symmetric and consists of a single component $\mathbf{E}=\mathbf{i}_\varphi E_\varphi$, $E_\varphi=E_\varphi(R,\theta)$ only. For the present application the following representation for $\mathbf{E}$ will be used

$$\mathbf{E}=\mathbf{i}_\varphi 2\pi j\omega 10^{-9} I \sin\alpha \sum_{n=1}^{\infty} P_n^{(1)}(\cos\alpha)\, P_n^{(1)}(\cos\theta) \begin{cases} \left(\dfrac{R}{c}\right)^{n} & \text{for } R<c \\ \left(\dfrac{c}{R}\right)^{n+1} & \text{for } R>c \end{cases} \tag{57}$$

where

$$P_n^{(1)}(\mu)=(1-\mu^2)^{1/2}dP_n(\mu)/d\mu \tag{58}$$

Indeed, the terms of equation 57 yield Cartesian field components

$$E_x=-\text{constant } P_n^{(1)}(\cos\theta)\sin\varphi \times (R^n, R^{-(n+1)})$$

$$E_y=\text{constant } P_n^{(1)}(\cos\theta)\cos\varphi \times (R^n, R^{-(n+1)}) \tag{59}$$

which agree with equations 10, and 11 for $m=1$.

The determination of the coefficients in equation 57 is carried out so as to obtain continuity in E at $R=c$ and a proper discontinuity in H_θ corresponding to the current distribution over $R=c$. For details foregoing refer to reference 3.

Now suppose that a conducting sphere of radius a is introduced in the foregoing field, with center at the origin. Inside the sphere $R<a$ the field E_φ may be obtained by superposition of terms

$$P_n^{(1)}(\cos\theta)S_n(\alpha R) \tag{60}$$

while outside this sphere the field E_φ can be represented as a sum of equation 57 and an additional field obtained from terms

$$P_n^{(1)}(\cos\theta)R^{-(n+1)} \tag{61}$$

the coefficients in these solutions are determined so that the net E_φ and H_θ are continuous at $R=a$. There results for E_φ for $R<a$

$$\frac{E_\varphi}{Ij\omega 2\pi 10^{-9}\sin\alpha} \sum_{n=1}^{\infty} \frac{(2n+1)P_n^{(1)}(\cos\alpha)P_n^{(1)}(\cos\theta)(a/c)^n S_n(\alpha R)/S_n(\alpha a)}{n(n+1)[n\mu+1+F_n(\alpha a)]} \tag{62}$$

where

$$F_n(u)=S'_n(u)/uS_n(u) \tag{63}$$

Outside the sphere, for $R>a$, the additional field must be added to the field of the coil in free space, is given by

$$\frac{\mathbf{E}_\varphi'}{Ij\omega 2\pi 10^{-9}\sin\alpha}=\sum_{n=1}^{\infty} \frac{[\mu(n+1)-1-F_n(\alpha a)]P_n^{(1)}(\cos\alpha)P_n^{(1)}(\cos\theta)(a/c)^n(a/R)^{n+1}}{n(n+1)[n\mu+1+F_n(\alpha a)]} \tag{64}$$

The additional induced emf in the circular coil due to the introduction of the sphere can be evaluated from equation 64 and is given by

$$\Delta(\text{emf})=2\pi c\sin\alpha E_\varphi=Ij\omega 10^{-9}2\pi c\sin^2\alpha \sum_{n=1}^{\infty} \frac{[\mu(n+1)-1-F_n(\alpha a)][P_n^{(1)}(\cos\alpha)]^2(a/c)^{2n+1}}{n(n+1)[n\mu+1+F_n(\alpha a)]} \tag{65}$$

Complex Permeability

It is known that by replacing μ by the complex permeability

$$\mu=\mu_0\epsilon^{-j\delta} \tag{66}$$

one may take into account magnetic hystersis, at least in an approximate manner. Indeed, on introducing the factor $\epsilon^{j\omega t}$ and taking real parts of

$$H=H_0\epsilon^{-j\omega t},\quad B=\mu_0H_0\epsilon^{(j\omega t-\delta)} \tag{67}$$

there results in the H,B-plane an elliptic hysteresis loop as shown in Fig. 3, with a "coercive force"

$$H_c=H_0\sin\delta \tag{68}$$

and a retentivity

$$B_r=H_0\mu_0\sin\delta \tag{69}$$

at the intersections with the axes. The area of the ellipse is

$$\int BdH=\pi\mu H_0^2\sin\delta \tag{70}$$

For different H_0, similar ellipses result.

While the ellipses furnish a poor approximation to the shapes of actual hysteresis loops, the advantages of the foregoing procedure lies in the retention of linearity of the field equations.

Substitution of 66 in equation 6 yields

$$\alpha^2=4\pi\sigma\mu_0\epsilon^{-j\delta}\omega 10^{-9}j \tag{71}$$

and it will be seen that α^2 is no longer pure imaginary but makes an angle $-\delta$ with the pure imaginary axis. As a result α is given not by equation 6 but by

$$\alpha=\sqrt{2}\,\epsilon^{j\left(\frac{\pi}{4}-\frac{\delta}{2}\right)}2\pi\sqrt{\mu_0 f\sigma 10^{-9}} \tag{72}$$

Except for this difference the calculation of the field disturbance caused by the sphere in alternating uniform magnetic field or in the field of a coil can be carried out as before. In particular, for a sphere in a uniform field the ratio $\Delta\psi/\psi_0=(\xi+j\eta)$ can be computed in the same manner. Both ξ and η will be affected by the introduction of δ.

As an example consider for the uniform field the case $\gamma=1$, $\mu=10(1-0.3j)$ so that $\delta=\tan^{-1}0.3=16.6992$ degrees. There results

$$\begin{aligned} \alpha a &=(1+j)\gamma\epsilon^{-j\delta/2} \\ &=\sqrt{2}\gamma\epsilon^{j\left(\frac{\pi}{4}-\frac{\delta}{2}\right)} \\ &=(1.1346+j0.8442)\gamma \end{aligned} \tag{73}$$

Letting $\gamma=1.00$, $\mu=10-3j$, $=10(1-0.3j)$, one obtains

$$\frac{\Delta\psi}{\psi_0}=1.5153-0.1964j$$

These values are included in Table I.

This is to be compared with the corresponding value $\Delta\psi/\psi_0=1.4923-0.0846j$ in absence of hysteresis, for $\mu=10$, $\gamma=1$.

Conducting Bodies of Nonspherical Shape

The calculation of the disturbance produced in an alternating magnetic field by the presence of conducting bodies of shape other than spherical is naturally more complicated, and only a few general remarks regarding it will be made.

Consider an oblong, axially symmetric body, say a prolate spheroid of semiaxes a, b, b. Resolve the initial field along the axis of symmetry and at right angles. If the long dimension is sufficiently long, one may as a first approximation, consider it infinitely long. The eddy currents for an infinitely long cylinder of radius a, both for a field parallel to its axis, and for a field, normal to its axis, can be solved. In the former case, for an applied field $H_0 \epsilon^{j\omega t}$, the net flux is given by

$$\frac{\Delta\psi}{\psi_0}=\frac{(\alpha a)I_0(\alpha a)}{2I_1(\alpha a)} \tag{74}$$

where $\psi_0=\pi a^2H_0$, and I_0, I_1 are the familiar Bessel functions of pure imaginary argument. For a field $H_0\epsilon^{j\omega t}$ normal to the cylinder axis the induced field is given by

$$\frac{E}{j\omega 10^{-8}H_0}=\cos\theta\,\frac{2aI_1(\alpha r)}{\dfrac{\alpha a}{\mu}I_0(\alpha a)+\left(1-\dfrac{1}{\mu}\right)I_1(\alpha a)}$$

where r, θ are polar co-ordinates in a plane normal to the axis and containing direction of the field H_0.

Actually the latter solution will apply for prolate ellipses even if a/b is not infinite; the former, however, has to be corrected, especially if μ is large. In the well-known solution of the (d-c) magnetization of an ellipsoid by means of a field parallel to its long axis, a high concentration of flux is obtained. This effect persists even with eddy currents, when the reluctance of the skin layer is appreciably smaller than that of the surrounding space.

A more exact treatment of the ellipsoid must be carried out, of course, by solving the field equations within the ellipsoid and outside it. This solution of these equations involves ellipsoidal harmonics and Mathieu functions, and falls outside the scope of the present paper.

Effects of Nonlinearity on Propagation in Ionized Media

GEORGE I. COHN
MEMBER AIEE

THE PRESENCE of an ionized media in the neighborhood of radio communication systems can degrade performance by:

1. Insertion of attenuation and distortion in each channel.
2. Interference between channels caused by generation of harmonics and sum and difference frequencies.

This paper is concerned with the nonlinear effects of the media on the propagating signal. These nonlinear effects constitute the interference signals. Under certain conditions extremely small nonlinear effects can produce significant interference signals. For example, consider here a 1-kw transmitter at one frequency and a receiver capable of detecting 1 micromicrowatt tuned to one of the nonlinearly generated frequencies; a difference of 15 orders of magnitude results. Even if the nonlinearity of the media is so slight that only a millionth of a millionth of the transmitter power is converted to the frequency the receiver is tuned to a tremendous interference signal may result under appropriate conditions of proximity.

The development presented here is restricted to a plane polarized wave propagating through a media which in the absence of electromagnetic fields is homogeneous. An additional restriction is that there are no electric or magnetic fields present which are not directly caused by the propagating wave under consideration. In a practical situation these restrictions will probably not prevail with a consequent considerable change in the phenomena taking place.

Separation of Macroscopic and Microscopic Phenomena

The analysis is divided into two parts:

1. Determination of the macroscopic propagation phenomena in a nonlinear media with the constitutive parameters expressed in a generalized form suitable for a wide variety of nonlinear media.
2. Determination of the constitutive parameters for the ionized media of interest.

This method of subdivision not only makes the analysis more tractable, but also makes it more general in that any restrictions introduced in one part do not cause a corresponding loss of generality in the results of the other part.

There are various ways to interpret Maxwell's equations

$$\nabla\times\mathbf{E}=-\partial_t\mathbf{B} \tag{F1}$$

$$\nabla\times\mathbf{H}=+\mathbf{i}\partial_t\mathbf{D} \tag{A1}$$

$$\nabla\cdot\mathbf{D}=\rho \tag{1}$$

$$\nabla\cdot\mathbf{B}=0 \tag{2}$$

(Important equations which undergo many modifications but essentially conserve their identity throughout a substantial portion of their analysis will be designated by means of a letter followed by a number. The letter is chosen for its mnemonic value, such as: F for Faraday's law and A for Ampere's law. The number indicates the particular form. This equation labeling scheme facilitates keeping track of the development.) The two extreme points of view suitable respectively for the two subdivisions of the problem are discussed in the following.

MAXWELL'S MACROSCOPIC PHENOMENOLOGICAL VIEW

This view, fathered by Maxwell, presents a scientific description of the observable macroscopic (compared with the atomic constituents of the media) phenomena. What is happening to the fundamental charged particles composing the media in which the phenomena are taking place is not described in this view. This phenomenological theory accounts for the influence of the media, i.e., the fundamental particles composing the media, by means of factors called constitutive parameters, μ, ϵ and σ, which relate the fields in the manner

$$\mathbf{B}=\mu\mathbf{H} \tag{3}$$

$$\mathbf{D}=\epsilon\mathbf{E} \tag{4}$$

$$\mathbf{i}=\sigma\mathbf{E} \tag{5}$$

in isotropic media. It is convenient to

Paper 59-1145, recommended by the AIEE Communication Theory Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted April 3, 1959; made available for printing August 13, 1959.

GEORGE I. COHN is with the Illinois Institute of Technology, Chicago, Ill.

This research was supported in part by the U. S. Air Force, through Wright Air Development Center Communication and Navigation Laboratory via Cook Research Laboratories Division of Cook Electric Company.

express the constitutive parameters in the factored form

$$\mu=\mu_r\mu_v \tag{6}$$

$$\epsilon=\epsilon_r\epsilon_v \tag{7}$$

where μ_v and ϵ_v are the permeability and capacitivity of vacuum, whereas μ_r and ϵ_r are the relative permeability and capacitivity of the media with respect to vacuum. A consequence of the view which deserves explicit statement is that for the charge density appearing in equation 1

$$\rho=\text{free charge density only} \tag{8}$$

The effect on the field because of the equal numbers of oppositely charged bound particles constituting the media is accounted for by the relative capacitivity ϵ_r. The effects on the fields because of the motions of the charges constituting the media are taken into account in three ways:

1. The motion of the unbound charges is subsumed in the conduction current by means of the conductivity σ.
2. The translatory motion of the bound charges is subsumed in the electric displacement field by means of the relative capacitivity ϵ_r.
3. The rotational motion of the constituent charges is subsumed in the magnetic induction field by means of the relative permeability μ_r.

LORENTZ'S MICROSCOPIC EXHAUSTIVE VIEW

This view, generated by Lorentz, attempts to present an exhaustive description of all electrical phenomena in terms of the elementary positive and negative charges constituting the media. The microscopic description dispenses with the solid-material media concept and instead considers matter only as an aggregate of positive and negative charges (which actually constitute the media) in free space. The microscopic view does not see the forest (material media) for the trees (constituent positive and negative charges). Contrast this with the macroscopic view which does not see the trees (constituent positive and negative charges) for the forest (material media). In the microscopic view electromagnetic fields are still related by the same set of Maxwell's equations F1, A1, 1, 2, but since the view does not encompass material media but only charges in vacuum it is necessary to replace the auxiliary relations 3 and 4 by

$$\mathbf{B}=\mu_v\mathbf{H} \tag{9}$$

$$\mathbf{D}=\epsilon_v\mathbf{E} \tag{10}$$

and to replace the charge density appearing in equation 1 by

$$\rho=\text{total charge density} \tag{11}$$

and to replace the current density relation 5 by

$$\mathbf{i}=\sum_k n_k q_k \mathbf{u}_k \tag{12}$$

where n_k is the number of particles per unit volume having a charge q_k and a velocity $\mathbf{u}_k$.

Maxwell's equations relate the fields to the charges and currents. In the microscopic point of view the currents are in turn related to the motions of the charges. Since the charge motions are unknown it is necessary to add Lorentz's dynamical equation of motion which in turn relates these motions to the fields

$$\frac{dm_k\mathbf{u}_k}{dt}=q_k[\mathbf{E}+\mathbf{u}_k+\mathbf{B}] \tag{13}$$

The set of equations F1, A1, 2, 3, and 9–13 must be solved simultaneously for the dynamical behavior of the charges. From this information the phenomenological theory of the description can be obtained. It should be pointed out that Lorentz's microscopic theory does not meet with complete success because it does not encompass within its framework the quantum mechanical laws obeyed by the microscopic constituents. However, in many cases, particularly where the charge density is not too great as in electron beams and ionized gases the microscopic theory of Lorentz meets with considerable success. In the macroscopic phenomenological view, solution for the behavior of the charged particles is obviated because these quantities do not explicitly occur in the formulation.

Subsumption of the dynamical behavior of the constituent charged particles by means of the constitutive parameters is of immense practical importance in a wide variety of situations. This importance lies in the simplification resulting from the subdivision separating the macroscopic aspects from the microscopic aspects of the problem. In a wide variety of media the constitutive parameters can be adequately determined with relative ease by empirical means compared to a theoretical determination. For such media the theoretical determination of the constitutive parameters can be dispensed with and only the phenomenological theory is relevant.

For media such as ionized gases the direct measurement of the constitutive parameters is not such a straightforward task as for substances composed of neutral molecules because the space charges present and the boundary conditions imposed by the measuring equipment profoundly affect each other. To separate out what part of the measured results is due to the original constitutive parameters and what part is due to the disturbance introduced by the measuring equipment may well be a more difficult task than the theoretical determination of the constitutive parameters.

Propagation in Nonlinear Media

RESTRICTION TO PLANE POLARIZED WAVE

The macroscopic aspect of propagation of a plane polarized wave in an isotropic and uniform (in the absence of any fields) media in the absence of any externally applied fields other than the wave itself is investigated in this section. The reference axes are oriented so that: the x-axis is in the direction of the electric field. (Equations relating specific information about a particular important variable that occurs frequently throughout the development will be designated by a number followed by the letter representing the variable. For example equations 1E, 2E, etc. designate the equations providing the first, second, etc. pieces of information about the variable E. This equation labeling scheme facilitates keeping track of the development.)

$$\mathbf{E}=1_x E \tag{1E}$$

the y-axis is in the direction of the magnetic field

$$\mathbf{H}=1_y H \tag{1H}$$

and the z-axis is in the direction of propagation

$$\pi=1_z EH \tag{14}$$

Since there is only an x-component of electric field and a y-component of magnetic field Maxwell's induction equations reduce to

$$\partial_z E=-\partial_t \mu H \tag{A2}$$

$$-\partial_z H=\sigma E+\partial_t \epsilon E \tag{B2}$$

This investigation is restricted to the case for which nonlinearity enters only through the conductivity and in such a manner that the conductivity can be expressed in a rapidly converging power series in terms of the electric field intensity

$$\sigma=\sum_{k=0}^{\infty}\sigma_k E^k \tag{1σ}$$

Substituting this expansion for the conductivity into the induction laws and placing all terms linear in the field quantities on the left-hand sides and all nonlinear terms on the right-hand sides gives

$$\partial_z E+\mu\partial_t H=0 \tag{A3}$$

$$\partial_z H+\epsilon\partial_t E+\sigma_0 E=-\sum_{k=1}^{\infty}\sigma_k E^{k+1} \tag{B3}$$

RESOLUTION INTO PARTIAL FIELDS

This pair of nonlinear partial differential equations can be conveniently solved by the reversion method.[1,2] This method consists of reducing the original set of nonlinear equations to a sequence of sets of linear equations. This is accomplished by expanding the fields in terms of partial fields

$$E=\sum_{m=1}^{\infty}E_m \tag{2E}$$

$$H=\sum_{m=1}^{\infty}H_m \tag{2H}$$

in such a way that each set of partial fields E_m and H_m satisfy the following requirements

1. E_m and H_m depend only on partial fields of the same or lower order.
2. E_m and H_m satisfy linear partial differential equations.

Resolution of the fields into partial fields satisfying these requirements can be achieved with the aid of an ordering parameter[1] introduced in the following manner

$$E=\sum_{m=1}^{\infty}1^m E_m \tag{3E}$$

$$H=\sum_{m=1}^{\infty}1^m H_m \tag{3H}$$

Since

$$1^m=1 \tag{15}$$

Equations 3E and 3H are the same as equations 2E and 2H. By leaving the ordering parameters in the form introduced in equation 3E and 3H and temporarily treating the ordering parameter as a non-numeric the desired equivalent sets of linear equations can be obtained by substituting the partial field expansions into the nonlinear equations and equating coefficients of like powers of the ordering parameter. Substituting equations 3E and 3H into equations A3 and B3 gives

$$\sum_{m=1}^{\infty}1^m(\partial_z E_m+\mu\partial_t H_m)=0 \tag{A4}$$

$$\begin{aligned}\sum_{m=1}^{\infty}1^m(\partial_z H_m+\epsilon\partial_t E_m+\sigma_0 E_m)=\\ -\sigma_1[1^1E_1+1^2E_2+1^3E_3+\ldots.]^2\\ -\sigma_2[1^1E_1+1^2E_2+1^3E_3+\ldots.]^3\\ -\sigma_3[1^1E_1+1^2E_2+1^3E_3+\ldots.]^4\ldots\end{aligned} \tag{B4}$$

Equating coefficients of like powers of the ordering parameters gives

$$\partial_z E_m+\mu\partial_t H_m=0 \tag{A5}$$

$$\partial_z H_m+\epsilon\partial_t E_m+\sigma_0 E_m=-f_m(t,z) \tag{B5}$$

where

$$f_1(t,z)=0 \tag{16}$$

$$f_2(t,z)=\sigma_1 E_1^2 \tag{17}$$

$$f_3(t,z)=\sigma_2 E_1^3+2\sigma_1 E_1 E_2 \tag{18}$$

$$f_4(t,z)=\sigma_3 E_1^4+3\sigma_2 E_1^2 E_2+\sigma_1(2E_1E_3+E_2^2) \tag{19}$$

$$f_5(t,z)=\sigma_4 E_1^5+4\sigma_3 E_1^3 E_2+\sigma_2(3E_1^2E_3+3E_1E_2^2)+\sigma_1(2E_1E_4+2E_2E_3) \tag{20}$$

etc.

Note that E_1 and H_1 satisfy the same partial differential equations as the total fields satisfy in the case for which there is no nonlinearity, and hence, would constitute the solution to the original problem if the media were linear. All higher order partial fields satisfy the same pair of differential equations except that the equations are no longer homogeneous but are now driven by distributed excitation functions that depend on lower order partial fields.

RESOLUTION INTO FOURIER COMPONENTS

The analysis presented here is restricted to determination of steady-state time behavior. Since the partial differential equations satisfied by the partial fields are linear the partial fields will contain only those frequencies which are present in their driving functions. Examination of equations 16–20 etc. reveals that each driving function contains the frequencies of the first partial field plus the various harmonics, sums, and differences which can be obtained through products of the same order as the driving function. For example if the first partial fields consist of a single frequency the mth order driving function can have harmonic frequencies through the mth order only.

$$f_m=\Re\sum_{n=0}^{m}f_m^n\,e^{jn\omega t} \tag{21}$$

Consequently

$$E_m=\Re\sum_{n=0}^{m}E_m^n e^{jn\omega t} \tag{4E}$$

$$H_m=\Re\sum_{n=0}^{m}H_m^n e^{jn\omega t} \tag{4H}$$

where f_m^n, E_m^n, and H_m^n are respectively the complex amplitudes of the nth harmonics of the mth driving function, mth partial electric field, and mth partial magnetic field. This choice of complex Fourier representation separates each partial differential equation involving mth order partial fields into $m+1$ ordinary differential equations for the various frequency components

$$\frac{d}{dz}E_m^n+jn\omega\mu H_m^n=0\quad n=0,1,2,\ldots.,m \tag{A6}$$

$$\frac{d}{dz}H_m^n+(\sigma_0+jn\omega\epsilon)E_m^n=-f_m^n(z)\qquad n=0,1,2,\ldots.,m \tag{B6}$$

REDUCTION BY LAPLACE TRANSFORMS

These equations will be solved by means of the Laplace transform

$$\mathfrak{L}f(z)=\bar{f}(s)=\int_0^\infty e^{-sz}f(z)dz \tag{22}$$

which reduces them to the algebraic equations

$$s\bar{E}_m^n-E_{m0}^n+jn\omega\mu\bar{H}_m^n=0 \tag{A7}$$

$$s\bar{H}_m^n-H_{m0}^n+(\sigma_0+jn\omega\epsilon)\bar{E}_{m0}^n=-\bar{f}_m^n \tag{B7}$$

where

$$E_{m0}^n=E_m^n(0) \tag{5E}$$

$$H_{m0}^n=H_m^n(0) \tag{5H}$$

Solving equations A7 and B7 for the transforms of the nth harmonics in the mth partial fields gives

$$\bar{E}_m^n=\frac{sE_{m0}^n-jn\omega\mu(H_m^n-\bar{f}_m^n)}{s^2-\gamma_n^2} \tag{6E}$$

$$\bar{H}_m^n=\frac{s(H_{m0}^n-\bar{f}_m^n)-(\sigma_0+jn\omega\epsilon)E_{m0}^n}{s^2-\gamma_n^2} \tag{6H}$$

where

$$\gamma_n^2=jn\omega\mu(\sigma_0+jn\omega\epsilon) \tag{23}$$

has been used to abbreviate the equation writing. The symbol gamma has been chosen for this cluster of symbols because it plays the role of a propagation factor in exactly the same manner as for a linear media.

MAGNETIC FIELD AND CONSTANT COMPONENTS

Since the harmonic components of the partial magnetic field can be obtained directly from equation A6

$$H_m^n(z)=-\frac{1}{jn\omega\mu}\frac{d}{dz}E_m^n(z)n\geq 1 \tag{7H}$$

it is not necessary to invert equation 6H. The formula for the constant component must be developed separately since division by zero is not allowed. For this case equations A6 and B6 reduce to

$$\frac{dE_m^0}{dz}=0 \tag{8A}$$

$$\frac{dH_m^0}{dz}+\sigma_0E_m^0=-f_m^0(z) \tag{B8}$$

Solving gives

$$E_m^0(z)=E_{m0}^0 \tag{7E}$$

$$H_m^0(z)=H_{m0}^0-\sigma_0E_{m0}^0z-\int_0^z f_m^0(s)ds \tag{8H}$$

INVERSION OF LAPLACE TRANSFORM

Inversion of the transform of the *n*th harmonic of the *m*th partial electric field is facilitated by partial fraction expansion to

$$E_m^n=\frac{1}{2}\frac{E_n^m-Z_n(H_{m0}^n-\bar{J}_m^n)}{s-\gamma_n}+\frac{1}{2}\frac{E_{n0}^m+Z_n(H_{m0}^n-\bar{J}_m^n)}{s+\gamma_n} \tag{8E}$$

where

$$Z_n=\sqrt{\frac{jn\omega\mu}{\sigma_0+jn\omega\epsilon}}=\frac{jn\omega\mu}{\gamma_n} \tag{24}$$

Using

$$\mathfrak{L}^{-1}\frac{1}{s-\gamma_n}=e^{\gamma_nz} \tag{25}$$

and

$$\mathfrak{L}^{-1}\bar{f}(s)\bar{g}(s)=\int_0^z g(s-z)f(s)ds \tag{26}$$

to invert equation 8E gives

$$E_m^n(z)=\frac{E_{m0}^n-Z_nH_{m0}^n}{2}e^{\gamma_nz}+\frac{1}{2}Z_ne^{-\gamma_nz}\int_0^z e^{\gamma_ns}f_n^m(s)ds+\frac{E_{m0}^n+Z_nH_{m0}^n}{2}e^{-\gamma_nz}-\frac{1}{2}Z_ne^{-\gamma_nz}\int_0^z e^{-\gamma_ns}f_n^m(s)ds \tag{9E}$$

The excitation takes place over a plane boundary at *z* equal zero. The treatment is restricted to a single frequency excitation all of which is taken into account by the first partial field. consequently

$$E_{m0}^n=0 \qquad n\geq 2 \tag{10E}$$

$$H_{m0}^n=0 \qquad n\geq 2 \tag{9H}$$

As shown subsequently, nonlinearity produces negatively traveling *n*th harmonics which may make equations 10E and 9H untrue. With sufficiently small nonlinearity these are approximately true and the current development uses this approximation. Thus equation 9E simplifies to

$$E_m^n(z)=\frac{1}{2}Z_n\left[e^{-\gamma_nz}\int_0^z e^{\gamma_ns}f_m^n(s)ds-e^{\gamma_nz}\int_0^z e^{-\gamma_ns}f_m^n(s)ds\right] \tag{11E}$$

for $m\geq 2$

For the first order partial fields the distributed driving function is zero so equation 9E simplifies to

$$E_1^n(z)=\frac{E_{10}^n-Z_nH_{10}^n}{2}e^{\gamma_nz}+\frac{E_{10}^n+Z_nH_{10}^n}{2}e^{-\gamma_nz} \tag{12E}$$

FIRST ORDER PARTIAL FIELDS

Since there is no constant excitation applied

$$E_{10}^0=0 \tag{13E}$$

$$H_{10}^0=0 \tag{10H}$$

Consequently

$$E_1^0(z)=0 \tag{14E}$$

Since only a forward traveling wave of the fundamental frequency is being applied at the driving boundary of a medium which is homogeneous in the absence of fields it might be expected that no backward traveling wave would be present at this boundary so that

$$E_{10}^1-Z_1H_{10}^1=0 \tag{27}$$

Nonlinearity will cause a negatively traveling wave at the excitation boundary which makes equation 27 untrue. However, for sufficiently small nonlinearity equation 27 is an adequate approximation. Using equation 27 reduces equation 12E to

$$E_1^1(z)=E_{10}^1e^{-\gamma_1z} \tag{15E}$$

Using equations 7H and 24 gives

$$H_1^1(z)=\frac{E_{10}^1}{Z_1}e^{-\gamma_1z} \tag{11H}$$

Using

$$E_m^n(t,z)=\Re E_m^n(z)e^{jn\omega t} \tag{16E}$$

$$H_m^n(t,z)=\Re H_m^n(z)e^{jn\omega t} \tag{12H}$$

and

$$\gamma_n=\alpha_n+j\beta_n \tag{28}$$

gives for the fundamental components of the first partial fields

$$E_1^1(t,z)=E_{10}^1e^{-\alpha_1z}\cos(\omega t-\beta_1z) \tag{17E}$$

$$H_1^1(t,z)=\frac{E_{10}^1}{|Z_1|}e^{-\alpha_1z}\cos(\omega t-\beta_1z-\underline{/Z_1}) \tag{13H}$$

SECOND-ORDER PARTIAL FIELDS

Substituting equation 17E into 17 gives

$$f_2(t,z)=\sigma_1E_{10}^{1^2}e^{-2\alpha_1z}\cos^2(\omega t-\beta_1z) \tag{29}$$

Converting the nonlinear combination of trigonometric functions into a linear combination gives

$$f_2(t,z)=\frac{\sigma_1}{2}E_{10}^{1^2}e^{-2\alpha_1z}\times[1+\cos 2(\omega t-\beta_1z)] \tag{30}$$

Expressing this in the exponential form gives

$$f_2(t,z)=\Re\frac{\sigma_1}{2}E_{10}^{1^2}e^{-2\alpha_1z}[1+e^{j2(\omega t-\beta_1z)}] \tag{31}$$

Consequently

$$f_2^0(z)=\frac{\sigma_1}{2}E_{10}^{1^2}e^{-2\alpha_1z} \tag{32}$$

$$f_2^1(z)=0 \tag{33}$$

$$f_2^2(z)=\frac{\sigma_1}{2}E_{10}^{1^2}e^{-2\gamma_1z} \tag{34}$$

Substituting these into equation 11E gives

$$E_2^0(z)=0 \tag{18E}$$

$$E_2^1(z)=0 \tag{19E}$$

$$E_2^2(z)=\frac{\sigma_1}{4}Z_2E_{10}^{1^2}\left[e^{-\gamma_2z}\int_0^z e^{(\gamma_2-2\gamma_1)s}ds-e^{\gamma_2z}\int_0^z e^{-(\gamma_2+2\gamma_1)s}ds\right] \tag{20E}$$

Integrating and simplifying gives

$$E_2^2(z)=\frac{\sigma_1}{4}Z_2E_{10}^{1^2}\left[\frac{2\gamma_2e^{-2\gamma_1z}}{\gamma_2^2-4\gamma_1^2}-\frac{e^{-\gamma_2z}}{\gamma_2-2\gamma_1}-\frac{e^{\gamma_2z}}{\gamma_2+2\gamma_1}\right] \tag{21E}$$

Thus, the second harmonic is the only nonzero part of the second partial field. Using equation 16E gives

$$E_2^2(t,z)=\frac{\sigma_1}{4}E_{10}^{1^2}|Z_2|\left[\frac{2|\gamma_2|}{|\gamma_2^2-4\gamma_1^2|}e^{-2\alpha_1z}\cos(2\omega t-2\beta_1z+\underline{/\gamma_2}-\underline{/\gamma_2^2-4\gamma_1^2}+\underline{/Z_2})-\frac{e^{-\alpha_2z}}{|\gamma_2-2\gamma_1|}\cos(2\omega t-\beta_2z-\underline{/\gamma_2-2\gamma_1}+\underline{/Z_2})-\frac{-e^{\alpha_2z}}{|\gamma_2+2\gamma_1|}\cos(2\omega t+\beta_2z-\underline{/\gamma_2+2\gamma_1}+\underline{/Z_2})\right] \tag{22E}$$

For small nonlinearities of the type discussed here equation 22E may represent the principal effect of the nonlinearity on the electric field. This contribution by the nonlinear media consists of three different traveling waves. The first wave has a phase velocity

$$v_{p2,1}=\frac{2\omega}{2\beta_1}=\frac{\omega}{\beta_1}=v_{p1} \tag{35}$$

which is the same as that of the fundamental. The second wave has a phase velocity

$$v_{p2,2}=\frac{2\omega}{\beta_2} \tag{36}$$

which is different from that of the first and the third wave has a phase velocity

$$v_{p2,3}=\frac{2\omega}{-\beta_2}=-v_{p2,2} \tag{37}$$

and hence is a negatively traveling wave. The first wave attenuates at twice the rate of the fundamental and hence soon becomes negligible compared with it. In order to make meaningful statements about the relative importance of the waves it is necessary to determine their relative amplitudes, attenuation factors and phase velocities. One very interesting feature which can be emphasized at this point is that the negatively traveling wave is increasing in the positive z-direction. For a media of indefinitely great extent this formula gives an ever increasing value for this wave as z increases. This is physically impossible. It is necessary to keep in mind that the higher order partial fields are negligible only so long as E_2 is not too large, consequently equation 22E is not valid for excessively large values of z.

In the principal applications of interest here the conduction current is generally small compared with the displacement current

$$\sigma_0 \ll \omega\epsilon \tag{2\sigma}$$

Consequently it is convenient to express the propagation factor in the form

$$\gamma_n=jn\omega\sqrt{\mu\epsilon}\sqrt{1+\frac{\sigma_0}{jn\omega\epsilon}} \tag{38}$$

which is suitable for expansion giving

$$\gamma_n=jn\omega\sqrt{\mu\epsilon}\left[1+\frac{1}{2}\frac{\sigma_0}{jn\omega\epsilon}-\frac{1}{8}\left(\frac{\sigma_0}{jn\omega\epsilon}\right)^2+\frac{1}{16}\left(\frac{\sigma_0}{jn\omega\epsilon}\right)^3+\dots\right] \tag{39}$$

Separating into real and imaginary parts gives

$$\alpha_n=\frac{\sigma_0}{2}\sqrt{\frac{\mu}{\epsilon}}\left[1-\frac{1}{2}\left(\frac{\sigma_0}{2n\omega\epsilon}\right)^2+\dots\right] \tag{40}$$

$$\beta_n=\frac{n\omega}{c}\left[1+\frac{1}{2}\left(\frac{\sigma_0}{2n\omega\epsilon}\right)^2+\dots\right] \tag{41}$$

Since the second term in each expansion is small compared to the first it will be neglected where sums are involved. However, in expressions involving differences it is necessary to consider the first two terms since the first terms alone cancel. Using this degree of approximation gives

$$\alpha_2 \simeq \alpha_1 \tag{42}$$

$$\beta_2 \simeq 2\beta_1\left[1-\frac{3}{8}\frac{\alpha_l^2}{\beta_l^2}\right] \tag{43}$$

$$\frac{2|\gamma_2|}{|\gamma_2^2-4\gamma_1^2|} \simeq \frac{1}{\alpha_l} \tag{44}$$

$$|\gamma_2-2\gamma_1| \simeq \alpha_l \tag{45}$$

$$|\gamma_2+2\gamma_1| \simeq 4\beta_l \tag{46}$$

$$|Z_2| \simeq \sqrt{\frac{\mu}{\epsilon}} \tag{47}$$

$$\underline{/\gamma_2} \simeq \frac{\pi}{2} \tag{48}$$

$$\underline{/\gamma_2^2-4\gamma_1^2} \simeq -\frac{\pi}{2} \tag{49}$$

$$\underline{/\gamma_2-2\gamma_1} \simeq 0 \tag{50}$$

$$\underline{/\gamma_2+2\gamma_1} \simeq \frac{\pi}{2} \tag{51}$$

$$\underline{/Z_2} \simeq 0 \tag{52}$$

where

$$\alpha_l=\frac{\sigma_0}{2}\sqrt{\frac{\mu}{\epsilon}} \tag{53}$$

$$\beta_l=\omega\sqrt{\mu\epsilon} \tag{54}$$

are the attenuation and phase factors for the corresponding linear media.

Using these approximations simplify equation 22E to

$$E_2^2(t,z)=\frac{\sigma_1}{2\sigma_0}E_{10}^{1^2}\left[e^{-2\alpha_1 z}\cos(2\omega t-\alpha\beta_1 z)-e^{-\alpha_1 z}\cos(2\omega t-\beta_2 z)-\frac{\alpha_l}{\beta_l}e^{\alpha_1 z}\sin(2\omega t+\beta_2 z)\right] \tag{23E}$$

If α_1 is sufficiently small it might be expected that the beat phenomena between the two forward wave components would be important. The beat envelope wavelength

$$\lambda_e=\frac{2\pi}{\beta_1-\frac{\beta_2}{2}} \tag{55}$$

to the degree of approximation used is

$$\lambda_e=\frac{2\pi}{\beta_1}\frac{8}{3}\frac{\beta_l^2}{\alpha_l^2} \tag{56}$$

or in normalized form

$$\frac{\lambda_e}{\lambda}=\frac{8}{3}\frac{\beta_l^2}{\alpha_l^2} \tag{57}$$

Using the attenuation length

$$L_\alpha=\frac{1}{\alpha_l} \tag{58}$$

and the wavelength

$$\lambda=\frac{2\pi}{\beta_l} \tag{59}$$

gives

$$\frac{\lambda_e}{\lambda}=\frac{2}{3}\left(4\pi\frac{L_\alpha}{\lambda}\right)^2 \tag{60}$$

Consequently the beat wavelength is much too large compared with the attenuation length for the beat phenomena to be significant. The beat wavelength will be greater than the attenuation length only when the attenuation length is small compared with a wavelength in which case the wave will be damped out too rapidly for significant beats to occur.

Conductivity of an Ionized Media

Rather than express the current density in terms of each individual charged particle it is more convenient to lump all the charged particles of the same type and velocity into a single specie, and express the current density as the sum of the current densities due to each specie

$$\mathbf{i}=\sum_{s=1}^{S}\mathbf{i}^s \tag{61}$$

The current density due to each specie is

$$\mathbf{i}^s=n^s q^s \mathbf{u}^s \tag{62}$$

where

q^s = charge per ion of the sth specie
$\mathbf{u}^s$ = drift velocity of the ions of the sth specie
n^s = number of sth specie ions per unit volume

A more exact treatment than given in the following requires that the current density sum be expressed in terms of classes

$$\mathbf{i}=\sum_{c=1}^{C}\mathbf{i}^c \tag{63}$$

where the current density for a single class is due to all the ions of that type and is given by the integral of the velocity distribution function

$$\mathbf{i}^c=q^c\int\frac{d\mathbf{u}^c}{dn}\,dn \tag{64}$$

This more exact statistical mechanics treatment is beyond the scope of this paper. The objective of this section is to pursue a sufficiently simple heuristic approach so that the delineation of the nature of the inherent nonlinearities and a determination of their order of magnitude will be easily obtained.

The drift velocity of the sth specie is

$$\mathbf{u}^s=\frac{1}{2}\mathbf{a}^s\tau^s \tag{65}$$

where

$\mathbf{a}^s$ = acceleration of the sth specie

τ^s = mean free time between collisions of the *s*th specie

In the absence of magnetic fields the acceleration is given by

$$\mathbf{a}^s=\frac{q^s}{m^s}\mathbf{E} \qquad (66)$$

The mean free time in terms of the collision frequency is

$$\tau^s=\frac{1}{\nu^s} \qquad (67)$$

The drift velocity in terms of the electric field and the collision frequency is therefore

$$\mathbf{u}^s=\frac{q^s}{2m^s\nu^s}\mathbf{E} \qquad (68)$$

Using this expression for the drift velocity in equation 62 gives

$$\mathbf{i}^s=\frac{n^s(q^s)^2}{2m^s\nu^s}\mathbf{E} \qquad (69)$$

Since the current density is related to the electric field by the conductivity

$$\mathbf{i}^s=\sigma^s\mathbf{E} \qquad (70)$$

the expression for the conductivity due to the *s*th specie is

$$\sigma^s=\frac{n^s(q^s)^2}{2m^s\nu^s} \qquad (3\sigma)$$

Using equations 5 and 61 gives the conductivity addition law

$$\sigma=\sum_{s=1}^{S}\sigma^s \qquad (4\sigma)$$

The media can be nonlinear via the conductivity if any of the four parameters n^s, m^s, q^s, and ν^s vary with the field intensity. In the treatment as formulated in the foregoing the charge per ion of the *s*th specie is constant by definition. However, if the formulation is based on defining the specie in terms of the mass then m^s would be constant by definition and q^s could be a variable dependent on the electric field intensity.

COLLISION FREQUENCY DEPENDENCE ON ELECTRIC FIELD INTENSITY

The velocity of an ion can be resolved into thermal dependent and electric-field dependent parts

$$\mathbf{C}^s=\mathbf{C}_T^s+\mathbf{C}_E^s \qquad (71)$$

where

$\mathbf{C}_T^s$ = ion velocity component due to the thermal motion

$\mathbf{C}_E^s$ = ion velocity component due to the accelerating electric field

For the case of isotropic scattering

$$\mathbf{C}_E^s=\frac{q^s}{m^s}\mathbf{E}(t-t_c) \qquad (72)$$

where

t_c = time of the preceding collision

Taking the scalar product of $\mathbf{C}^s$ with itself gives

$$C^{s2}=C_T^{s2}+2\mathbf{C}_T^s\cdot\mathbf{C}_E^s+C_E^{s2} \qquad (73)$$

Since $\mathbf{C}_T^s$ is randomly oriented and $\mathbf{C}_T^s$ is in the same direction for all ions in a small but not too small region of space

$$\overline{\mathbf{C}_T^s\cdot\mathbf{C}_E^s}=0 \qquad (74)$$

Consequently, taking the average value of both sides of equation 73 gives

$$\overline{C^{s2}}=\overline{C_T^{s2}}+\overline{C_E^{s2}} \qquad (75)$$

Neglecting the dependence of the mean free path λ^s on the electric field intensity and dividing both sides by the square of the mean free path gives

$$\frac{\overline{C^{s2}}}{\lambda^{s2}}=\frac{\overline{C_T^{s2}}}{\lambda^{s2}}+\frac{\overline{C_E^{s2}}}{\lambda^{s2}} \qquad (76)$$

Approximating the squares of the collision frequencies by

$$\nu^{s2}=\frac{\overline{C^{s2}}}{\lambda^{s2}} \qquad (77)$$

and

$$\lambda_T^{s2}=\frac{\overline{C_T^{s2}}}{\nu^{s2}} \qquad (78)$$

gives

$$\nu^{s2}=\nu_T^{s2}+\frac{\overline{C_E^{s2}}}{\lambda^{s2}} \qquad (79)$$

When the second term on the right-hand side of equation 79 is very small compared with the first term, as is usually the case, the residual approximation error in equation 79 is much smaller than the approximation errors in equations 77 and 78. Substituting equation 72 into the formula for the mean square

$$\overline{C_E^{s2}}=\frac{1}{\tau}\int_{t_c}^{t_c+\tau^s}C_E^{s2}\,dt \qquad (80)$$

Integrating and expressing in terms of collision frequency gives

$$\overline{C_E^{s2}}=\frac{1}{3}\left(\frac{q^sE}{m^s\nu^s}\right)^2 \qquad (81)$$

Substituting this into equation 79 gives

$$\nu^{s2}=\nu_T^{s2}+\frac{1}{3}\left(\frac{q^sE}{m^s\lambda^s\nu^s}\right)^2 \qquad (82)$$

Expressing this equation as a conventional quadratic in terms of the collision frequency squared gives

$$\nu^{s4}-\nu_T^{s2}\nu^{s2}-\frac{1}{3}\left(\frac{q^sE}{m^s\lambda^s}\right)^2=0 \qquad (83)$$

Solving for the square of the collision frequency gives

$$\nu^{s2}=\frac{1}{2}\nu_T^{s2}\pm\sqrt{\frac{1}{4}\nu_T^{s4}+\frac{1}{3}\left(\frac{q^sE}{m^s\lambda^s}\right)^2} \qquad (84)$$

The negative sign is extraneous since the collision frequency and its square cannot be negative. Taking the root gives

$$\nu^s=\frac{1}{\sqrt{2}}\nu_T^s\sqrt{1+\sqrt{1+\frac{1}{3}\left(\frac{2q^sE}{m^s\lambda^s\nu_T^{s2}}\right)^2}} \qquad (85)$$

The average energy gained by the ion from the electric field between collisions is

$$W_E^s=q^sE\lambda^s \qquad (86)$$

The average thermal kinetic energy is

$$W_T^s=\frac{1}{2}m^s\lambda^{s2}\nu_T^{s2} \qquad (87)$$

Consequently equation 85 can be conveniently expressed in the form

$$\nu^s=\frac{1}{\sqrt{2}}\nu_T^s\sqrt{1+\sqrt{1+\frac{1}{3}\left(\frac{W_E^s}{W_T^s}\right)^2}} \qquad (88)$$

If the average energy gained from the electric field is small compared with the average thermal kinetic energy

$$\left(\frac{W_E^s}{W_T^s}\right)^2<<1 \qquad (89)$$

An approximation for equation 88 is

$$\nu^s=\nu_T^s\left[1+\frac{1}{24}\left(\frac{W_E^s}{W_T^s}\right)^2\right] \qquad (90)$$

or in terms of the electric field

$$\nu^s=\nu_T^s\left[1+\frac{1}{6}\left(\frac{q^sE}{m^s\lambda^s\nu_T^{s2}}\right)^2\right] \qquad (91)$$

Utilizing this result in equation 3σ and simplifying to the same degree of approximation gives

$$\sigma^s=\frac{n^sq^{s2}}{2m^s\nu_T^s}\left[1-\frac{1}{6}\left(\frac{q^sE}{m^s\lambda^s\nu_T^{s2}}\right)^2\right] \qquad (5\sigma)$$

Consequently

$$\sigma_0^s=\frac{n^sq^{s2}}{2m^s\nu_T^s} \qquad (6\sigma)$$

$$\sigma_1^s=0 \qquad (7\sigma)$$

$$\sigma_2^s=-\frac{\sigma_0^s}{6}\left(\frac{q^s}{m^s\lambda^s\nu_T^{s2}}\right)^2 \qquad (8\sigma)$$

For electrons

$$\frac{q_e}{m^e}=1.76\times10^{11}\ \text{coulomb/kg/(kilogram)} \qquad (92)$$

in nitrogen at a pressure of

$$p=76\ \text{millimeters mercury} \qquad (93)$$

at a temperature of

$$T = -54 \text{ degrees centigrade} \tag{94}$$

the mean free path and collision frequency are approximately

$$\lambda^{e} = 3.84 \times 10^{-6} \text{ m (meter)} \tag{95}$$

and

$$\nu^{e} = 2.4 \times 10^{10}/\text{second} \tag{96}$$

Consequently

$$\frac{\sigma_2^{e}}{\sigma_0^{e}} = -1.06 \times 10^{-11} \text{ m}^2/\text{volt}^2 \tag{9σ}$$

For the examples such as given in the introduction this could lead to undesirable interference under a variety of conditions.

For singly ionized nitrogen atoms

$$\frac{q^{N\pm}}{m^{N\pm}} = \pm 6.85 \times 10^{6} \text{ coulomb/kg} \tag{97}$$

In nitrogen at the foregoing pressure and temperature

$$\lambda^{N\pm} = 7 \times 10^{-7} \text{ m} \tag{98}$$

and

$$\nu^{N\pm} = 8 \times 10^{8}/\text{second} \tag{99}$$

Consequently

$$\frac{\sigma_2^{N\pm}}{\sigma_0^{N\pm}} = -4 \times 10^{-13} \text{ m}^2/\text{volt}^2 \tag{10σ}$$

The contribution of these heavy ions to the nonlinearity can be relatively important even though this ratio is so much smaller than that for the electrons because of the much greater densities of the heavy ions which may be present under various circumstances.

Ion Mass Dependence on Electric Field Intensity

The principal phenomena of interest here occur at electric field intensities sufficiently low that relativistic mass variation and mass variation due to the creation of new ion pairs can be neglected by comparison. The principal phenomena of importance here are caused by labile-cluster ions. Addition of neutral molecules to ions form heavier ions which are called labile-cluster ions. This clustering process can form very heavy ions. At each collision some of the neutral molecules or atoms may be knocked out of the labile cluster thereby changing its mass. The greater the electric field intensity the more energetic the collisions are and the greater the number of neutral particles knocked out of the labile cluster per collision on the average. Consequently, the average value of the labile-cluster ion mass depends on the electric field intensity, the larger the electric field intensity the smaller the average mass.

As an example consider nitrogen at ordinary temperatures with a small percentage of the molecules ionized. For low accelerating electric field intensities the most abundant positive ion is N_4^+ and the next most abundant is N_2^+. In addition N_1^+ as well as N_6^+ and heavier ions are present but in less abundance. As the electric field intensity is increased the collisions become more violent and the relative abundance of the lighter ions increases at the expense of the relative abundance of the heavier ions. The conductivity due to the singly charged positive nitrogen ions, from equation 3σ, is

$$\sigma^{N^+} = \frac{n^{N^+} e^2}{2m^{N^+} \nu^{N^+}} \tag{11σ}$$

The average mass of the positive nitrogen ions is given by

$$m^{N^+} = \sum_{g=1}^{G} p^{N_g^+} m^{N_g^+} \tag{100}$$

where

$m^{N_g^+}$ = mass of the positive nitrogen ion containing g nitrogen atoms

$p^{N_g^+}$ = percentage of the time that, or the probability that, a positive nitrogen ion contains g nitrogen atoms

This probability depends on the electric field intensity; the power series expansion is

$$p^{N_g^+}(E) = \sum_{k=0}^{\infty} p_k^{N_g^+} E^k \tag{101}$$

Substituting this into equation 100 gives

$$m^{N^+} = \sum_{k=0}^{\infty} m_k^{N^+} E^k \tag{102}$$

where

$$m_k^{N^+} = \sum_{g=1}^{G} p_k^{N_g^+} m^{N_g^+} \tag{103}$$

Substituting equation 102 into 11σ gives

$$\sigma^{N^+} = \sum_{k=0}^{\infty} \sigma_k^{N^+} E^k \tag{12σ}$$

where

$$\sigma_0^{N^+} = \frac{n^{N^+} e^2}{2m_0^{N^+} \nu^{N^+}} \tag{13σ}$$

$$\sigma_1^{N^+} = -\sigma_0^{N^+} \frac{m_1^{N^+}}{m_0^{N^+}} \tag{14σ}$$

$$\sigma_2^{N^+} = \sigma_0^{N^+} \left[-\frac{m_2^{N^+}}{m_0^{N^+}} + \left(\frac{m_1^{N^+}}{m_0^{N^+}} \right)^2 \right] \tag{15σ}$$

$$\vdots$$

etc.

In this development the effect of the variable labile-cluster ion mass on the collision frequency has been neglected.

A good approximation to the average mass, equation 100, may be given by the contributions from the two most abundant nitrogen ions

$$m^{N^+} = p^{N_2^+} m^{N_2^+} + p^{N_4^+} m^{N_4^+} \tag{104}$$

since

$$p^{N_2^+} >> p^{N_g^+} \qquad g \neq 2,4 \tag{105}$$

and

$$p^{N_4^+} >> p^{N_g^+} \qquad g \neq 2,4 \tag{106}$$

However, this may be inadequate for the determination of the nonlinearity because of the probability that

$$p_k^{N_g^+} >> p_k^{N_2^+} \qquad \text{k} > 1 \text{ and } g \neq 2,4 \tag{107}$$

and

$$p_k^{N_6^+} >> p_k^{N_4^+} \qquad k > 1 \text{ and } g \neq 2,4 \tag{108}$$

That is, relatively small numbers of massive labile-cluster ions may give much greater contributions to the nonlinearity than the relatively large numbers of lighter ions because of the much greater sensitivity of their mass to the electric field intensity.

Ion Density Dependence on Electric Field Intensity

The phenomena described in the previous section can be treated in a more appropriate fashion by redefining the specie so that specification of the ion mass is necessary for specification of the specie. In this way the mass of the ion is no longer a variable and the ion density becomes a variable instead. For the positive nitrogen ions discussed in the preceding section

$$\sigma^{N^+} = \sum_{g=1}^{G} \sigma^{N_g^+} \tag{16σ}$$

where

$$\sigma^{N_g^+} = \frac{n^{N_g^+} e^2}{2m^{N_g^+} v^{N_g^+}} \tag{17σ}$$

The density of each ion specie depends on the electric field intensity, the power series expansion is

$$n^{N_g^+} = \sum_{k=0}^{\infty} n_k^{N_g^+} E^k \tag{109}$$

Substituting equations 109 into 17σ into 16σ again gives 12σ but now

$$\sigma_0^{N^+} = \frac{e^2}{2}\sum_{g=1}^{G}\frac{n_0^{N_g^+}}{m^{N_g^+}\nu^{N_g^+}} \qquad (18\sigma)$$

$$\sigma_1^{N^+} = \frac{e^2}{2}\sum_{g=1}^{G}\frac{n_1^{N_g^+}}{m^{N_g^+}\nu^{N_g^+}} \qquad (19\sigma)$$

$$\sigma_2^{N^+} = \frac{e^2}{2}\sum_{g=1}^{G}\frac{n_2^{N_g^+}}{m^{N_g^+}\nu^{N_g^+}} \qquad (20\sigma)$$

$$\vdots$$

etc.

A good approximation to $\sigma_0^{N^+}$ may be obtained by taking into account only the two most abundant specie

$$\sigma_0^{N^+} = \frac{e^2}{2}\left[\frac{n_0^{N_2^+}}{m^{N_2^+}\nu^{N_2^+}} + \frac{n_0^{N_4^+}}{m^{N_4^+}\nu^{N_4^+}}\right] \qquad (21\sigma)$$

The corresponding approximation is likely to be inadequate for determination of the nonlinearity because even relatively small numbers of the massive labile-cluster ions may cause substantial nonlinearity because of the weak bonds holding the added neutral molecules.

Conclusions

Steady-state propagation of a plane polarized wave in a homogeneous (in the absence of fields) nonlinear conducting media containing no electric or magnetic fields except those due directly to the wave has been investigated. Detailed results have been obtained for the case of single frequency excitation through quadratic terms in the electric field intensity. The principal nonlinear effects noted for single frequency excitation are the generation of three double frequency waves; two propagating in the forward direction and one propagating in the backward direction. One forward propagating wave travels with the same phase velocity as the fundamental but attenuates at twice the rate. The other forward propagating wave travels with a phase velocity slightly greater than that of the fundamental and attenuates at a slightly lower rate. The backward propagating wave has the same magnitude of phase velocity as the second forward propagating wave and increases exponentially with distance (for moderate distances) at the same rate as the second forward wave decreases with distance.

For an ionized gas the nonlinearity is due to the dependence of the collision frequency, the ion masses and the ion densities on the electric field intensity. A first-order approximation for the collision frequency showed that although the dependence on the electric field is very small it may still be significant in terms of producing an objectionable amount of nonlinearity. The variable ion densities or masses of labile-cluster ions are expected to cause much greater nonlinearity than that caused by the collision frequency dependence on the electric field. Continued investigation is required to obtain an estimation of this effect.

Transmission Aspects of an Electronic Switchboard Employing Time-Division Multiplexing

J. C. PERKINS, JR.
ASSOCIATE MEMBER AIEE

THE AN/TTC-12 switchboard is a newly designed electronic switchboard for military application employing solid-state switching techniques. This paper describes the transmission characteristics and performance of the system with respect to the multiplex methods employed. The systems logic and design philosophy of the switchboard are thoroughly described in reference 1.

Multiplex Method

Undoubtedly the major problem which confronts the design of any time-division multiplex (TDM) system is that of sampling loss. In a conventional system, each multiplexed channel will experience an insertion loss which is inversely proportional to the duty cycle τ/T, where τ is the duration of the individual samples or time-slot pulse width, and T is the time between samples or frame period. To achieve a large number of channels on a common transmission medium it is necessary that τ be made small, and T as large as possible consistent with the Nyquist criterion that the repetition frequency $1/T$ be at least twice as great as the highest signal frequency of the channel. Obviously, these requirements lead to high multiplex losses which in turn introduce the attendant problems of high-gain amplifier stability and signal-to-noise problems.

In the recent publications of Bennett[2] and Desoer,[3] a method for resonant transferring of stored signal energy through periodically operating switches with little or no loss is described. A simplified description of this principle, known as "resonant transfer," is illustrated in the circuit of Fig. 1(A).

Assume that the initial conditions of the circuit are such that switch S is open and a charge, V_1, exists on capacitor C_1. With closure of the switch, an oscillatory current i, whose frequency is determined by the LC product of the series resonant circuit, will flow. If the time the switch remains closed, τ, is selected to be half the natural period of oscillation, the conditions shown in Fig. 1(B) will exist. The energy in C_1 will have decreased to zero, the current having completed one-half cycle, and the total charge now ap-

pears as V_2 across capacitor C_2. Thus an energy transfer has been completed between capacitors with no loss, assuming, of course, ideal components and zero switch resistance.

In application to a TDM system, the switch S is replaced by periodic sampling gates and the capacitors become end elements of the conventional low-pass filters used in a pulse-amplitude modulated (PAM) system to recover the intelligence. With the resonant transfer scheme as a base, the fundamental building blocks of a multiplex path become, as shown in Fig. 2, transmitting filter and gate, common transmission medium (highway), receiving gate and filter, and low-gain amplifier to overcome minor losses in the transfer process, filters, transformers, etc.

System Requirements

The selection of the sampling time τ frame time T, and the subsequent design criteria for the individual blocks in the multiplex path was dictated largely by the transmission specifications of the switchboard and the resonant-transfer method of time division.

In addition to having adequate bandwidth for voice transmission, each channel had to be capable of handling data information, which resulted in a phase-delay distortion specification of 10 μsec (microseconds) maximum per board. This stringent requirement was necessary since a connection could be extended through ten boards in tandem. A frame repetition frequency of 12.5 kc was selected for a theoretical maximum bandwidth of 6.25 kc of which approximately 5 kc would be attainable practically. This usable bandwidth was necessary to provide maximum phase linearity of the filters in their pass band to meet the delay requirement.

The allotted time for individual channels of 2.5 μsec in each frame period consisting of 80 μsec, provides a total of 32 channels per multiplex highway. As is the usual case in engineering design, this selection was a compromise of conflicting factors. A binary number of channels was desirable to simplify the switching circuitry. In addition, the number of channels per highway should be as large as possible to reduce the total equipment requirements. The transmission specifications, however, required an insertion loss stability of ±0.5 db (decibels) between any two connections through the board and a crosstalk ratio of greater than 50 db.

The power loss of resonant-transfer multiplexing is dependent on the effective pulse width of the combined transmit and receive gates; therefore, a wide sampling pulse is desirable to reduce level variations between channels as a result of differences in delay and the rise and fall times of the transistor circuitry. The channel time slot of 2.5 μsec was equally divided between sampling and guard time. A long guard time is desirable to allow signal energy stored in the distributed capacity of the highway to decay before the adjacent channel sample occurs; however, a clamping circuit was devised, as will be subsequently discussed, which insures a rapid dissipation of this crosstalk energy within the allotted time.

The output of any line circuit in the switchboard was required to contain no carrier leak or other frequency component produced by the modulation processes at a level greater than 30 db below the reference of 0 dbm (db referred to 1 milliwatt). Double polarity sampling, which balances out the repetition frequency and its harmonics, was chosen as

the modulation method to alleviate severe attenuation requirements on the low-pass filters.

A completely balanced transmission path was considered desirable to reduce extraneous noise and crosstalk coupling; however, the duplication of equipment and the increased complexity of the solid-state switching circuitry made this approach prohibitive. Single-ended multiplexing was selected and special care was given to its packaging: in particular to shielding, lead length, and the grounding system. Resonant transfer provides an additional asset in this respect since signal levels throughout the system are all at comparable levels. Signal level differences of 40 db or more are commonly encountered in straight sampling systems which further aggravate the noise and crosstalk problems.

Gate Design

The ultimate success of resonant-transfer multiplexing is largely dependent on the design of a gate circuit which has extremely low "on" resistance, a high-peak-signal current capacity, and a stable pulse width. In addition, the "off" impedance must be high to prevent highway loading and signal leakage into other time slots.

Transistor gates were investigated; however, they do not lend themselves readily to balanced modulator arrangements. A germanium diode quad was selected in the bridge configuration shown in Fig. 3(A) to produce the desired double polarity sampling. In the normal off condition the diode bridge is back-biased by the supply voltages of ±12 volts. The bridge is driven into conduction by a blocking oscillator which is triggered by the *MX* pulse assigned to any given line. The voltage conditions across the diodes are shown in Fig. 3(B) during the period of a single pulse.

During conduction the pulse current in the bridge must be several times larger than the peak signal current to be passed to prevent signal limiting. The peak signal current during the transfer time will be T/τ (or $80/1.25 = 64X$) larger than the steady-state signal current, i.e., all the charge stored in the frame period must be transferred in the short time of the sampling pulse to achieve zero-loss transmission. Obviously, the higher the impedance level of the signal appearing at the gate, the more relaxed will be the current requirement of the bridge. The maximum limit to which this can be carried is imposed by the back-bias of the bridge during the off period. Peak signals above this bias will tend to break through the gate, producing crosstalk in all channels. With a ± 12-volt battery supply, the impedance was set at 6 kilohms as a suitable compromise between minimum current and allowable peak voltage for a +3 dbm signal, the maximum signal level to be accommodated by the switchboard. Limiters are provided in the form of two Zener diodes back to back across the line-transformer secondary to insure that input signals do not exceed this peak voltage.

The peak transfer current for this signal level can be readily computed as approximately 50 ma (milliamperes), and the bridge pulse current must be in the order of 100 ma or more if limiting in the gate is to be avoided. At first glance, the instantaneous power-pulse requirements appear excessively large: peak current of 100 ma and an amplitude of approximately 26 volts (24 volts to overcome the bias plus the forward drop of two diodes) for a peak power of 2.6 watts. This condition is true if the diode bridge is to be driven from a straight pulse amplifier where the bias is supplied through a split secondary winding of an output transformer. However, in the blocking oscillator gate, the diode bridge replaces the clamping diode usually associated with this circuit to keep the transistor out of saturation. When the transistor enters the conduction state, both the collector and emitter tend toward ground thus removing the diode bridge bias during the on time. Consequently, the transistor supplies only the diode current and the magnetizing current to the transformer primary required to sustain the regenerative action. Short-circuiting the bias during sampling thus greatly reduces the pulse power required of the driving transistor stage.

blocking oscillator tends to simplify the pulse-distribution circuitry. Pulse stretching as a result of transistor storage effects is no longer a major consideration. Pulse width within the blocking oscillator is normally determined by the selection of the output transformer parameters. Variations in manufacture between units exceeded the desired specification of 1.25 ± 0.02 µsec; therefore the transformers were designed for a slightly wider pulse and the oscillators trimmed to the final value by padding the capacitor in the *R-C* network between the emitter and tertiary feedback winding.

Filter Design

The basis of the low-pass filter design for the multiplex path is in accordance with the insertion parameter theory. It is not intended to discuss here the intricacies of the specific design; however, several parameters should be mentioned which dictate the design approach.

The impedance level at the filters of 6 kilohms was previously determined by gate considerations. Filter synthesization on a steady-state matched-impedance basis does not provide entirely satisfactory transmission characteristics. This condition arises as a result of the time-varying load applied to the filter by the periodic switches. In addition to the departures encountered in expected transmission loss of the filters within their pass band as described in reference 3, wide fluctuations are experienced in the characteristic in-band impedance resulting in a high reflection coefficient for the line.

The critical elements in the filter design are the storage capacitors of the transfer circuit. These capacitors are required to perform two distinct functions: 1. capacitor C_1 must completely transfer its charge to C_2 during the sampling time, and 2. capacitor C_2 must completely distribute the received charge to the load during the remainder of the frame period $T-\tau$, so that its net charge is exactly zero at the start of the next transfer. A filter design which meets these conditions will insure satisfactory steady-state transmission and impedance characteristics of the multiplex path.

Fig. 4 consists of several oscillograms which illustrate these charge and discharge conditions. The oscillograph sweep is synchronized to the sampling frequency of 12.5 kc. Fig. 4(A) shows the voltage across capacitors C_1 and C_2 respectively for properly designed filters. Mistuning of the filters produces the results in Fig. 4(B). The amount of mistuning shown

has very little effect on the frequency-response characteristic of the multiplex path; however, the input impedance variations of the line are quite large, as indicated in Fig. 5. Expanded scale photographs of the charge and discharge of the capacitors during the sampling time are shown in Fig. 4(C) with the diode bridge pulse as a reference.

Amplifier Design

To establish a call between line circuits within the switchboard, two steps of multiplexing are required: one between the calling line and a link, and the other between the link and the called line. Although the multiplexing losses are low in comparison to more conventional time-division systems, some amplification is required to achieve zero loss between voice drops. It was desirable to make up this loss at a single point to prevent duplication of equipment in both link and line circuits. An amplifier of 10-db power gain proved adequate to restore both multiplex losses and those due to filters, transformers, etc.

A schematic of the audio amplifier is shown in Fig. 6. Conventional techniques are used to provide bias stabilization. Both series and shunt feedback are utilized to stabilize gain against Beta variations and to control impedance levels; the balanced arrangement permitting the complete elimination of capacitors from the circuit. It will be noted that this amplifier can be operated with single-ended input since the bases are at ground potential. The input transformer is used to provide impedance transformation from the 6-kilohm level of the filters and a d-c return for the diode bridge gate.

Highway Clamping

As in other TDM systems, crosstalk varies with position in the frame period; the maximum crosstalk coupling occurring between adjacent channels in time as a result of pulse deformation by the transmission medium. In the electronic switchboard, distributed capacity of the highway is the major contributor to this form of crosstalk. To ease packaging requirements in the multiplex portion of the system, and to insure satisfactory crosstalk levels under varying highway conditions, a clamping circuit is used to discharge the highway in the guard time between sampling pulses. This circuit is another blocking oscillator gate with the diode bridge connected in shunt between the highway and ground as shown in Fig. 7. The blocking oscillator is triggered at a 400-kc pulse-repetition frequency from the master clock of the system and provides a pulse width of approximately 0.7 μsec. The pulse train is delayed by 0.3 μsec to prevent possible overlapping with the sampling pulses of the multiplex channels.

The short-circuiting action of the bridge between three active channels is indicated in the waveform sketches of Fig. 7.

System Performance

A block diagram of the complete transmission path through the switchboard is shown in Fig. 8. For simplicity, only a single direction of transmission is shown between two line circuits, the opposite direction being identical in circuitry.

The tapped chokes bridging the audio path in the link circuit are provided for insertion and monitoring of supervisory and signaling tones and to allow access for the operator's position. The chokes also provide d-c return for the diode bridge gates through the low-pass filters during the time that the audio path of the link is split for these operations.

Transmission measurements have been made on a large number of calls placed through the engineering test model of this board which is equipped with 30 line circuits, divided between two highways, and four complete links. A fully equipped service test model is presently undergoing tests. The frequency response of a typical connection through the switchboard is shown in Fig. 9. The total harmonic distortion for a 0-dbm test tone is less than 2% for any connection.

Demodulation products in the output, primarily composed of the side bands around the sampling frequency of 12.5 kc, average 32 to 34 db below test-tone output. Idle channel noise measures less than 15 dba, *FIA* weighted, for all connections. Maximum crosstalk between adjacent channels measures 55 db below the referenced output of 0 dbm.

The extremely low phase-delay distortion has proved to be a somewhat troublesome specification. To a large extent, the difficulty is centered around measurement techniques of sufficient accuracy to determine the existing conditions. Repeatable measurements of phase-angle differences to an accuracy of 0.01 degree is required. With the present filter design, a typical delay-distortion curve is shown in Fig. 10. These data indicate a difference of approximately 20 μsec for each multiplex hop or a total of 40 μsec per switchboard, which is approaching the practical limit obtainable from the filter design. Correction of this distortion to within the specification limits is expected to be accomplished in each link circuit by a phase equalizer presently being designed. Concurrently, a program to develop rapid, accurate measurement equipment is in progress.

The Computation of Correlation and Spectral Functions by Orthogonal Filtering

ELMER G. GILBERT
NONMEMBER AIEE

THE INCREASED consideration of random time functions in engineering and science has led to the development of various digital and analog techniques for the computation of autocorrelation and cross-correlation functions or their frequency domain equivalents, spectral density and cross-spectral density. Analog techniques, which are the subject of this paper, have been limited primarily to either the time domain[1–3] (employing the operations of time delay, multiplication, and averaging) or the frequency domain[4,5] (employing the operations of narrow-band filtering, multiplication, and averaging). A more general but little-known procedure, which was originally introduced by Lampard,[6] is to represent the autocorrelation or cross-correlation function by a finite series of predetermined orthogonal approximating functions and to determine coefficients in the series by the operations of orthogonal filtering, multiplication, and averaging. Advantages of the series method include analytic representations for both the correlation and spectral functions and the possible elimination of delay lines or narrow-band filters.

The purpose of this paper is to develop more fully the series method for computation of correlation and spectral functions. After reviewing the series representation and its determination, the following topics are treated: the relationship of time-domain and frequency-domain techniques to the series method; orthonormal approximating functions; analog computer circuits for orthonormal filtering; approximation errors due to a finite number of terms in the approximating series, computer component errors, and finite averaging time.

Series Representation and Its Determination

The cross-correlation function of $f(t)$ and $g(t)$ is defined by

$$\psi_{fg}(\tau)=\overline{f(t)g(t+\tau)}=\overline{f(t-\tau)g(t)} \tag{1}$$

where the bars denote averages over all time. It is assumed that f and g have finite power and that at least one of the spectral densities $\Psi_{ff}(j\omega)$ or $\Psi_{gg}(j\omega)$ is bounded. (Upper-case-letter functions of $j\omega$ are the Fourier transforms of corresponding lower-case-letter functions.) As shown in Appendix I, these are sufficient conditions to assure that:

$$\int_{-\infty}^{\infty} \psi_{fg}^2(\tau)d\tau<\infty \tag{2}$$

a condition which is required if the series representation is to hold. Since one of the spectral densities must be bounded, all periodic and constant components of that spectral must be excluded.

Let the series representation of ψ_{fg} be given by

$$\psi_{fg}^*=\sum_{n=1}^{N} [a_n\phi_n(\tau)+b_n\phi_n(-\tau)] \tag{3}$$

where the ϕ_n are orthonormal, i.e., they satisfy the conditions

$$\int_{-\infty}^{\infty} \phi_n(\tau)\phi_m(\tau)d\tau=0,\ n\neq m \atop \qquad\qquad =1,\ n=m \tag{4}$$

Orthonormality, rather than orthogonality, is stipulated for convenience. The second group of terms $b_n\phi_n(-\tau)$ in equation 3 is required because it is assumed that:

$$\phi_n(\tau)=0,\ \tau\leq 0 \tag{5}$$

Since equation 2 is satisfied, the integral square error

$$I=\int_{-\infty}^{\infty} (\psi_{fg}-\psi_{fg}^*)^2d\tau \tag{6}$$

is finite for finite a_n and b_n. Minimization of I in respect to the a_n and b_n gives the following results:

$$I_{\min}=\int_{-\infty}^{\infty} \psi_{fg}^2d\tau-\sum_{n=1}^{N} (a_n^2+b_n^2) \tag{7}$$

$$a_n=\int_{-\infty}^{\infty} \psi_{fg}(\tau)\phi_n(\tau)d\tau \tag{8}$$

and

$$b_n=\int_{-\infty}^{\infty} \psi_{fg}(\tau)\phi_n(-\tau)d\tau \tag{9}$$

Note that $I_{\min}$, which must always be positive, can only decrease as the number of terms in the series increases.

The cross-spectral density approximation is given by the Fourier transform of equation 3 as

$$\Psi_{fg}^*(j\omega)=\sum_{n=1}^{N}[a_n\Phi_n(j\omega)+b_n\Phi_n(-j\omega)] \tag{10}$$

Application of Parseval's theorem to $I_{\min}$ gives:

$$\begin{aligned} I_{\min}&=\frac{1}{2\pi}\int_{-\infty}^{\infty} |\Psi_{fg}(j\omega)-\Psi_{fg}^*(j\omega)|^2d\omega \\ &=\frac{1}{2\pi}\int_{-\infty}^{\infty} |\Psi_{fg}(j\omega)|^2d\omega- \\ &\qquad\sum_{n=1}^{N}(a_n^2+b_n^2) \end{aligned} \tag{11}$$

To obtain the representation for the autocorrelation function and spectral density of $f(t)$ it is only necessary to let $g=f$. Since $\psi_{ff}(-\tau)=\psi_{ff}(\tau)$, $b_n=a_n$ and equations 3 and 10 become simply:

$$\begin{aligned} \psi_{ff}^*(\tau)&=\sum_{n=1}^{N} a_n[\phi_n(\tau)+\phi_n(-\tau)] \\ &=\sum_{n=1}^{N} a_n\phi_n(|\tau|) \end{aligned} \tag{12}$$

and

$$\begin{aligned} \Psi_{ff}^*(j\omega)&=\sum_{n=1}^{N} a_n[\Phi_n(j\omega)+\Phi_n(-j\omega)] \\ &=2\sum_{n=1}^{N} a_n Re\Phi_n(j\omega) \end{aligned} \tag{13}$$

The procedure for evaluating the a_n in terms of $f(t)$ and $g(t)$ rather than $\psi_{fg}(\tau)$ is found by substituting equation 1 into equation 8 to obtain:

$$a_n=\int_{-\infty}^{\infty} \overline{f(t-\tau)g(t)}\phi_n(\tau)d\tau$$

Interchanging the order of the operations averaging and integration over τ gives:

$$a_n=\overline{g(t)h_n(t)} \tag{14}$$

where

$$h_n(t)=\int_{-\infty}^{\infty} f(t-\tau)\phi_n(\tau)d\tau \tag{15}$$

the response of a linear filter with input

$f(t)$ and impulse response $\phi_n(\tau)$. Since equation 5 holds, the impulse response $\phi_n(\tau)$ must be realizable. Fig. 1(A) shows the physical systems needed for evaluation 14. For computation of b_n a similar development gives the result in Fig. 1(B).

After the a_n and b_n have been computed the linear systems with impulse responses $\phi_n(\tau)$ can be employed as a function generator to machine plot the series representation $\psi_{fg}{}^*$. The scheme is shown in Fig. 2. The linear system synthesized has an impulse response $\sum_{n=1}^{N} a_n\ \phi_n(t)$. Thus when it is excited by an impulse $u_0(t)$, or a set of initial conditions producing the same effect as an impulse, an output equal to the positive τ portion of $\psi_{fg}{}^*$ is obtained for recording. The negative τ portion of $\psi^*{}_{fg}$ is recorded in exactly the same way by substituting the b_n for the a_n.

Generalizations of the foregoing procedures are possible. First of all, the approximating functions for negative τ need not be $\phi_1(-\tau), \ldots \phi_N(-\tau)$. Any number of other orthonormal functions, say $\bar{\phi}_1(-\tau), \ldots \bar{\phi}_M(-\tau)$, may be used by substituting $\bar{\phi}_n(-\tau)$ for $\phi(_n-\tau)$ in all the above results. Second, the approximating functions need not be orthogonal. When the ϕ_n are not orthogonal the computed results $\int_{-\infty}^{\infty} \psi_{fg}(\tau)\phi_n(\tau)d\tau$ and $\int_{-\infty}^{\infty} \psi_{fg}(\tau)\phi_n(-\tau)d\tau$ appear in $2N$ linear algebraic equations in $2N$ unknowns, a_n and b_n. While nonorthogonal functions are generally easier to realize as impulse responses, the solution of the linear equations for a_n and b_n is lengthy and tends to aggrevate the effect of errors in the computed $\int_{-\infty}^{\infty} \psi_{fg}(\tau)\phi_n(\tau)d\tau$ and $\int_{-\infty}^{\infty} \psi_{fg}(\tau)\phi_n(-\tau)d\tau$. Lastly, constrained or weighted integral-square-error approximations may be employed to diminish certain undesirable characteristics of the integral-square-error approximation.[7]

Relationship to Time-Domain and Frequency-Domain Techniques

In the usual time-domain computation of a correlation function the ϕ_n are made orthogonal (but not orthonormal) by causing the ϕ_n to be nonoverlapping functions of τ. Thus $\phi_n(t)=u_0(t-n\Delta\tau)$, the impulse response of a delay line with taps separated by $\Delta\tau$. By equations 8 and 9 it is seen that $a_n=\psi_{fg}(n\Delta\tau)$ and $b_n=\psi_{fg}(-n\Delta\tau)$. Actually, because of delay line errors in phase and gain, the $\phi_n(\tau)$ have finite width and height and only approximate $u_0(t-n\Delta\tau)$. Still, with a sufficiently good delay line the ϕ_n do not overlap appreciably and are essentially orthogonal.

A similar situation exists for the frequency-domain computation of spectral density. The functions ϕ_n are made orthogonal by causing their transforms $\Phi_n(j\omega)$ to be nonoverlapping in the frequency domain, i.e., by making the $\Phi_n(j\omega)$ be narrow band filters. (By Parseval's theorem:

$$\int_{-\infty}^{\infty}\phi_n(t)\phi_m(t)dt=\frac{1}{2\pi}\int_{-\infty}^{\infty}\Phi_n(j\omega)\times \Phi_m(-j\omega)d\omega$$

Hence functions orthogonal in the frequency domain are also orthogonal in the time domain.)

Orthonormal Approximating Functions

The primary factors governing the choice of orthonormal functions are functional form and physical realization. The functional form should yield series representations for ψ_{fg} and Ψ_{fg} which are accurate for reasonably small N and are easy to use; physical realization should be simple, accurate, and inexpensive.

When delay elements are allowed in the realization of the orthonormal functions

their formulation is particularly straightforward because the functions can be made nonoverlapping in time. For example, by choosing the functions to be constant in adjacent time intervals of width $\Delta\tau$ the expressions

$$\begin{aligned}\phi_n(t)&=0,\ t\leq(n-1)\Delta\tau,\ t>n\Delta\tau\\&=\frac{1}{\sqrt{\Delta\tau}},\ (n-1)\Delta\tau<t\leq n\Delta\tau\end{aligned}\tag{16}$$

and

$$\Phi_n(j\omega)=\frac{\epsilon^{-j\omega(n-1)\Delta\tau}-\epsilon^{-j\omega n\Delta\tau}}{\sqrt{\Delta\tau}\,(j\omega)}\tag{17}$$

result. Here a stepwise representation of $\psi_{fg}(\tau)$ is achieved. The frequency-domain approximation is a harmonic series of sines and cosines (of fundamental period $\omega=2\pi/\Delta\tau$) weighted by $1/\omega$. A physical realization of the functions is shown in Fig. 3. In practice the integrator might be an R-C low-pass filter with time constant much greater than $\Delta\tau$. Thus it is possible to go from a point by point determination of $\psi_{fg}(at\ \tau=n\Delta\tau)$ to a series representation of both ψ_{fg} and Ψ_{fg} by the simple addition of an integrator to a tapped delay line.

Variations of these functions are possible. The adjacent time intervals need not be equal, nor does the last function $\phi_N(t)$ have to be zero $t>N\Delta\tau$. An example of the latter is the function:

$$\begin{aligned}\phi_N(t)&=0,\ t\leq(N-1)\Delta\tau\\&=\sqrt{2a}\,\epsilon^{a(n-1)\Delta\tau}\,\epsilon^{-at},\ t>(N-1)\Delta\tau\end{aligned}\tag{18}$$

Still more varied functions may be realized with delay elements if the nonoverlapping requirement is not enforced. But then, of course, orthogonalization is not so easily carried out.

Attempts to form orthogonal functions which are nonoverlapping in the frequency domain encounter theoretical limitations because of realizability considerations. (The Paley-Weiner theorem shows that $\Phi_n(j\omega)$ is not realizable if $\Phi_n(j\omega)=0$ in any finite frequency range.) Band-pass filters with extremely sharp cutoff can be made essentially nonoverlapping, but their realization is difficult and the form of the approximating functions is not simple.

Of greatest practical value are orthonormal functions $\Phi_n(j\omega)$ which are rational in $j\omega$. They may be easily realized by lumped element systems (an important advantage in the low-frequency regions where delay elements are difficult to construct) and have functional forms which are simple and analytically tractable. Fortunately, orthogonalization of such functions is not difficult even though they are overlapping in both the time and frequency domains. The orthogonalization procedure is carried out in the frequency domain and has been described elsewhere.[7]

The set of functions $\Phi_1, \Phi_2, \ldots \Phi_n$ considered here have poles at $j\omega=s_1, s_2, \ldots s_n$ (the s_n must have negative real parts since $\int_{-\infty}^{\infty}\phi_n^2dt=1<\infty$). When s_n is real with $s_n=-\alpha_n$:

$$\Phi_n=\frac{(j\omega+s_1)\ldots(j\omega+s_{n-1})}{(j\omega-s_1)\ldots(j\omega-s_{n-1})}\,\frac{\sqrt{2\alpha_n}}{j\omega+\alpha_n}\tag{19}$$

When s_n and s_{n+1} are complex conjugates with real parts $-\alpha_n$ and magnitudes β_n,

$$\Phi_n=\frac{(j\omega+s_1)\ldots(j\omega+s_{n-1})}{(j\omega-s_1)\ldots(j\omega-s_{n-1})}\times\frac{2\beta_n\sqrt{\alpha_n}}{(j\omega)^2+2\alpha_nj\omega+\beta_n^2}\tag{20}$$

and

$$\Phi_{n+1}=\frac{(j\omega+s)\ldots(j\omega+s_{1n-1})}{(j\omega-s_1)\ldots(j\omega-s_{n-1})}\times\frac{2\sqrt{\alpha_n}j\omega}{(j\omega)^2+2\alpha_nj\omega+\beta_n^2}\tag{21}$$

The corresponding time functions $\phi_n(t)$ are not written so easily and therefore are not given here. When all the s_n are real and equal, the functions ϕ_n are proportional to the Laguerre functions utilized by Lampard.

A realization of the foregoing functions is shown in Fig. 4. Since the higher number functions include the dynamic characteristics of the lower number functions, the cascade arrangement provides minimum complexity. Operational amplifier circuits for the sections shown in Fig. 4 are given in Fig. 5. Except for the normalization factors $+1/2\sqrt{\alpha_n}$ and $-1/\sqrt{2\alpha_n}$ these sections may be fitted directly into Fig. 4. Fig. 5. Operational amplifier circuits for sections shown in Fig. 4

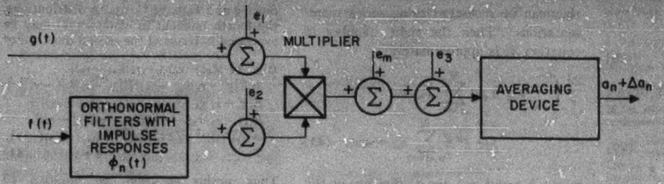

Fig. 6. Diagram showing component errors

$(n+1)$th sections in Fig. 4 are combined and the output $F_n(j\omega)$ does not appear.

The singularities s_n of the approximating functions are defined by the potentiometer settings α_n and β_n. Thus the form of the series approximation may be conveniently changed by simple computer adjustment without any preliminary calculations. This flexibility often permits good approximation accuracy with a rather small N, an advantage which the Laguerre functions do not have.

Approximation Errors

Three distinct sources of approximation error exist: 1. the finite number of terms in the approximating series, 2. deviations in the a_n and b_n due to computer component errors, and 3. statistical deviations in the a_n and b_n due to finite averaging time. The first error source yields an error magnitude measured by $I_{\min}$ in equation 7. If the deviations in a_n and b_n caused by the last two error sources are denoted by Δa_n and Δb_n, then it can be shown that the total integral square approximation error is:[7]

$$I=I_{\min}+\Delta I=I_{\min}+\sum_{n=1}^{N}(\Delta a_n^2+\Delta b_n^2) \tag{22}$$

Thus ΔI represents the integral square error due to sources *2* and *3*. Practically there is no point in striving to make either $I_{\min}<<\Delta I$ or $\Delta I<<I_{\min}$. The three error sources will now be examined in detail.

Errors Due to Finite N

The N required for a given approximation accuracy varies widely with the choice of the approximating functions ϕ_n. Often, several of the rational functions given in equations 19, 20, and 21 will give a very satisfactory representation if they are chosen with care. However, since ψ_{fg} is initially unknown, careful choice of the functions is usually not feasible and large number of ϕ_n with varied characteristics are needed. The necessary variation of characteristics can be achieved with rational functions by distributing the points of singularity s_n throughout the complex plane in the frequency range of importance. In any case, N should not differ greatly from the N demanded in the more usual time or frequency-domain computations of ψ_{fg}. Once a reasonable representation of ψ_{fg} has been computed using a large number of terms, inspection may lead to a more efficient choice of the ϕ_n.

An additional complication arises in evaluating the goodness of the approximation since $\int_{-\infty}^{\infty}\psi_{fg}^2 d\tau$ is not known and $I_{\min}$ cannot be computed. However, comparative calculations are possible, since $\sum_{n=1}^{N}(a_n^2+b_n^2)$ can be computed and becomes larger as approximation accuracy improves. Furthermore, a check on the approximation error at $\tau=0$ is readily made since $\psi_{fg}(0)=\overline{f(t)g(t)}$ is easily computed. This check is valuable when the rational approximating functions are utilized because the discontinuities in many of the $\phi_n(\tau)$ at $\tau=0$ often cause the approximation error to be greatest at $\tau=0$. Of course, the accuracy of these checks is limited by computer component errors and finite averaging time.

Computer Component Errors

The component errors considered in this section are indicated in Fig. 6. The quantities e_1, e_2, and e_3 are constants representing the effects of offsets in the computer circuitry. The multiplier static error is e_m and is a function of the two inputs to the multiplier. Dynamic errors in the multiplier and realization of the ϕ_n are usually of lesser importance and are neglected.

Referring to Fig. 6, it is seen that (assuming infinite averaging time):

$$\begin{aligned} a_n+\Delta a_n &= \overline{(g+e_1)(h_n+e_2)}+\overline{e_m(g+e_1,\ h_n+e_2)} \\ &\quad +\overline{e_3} \\ &= e_1\overline{h_n}+e_2\overline{g}+\overline{gh_n}+e_1e_2+ \\ &\quad \overline{e_m(g+e_1,\ h_n+e_2)} \\ &\quad +e_3 \end{aligned} \tag{23}$$

If $\bar{f}$ and $\bar{g}$ are both zero, the first two error terms in equation 23 vanish. Because this is advantageous it will be assumed that the constant components of both f and g have been extracted. Then neglecting the second order term, e_1e_2 gives:

$$\Delta a_n=e_3+\overline{e_m(g+e_1,\ h_n+e_2)} \tag{24}$$

Since the average multiplier error is difficult to compute, the bound

$$|\Delta a_n|\le|e_3|+|e_m|\ \text{maximum} \tag{25}$$

is more useful. The same result applies to Δb_n. From the above it can be seen that multiplier error and integrator drift are the important component errors.

To keep the effect of these errors as small as possible, the levels of f, g, and h_n should be scaled as large as possible, observing saturation limitations. In this regard servo multipliers are severely limited, even when their linear-system bandwidth is sufficiently large. Velocity and acceleration limits can be encountered long before full-scale amplitudes are reached.

Statistical Errors Due to Finite Averaging Time

The time averaging of $g(t)h_n(t)$ which yields a_n must necessarily be carried out by a low-pass filter or integrator. In either situation a statistical error results because the average is not carried out over all time.[5,9] To derive the results that follow it is assumed that f and g belong to stationary and ergodic random processes.

If the average of $g(t)h_n(t)$ is measured at time t the result can be expressed by:

$$a_n+\Delta a_n=\int_0^{\infty} g(t-\tau)h_n(t-\tau)w(\tau)d\tau \tag{26}$$

where Δa_n is the statistical error in a_n, and $w(t)$ is the impulse response of the averaging device. When the averaging device is a first-order low-pass filter with time constant T,

$$\begin{aligned} w(t) &= \frac{1}{T}e^{-t/T}, & t>0 \\ &= 0, & t\le 0 \end{aligned} \tag{27}$$

and when the averaging device is an integrator with averaging time T,

$$w(t)=\frac{1}{T}, \quad 0<t\leq T$$
$$=0, \quad t\leq 0, \quad t>T \tag{28}$$

The proper gain of the averaging device is achieved by requiring

$$\int_0^\infty w(t)dt=1 \tag{29}$$

Because $g(t)$ and $f(t)$ are stationary and ergodic, the expected value of $a_n+\Delta a_n$ is

$$\begin{aligned} E[a_n+\Delta a_n]&=a_n+E[\Delta a_n]\\ &=\int_0^\infty E[g(t-\tau)h_n(t-\tau)]w(\tau)d\tau\\ &=E[gh_n]\int_0^\infty w(\tau)d\tau\\ &=E[gh_n]=\overline{g(t)h_n(t)}=a_n \end{aligned} \tag{30}$$

Thus $E\ [\Delta a_n]=0$ and the estimate of a_n is unbiased. In an analogous fashion the same result can be developed for Δb_n.

In order to derive reasonably simple expressions for the variance of Δa_n it is necessary to further assume that g and f are Gaussian. For processes which are not Gaussian the results presented here will at least serve as an approximate guide. In Appendix II it is shown that:

$$\begin{aligned} E\left[\sum_{n=1}^N \Delta a_n^2+\Delta b_n^2\right]&=E[\Delta I]\\ &=\frac{k}{\pi}\int_{-\infty}^\infty\left[\Psi_{gg}\Psi_{ff}\sum_{n=1}^N|\Phi_n|^2+\Psi_{fg}^2\times\right.\\ &\qquad\left.\sum_{n=1}^N Re\Phi_n^2\right]d\omega \end{aligned} \tag{31}$$

where

$$\begin{aligned} k&=\int_0^\infty w(t)^2dt\\ &=\frac{1}{T}\text{ for equation 27}\\ &=\frac{1}{2T}\text{ for equation 28} \end{aligned} \tag{32}$$

Thus the average increment of integral-square-approximation error is inversely proportional to the averaging time.

Since equation 31 is somewhat too complicated to use for simple estimates of ΔI, the following upper bound on $E[\Delta I]$ is derived in Appendix III:

$$E[\Delta I]\leq\frac{2k}{\pi}\int_{-\infty}^\infty \Psi_{gg}\Psi_{ff}\sum_{n=1}^N|\phi_n|^2d\omega \tag{33}$$

Once $\sum_{n=1}^N |\Phi_n|^2$ has been evaluated for a given set of approximating functions, the above integral can be quickly estimated to determine a suitable averaging time. If Ψ_{gg} and Ψ_{ff} are not known initially, they can be measured using series representations. Then the right member of equation 33 is approximately:

$$\begin{aligned} \frac{2k}{\pi}\int_{-\infty}^\infty \Psi_{gg}{}^*\Psi_{ff}{}^*\sum_{n=1}^N|\Phi_n|^2d\omega\\ =k\sum_{n,m=1}^N a_{gn}a_{fm}c_{nm} \end{aligned} \tag{34}$$

where a_{gn} and a_{fm} are coefficients in the series $\Psi_{gg}{}^*$ and $\Psi_{ff}{}^*$ and

$$c_{nm}=\frac{8}{\pi}\int_{-\infty}^\infty Re\Phi_n Re\Phi_m\sum_{j=1}^N|\Phi_j|^2d\omega \tag{35}$$

All of these results can be applied to autocorrelation function measurements by replacing the g subscripts by f subscripts.

Appendix I

Let λ be an arbitrary real parameter. Then the spectral density of the time function $\lambda f+g$ must be nonnegative. Thus:

$$0\leq\Psi_{(\lambda f+g)(\lambda f+g)}=\lambda^2\Psi_{ff}+\lambda\Psi_{fg}+\lambda\Psi_{gf}+\Psi_{gg}$$

But $\Psi_{gf}=\text{conj }\Psi_{fg}$, so:

$$\lambda^2\Psi_{ff}+2\lambda Re\Psi_{fg}+\Psi_{gg}\geq 0$$

Since the result must hold for all values of λ the discriminant must be negative or zero and

$$4(Re\Psi_{fg})^2-4\Psi_{ff}\Psi_{gg}\leq 0$$

or

$$(Re\Psi_{fg})^2\leq\Psi_{ff}\Psi_{gg} \tag{36}$$

Similar consideration of the spectra density of $\lambda f+jg$ yields the result:

$$(Im\Psi_{fg})^2\leq\Psi_{ff}\Psi_{gg} \tag{37}$$

Addition of equations 36 and 37 gives:

$$|\Psi_{fg}|^2\leq 2\Psi_{ff}\Psi_{gg} \tag{38}$$

Now if one of the spectral densities is bounded (say $\Psi_{ff}\leq M$), then:

$$\begin{aligned} \int_{-\infty}^\infty \psi_{fg}^2(\tau)d\tau&=\frac{1}{2\pi}\int_{-\infty}^\infty|\Psi_{fg}|^2d\omega\leq\\ &\frac{1}{\pi}\int_{-\infty}^\infty\Psi_{gg}\Psi_{ff}d\omega\leq\frac{M}{\pi}\int_{-\infty}^\infty\Psi_{gg}d\omega \end{aligned}$$

and

$$\int_{-\infty}^\infty \psi_{fg}^2(\tau)d\tau\leq M2\phi_{gg}(0)<\infty \tag{39}$$

This is the desired result.

Appendix II

The variance of Δa_n can be written as

$$E[\Delta a_n^2]=E[(a_n+\Delta a_n)^2]-a_n^2$$

Substituting $a_n+\Delta a_n$ from equation 26 and for convenience letting $t=0$ gives:

$$\begin{aligned} E[\Delta a_n^2]=\int_0^\infty\int_0^\infty E[g(-\tau_1)h_n(-\tau_1)\times\\ g(-\tau_2)h_n(-\tau_2)]w(\tau_1)w(\tau_2)d\tau_1d\tau_2-a_n^2 \end{aligned} \tag{40}$$

Since g and h_n have Gaussian distributions, the fourth moment in equation 40 may be expressed in terms of the second moments:[10]

$$\begin{aligned} &E[g(-\tau_1)h_n(-\tau_1)g(-\tau_2)h_n(-\tau_2)]\\ &\quad=E[g(-\tau_1)h_n(-\tau_1)]E[g(-\tau_2)h_n(-\tau_2)]+\\ &\quad E[g(-\tau_1)g(-\tau_2)E[h_n(-\tau_1)h_n(-\tau_2)]+\\ &\quad E[g(-\tau_1)h_n(-\tau_2)]E[g(-\tau_2)h_n(-\tau_1)]\\ &\quad=\psi_{gh}^2(0)+\psi_{gg}(\tau)\psi_{hh}(\tau)+\psi_{hg}(\tau)\psi_{hg}(-\tau),\\ &\qquad\tau=\tau_1-\tau_2 \end{aligned} \tag{41}$$

Thus, noting equation 29, equation 40 becomes:

$$E(\Delta a_n^2)=\int_0^\infty\int_0^\infty\theta(\tau_1-\tau_2)w(\tau_1)\times w(\tau_2)d\tau_1d\tau_2 \tag{42}$$

where

$$\theta(\tau)=\theta(-\tau)=\psi_{gg}(\tau)\psi_{hh}(\tau)+\psi_{hg}(\tau)\psi_{hg}(-\tau) \tag{43}$$

By defining

$$\phi_{ww}(\tau)=\int_0^\infty w(\tau_1)w(\tau+\tau_1)d\tau_1 \tag{44}$$

equation 42 can be written as:

$$E[\Delta a_n^2]=\int_{-\infty}^\infty\theta(\tau)\theta_{ww}(\tau)d\tau\leq k\int_{-\infty}^\infty\theta(\tau)d\tau \tag{45}$$

where $k=\phi_{ww}(0)$ is the upper bound of $\phi_{ww}(\tau)$. Since the averaging times are usually very long compared to values of $|\tau|$ where $\psi_{ff}(\tau)$, $\psi_{gg}(\tau)$, $\psi_{fg}(\tau)$, and consequently $\theta(\tau)$ have appreciable magnitude, $E[\Delta a_n^2]$ approaches closely the upper bound given in equation 45. Thus:

$$E[\Delta a_n^2]\cong k\int_{-\infty}^\infty\theta(\tau)d\tau \tag{46}$$

Application of Parseval's theorem to equation 46 gives:

$$E[\Delta a_n^2]\cong\frac{k}{2\pi}\int_{-\infty}^\infty[\Psi_{gg}(j\omega)\Psi_{hh}(-j\omega)+\Psi_{hg}^2(j\omega)]d\omega \tag{47}$$

But from equation 15

$$\Psi_{hh}(-j\omega)=\Psi_{hh}(j\omega)=\Psi_{ff}(j\omega)|\Phi_n(j\omega)|^2$$

and

$$\Psi_{hg}(j\omega)=\Psi_{fg}(j\omega)\Phi_n(-j\omega)$$

Thus

$$E[\Delta a_n^2]\cong\frac{k}{2\pi}\int_{-\infty}^\infty[\Psi_{gg}\Psi_{ff}|\Phi_n|^2+(\Psi_{fg}(j\omega)\Phi_n(-j\omega))^2]d\omega \tag{48}$$

Similarly,

$$\begin{aligned} E[\Delta b_n^2]&\cong\frac{k}{2\pi}\int_{-\infty}^\infty[\Psi_{gg}\Psi_{ff}|\Phi_n|^2+(\Psi_{fg}(-j\omega)\Phi_n(-j\omega))^2]d\omega\\ &\cong\frac{k}{2\pi}\int_{-\infty}^\infty[\Psi_{gg}\Psi_{ff}|\Phi_n|^2+(\Psi_{fg}(j\omega)\Phi_n(j\omega))^2]d\omega \end{aligned} \tag{49}$$

Summation of the terms in equations 48 and 49 gives equation 31.

Appendix III

Equation 47 can be written as:

$$E[\Delta a_n^2]=\frac{k}{2\pi}\int_{-\infty}^{\infty}[\Psi_{gg}(j\omega)\Psi_{hh}(j\omega)+$$

$$Re\Psi_{hg}^2(j\omega)+jIm\Psi_{hg}^2(j\omega)]d\omega$$

Since $E[\Delta a_n^2]$ is real the integral of $Im\Psi_{hg}^2$ must vanish. Hence:

$$E[\Delta a_n^2]=\frac{k}{2\pi}\int_{-\infty}^{\infty}[\Psi_{gg}\Psi_{hh}+Re\Psi_{hg}^2]d\omega$$

But $Re\Psi_{hg}^2(j\omega)\leq(Re\Psi_{hg}(j\omega))^2$. Hence:

$$E[\Delta a_n^2]\leq\frac{k}{2\pi}\int_{-\infty}^{\infty}[\Psi_{gg}\Psi_{hh}+(Re\Psi_{hg})^2]d\omega$$

Application of inequality 36 with f replaced by h gives:

$$E[\Delta a_n^2]\leq\frac{2k}{2\pi}\int_{-\infty}^{\infty}\Psi_{gg}\Psi_{hh}d\omega$$

$$=\frac{k}{\pi}\int_{-\infty}^{\infty}\Psi_{gg}\Psi_{ff}\Phi_n^2d\omega \quad (50)$$

Similarly, the same upper bound applies to $E[\Delta b_n^2]$.

The summation

$$\sum_{n=1}^{N}(E[\Delta a_n^2]+E[\Delta b_n^2])$$

$$=E\left[\sum_{n=1}^{N}\Delta a_n^2+\Delta b_n^2\right]$$

therefore gives equation 33.

All of the foregoing results can be applied to autocorrelation function measurements by replacing the g subscripts by f subscripts.

R. A. VANDERLIPPE
NONMEMBER AIEE

A. L. WHITMAN
MEMBER AIEE

TWO teletypewriter selective calling line systems, the TADS (Teletypewriter Automatic Dispatch System) system[1] and the *83B1* system,[2] have been described in recent papers. These systems are for single multistation lines; those in service at the present time have an average of about ten stations on a line although, theoretically, if the traffic offered per station is low, there may be as many as 40 stations on a line. As soon as the required number of stations exceeds that which can be efficiently handled on one line, other lines are required, with the need for transferring messages from one line to another.

For simple networks of not more than three lines, the transferring can be done efficiently and economically by an existing automatic relay arrangement using reperforator-transmitters with intermediate punched tape as the switching device. For more than three lines such a switching device becomes increasingly more complicated and prohibitively expensive.

To fill the need for interconnecting from four to nine selective calling lines a new automatic switching unit, known as the *84A1* teletypewriter switching unit, was developed. In the interests of simplicity and economy, the requirements for the system were set with certain recognized limitations. As a result, the capacity of the switching unit to handle crossoffice traffic efficiently is limited. There is no fixed upper limit of capacity; what happens if the system becomes overloaded is that the messages are subject to longer delays in delivery. The plan for the *84A1* system was laid out on the basic assumption that it would be used in situations where the principal communities of interest would be along the individual selective calling lines, and that only a relatively small amount of traffic would be exchanged between lines. Quantitatively, about 60% of the total traffic on a particular line should be intraline, with only 40% interline.

This will indicate why the system has been called a "small" system. It is in no sense competitive, so far as traffic-handling capacity is concerned, with the larger and more elaborate automatic switching systems of the *81* type.[3] However, it is believed that it will fill a significant need for businesses which do not need or cannot afford the larger systems. In addition, where the customer has a need to terminate some half-duplex multistation circuits, these circuits could terminate on an *84A1* switching unit. The transfer of traffic between the two systems could be effected manually by the torn tape method or by an automatic interconnection now under consideration.

A significant difference between the *84* and *81* systems, is that the lines of the *84* system operate half duplex (HDX), while the lines of the *81* system are full duplex (FDX). Half-duplex operation permits free interchange of traffic between stations on one line without the intervention of the switching center. If a substantial proportion of the traffic is of this kind, HDX operation relieves the switching center of a large part of its load.

The multiple-address capacity of the switching unit is limited only by the total number of stations on the lines switched by the unit. Since the director processes each address separately, it will continue to set up crossoffice paths

---

Paper 59-1105, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11-16, 1959. Manuscript submitted April 22, 1959; made available for printing July 15, 1959.

E. R. SHIMMIN is with the Pacific Telephone and Telegraph Company, San Francisco, Calif.; R. A. VANDERLIPPE and A. L. WHITMAN are with Bell Telephone Laboratories, Inc., New York, N. Y.

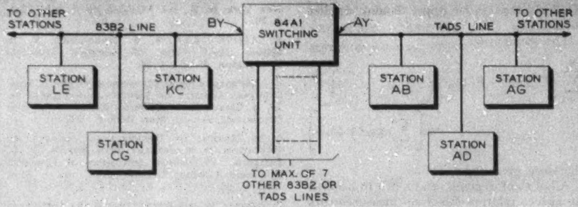

Fig. 1. Typical circuit layout of 84A1 switching system

for as many addresses as the originating operator has punched in the tape.

Group codes may be used in a limited way. A single group code will call in stations on only one line. The switching unit will not set up connections to two or more lines on one code. A group code, reaching its destination line, will connect, on that line, all of the stations to which the code applies. As many group codes can be used as desired, provided that each of them calls stations on only one line.

The unit will not handle a single broadcast code for all lines or all stations of a system.

Typical Circuit Layout

Fig. 1 shows a typical circuit layout of an *84A1* system, with the connecting selective calling lines, which may be of either the TADS[1] or the *83B2*[2] variety. Parenthetically, the *83B2* system is a slightly modified version of the *83B1* system described in reference 2, the changes being principally to increase flexibility in the assignment of call directing codes (CDCS) and to simplify and improve interline switching arrangements.

It is recalled that the basic features of the selective calling lines are HDX operation, at 60, 75, or 100 words per minute. The selective calling features are principally the automatic starting of the station tape transmitters, and automatic selection of the desired receiving stations, so that the message is received at only the stations to which it is addressed.

The switching center, on the line side, operates just like any other station on the line except that for convenience of circuit design the selective calling control station, with the transmitter start circuit, is always located at the switching center. The connection between the lines and the switching unit is made, as Fig. 2 shows, with two reperforator-transmitters for each line, one for incoming traffic (ICL RT) and the other for outgoing traffic (OGL RT). The reperforator of the ICL RT is called in by its CDC just like any other receiver on the line. The tape transmitter of the OGL RT is started in its turn (when it is waiting with a message which has been switched across the office for the line) by a transmitter start code just like any other transmitter on the line.

One difference is that the reperforator-transmitters handle only traffic to and from the switching unit. If the location of the switching center is also a business office, it will be necessary to provide one or more extra line stations there. To relieve the crossoffice load as far as possible, these local stations should be on the lines which have the most traffic for the switching center location. The "local outlet" of the switching center is provided by one or more line stations.

The *84A1* switching unit can switch traffic to and from up to nine selective calling lines. A tenth line-termination circuit is provided as a spare. The number of stations on each line, and the total number of stations in a system, will vary greatly with the amount and kind of traffic. It was said before that the present average number of stations on a selective calling line is about ten. It is thought that more than 20 stations on a line will be found only rarely and then only when some of the stations are of a stand-by nature, with very light traffic requirements.

All transmission from the stations should be by automatic transmitters, from punched tape. While manual keyboard sending is possible on *83B2* lines, it prevents the realization of the benefits of an automatic system and is not recommended. TADS lines are not arranged for keyboard sending.

Trunks Between Switching Centers

One or more of the lines connecting to an *84A1* switching unit can be used as trunks to other switching centers. Way stations can be located along these trunks. However, because of the limited switching capacity of the *84A1* unit, the switching load offered by other lines must be reduced to allow for the heavier load introduced by the trunk. Before a multicenter system is projected, the probable traffic should be carefully analyzed to make sure that objectionable bottlenecks are not likely to occur.

The most successful operation of such a system would be expected when the local communities of interest around each switching center were large, while the demand for intercenter traffic was relatively small.

If more than two centers are used they must be in tandem; no provision for triangular trunking is made. Thus messages from one center which must be switched through a second to reach a third impose additional burdens on the switching capacity.

Functions of the Switching Unit

The block diagram of Fig. 3 illustrates the principal functions of the switching unit. For convenience in mapping the traffic flow across the page, the incoming lines are on the left and the outgoing lines on the right. It needs to be appreciated that an HDX circuit operates either incoming or outgoing (though not both at the same time) and consequently line no. *1* at both left and right ends of the diagram is the same line.

This means that, so far as the line itself is concerned, it cannot be sending into the switching center and receiving from it at the same time. On the other hand, on the office side of the reperforator-trans-

mitters, the transmission is essentially FDX. The ICL RT of line *1* can be sending a message crossoffice to one or more other line outlets at the same time that the OGL RT of line *1* is receiving a crossoffice message from some other incoming line.

For purposes of this description, it will be assumed that a message is being received on the incoming line RT from line no. *1* of Fig. 3. As soon as the first character of the incoming message is punched in the reperforator tape, the pivoted transmitter moves away from the punchblock and a loop of tape starts to form between them. A contact is operated which gives a "tape available" signal to the switching unit and makes a "bid" for the director. The director selector automatically searches until it finds line no. *1*, the "busy" incoming line. The director then causes the RT transmitter to step, one character at a time, as it reads the CDCs. When it has read a valid code, it proceeds to set up a crossoffice path to the indicated OGL RT and sends the CDC across the office. For multiple-address messages, the operation is repeated for each CDC until all the necessary crossoffice connections have been made. When a multiple-address message is switched, only the CDCs for a particular line appear in that line's outgoing reperforator.

After all of the CDCs comes the end-of-address code, which is carriage return, line feed, letters shift (CR LF LTRS). On this code the director is released, the incoming transmitter starts and the text of the message is sent across the office at 100 words per minute. It is received as punched tape in the reperforators of all of the OGL RTS which were connected in accordance with the addresses.

The OGL RT bid for a chance to send to its outgoing selective calling line is not made when the OGL pivoted transmitter first moves away from the punch as it receives a CDC from the director. The bid is withheld until the end-of-address code. This is necessary to prevent the outgoing lines from timing out in cases where the director encounters a delay in making a connection because one of the outlets it wants is already busy with another crossoffice connection.

When, however, after CR LF LTRS, the bids are made, the selective calling lines operate in their normal fashion, i.e., each transmitter waits until it is properly polled by the transmitter start circuit of the line, when it starts and sends the message to the line.

Finally the CDCs sent on the outgoing line select the one or more receiving stations to which the message is addressed, and the text of the message is printed at these stations only.

At the end of the text the disconnect code, figures shift, *H*, letters shift (FIGS H LTRS) disconnects the crossoffice paths in the *84A1* unit and prepares them to receive other requests for crossoffice connections. The disconnect code on the outgoing line disconnects the one or more receivers, put the stations in condition to respond to selective calling or transmitter start codes, and restarts the search pattern of the transmitter start circuit so that the next transmitter with a message to send may get its chance.

Trunk Route Codes

If the director reads a CDC for a station on a line out of a distant switching center, it will automatically supply an extra CDC, known as a trunk route code, which is required to advance the message toward its destination. The trunk route code is simply the CDC for the reperforator on the trunk at the distant center. This feature simplifies the format for the originating operator as it removes the necessity of determining in advance for each address which switching center serves its station.

If a message requiring a trunk route code is willfully intercepted, the trunk route code will be supplied in the intercept operation. This makes it possible to introduce the intercept tape at a way station on the trunk without further addition of CDCs.

Message Format

The successful performance of the various automatic operations involved in this travel of a message from an incoming line across the switching unit office to an outgoing line requires a considerable degree of rigidity in the format of the address and control codes. A sample of format is given in Fig. 4. A few words of explanation are needed.

As is described in the selective calling system papers,[1,2] all of the CDCs consist of 2-letter combinations. For timing and other reasons each CDC is followed by a LTRS character. Six of the letters of the alphabet are not used in CDCs, either because they are reserved for control codes, such as *V*, *M*, and *H*, or because they can be generated by a short open on the line (of one or more code element lengths), such as *T* and *O*, and hence are more likely to be falsely generated by hits than characters with more complicated combinations of marks and spaces.

The letter *Y* is reserved for the second letter of all codes used to connect the

reperforator sides of the switching unit RTs. This restriction allows a distinction between intraline and interline CDCs (to be described later), to be made simply and cheaply.

To summarize, six of the letters of the alphabet, *T*, *O*, *M*, *V*, *H*, and *Y*, cannot be used in CDCs. If any one of these letters appears at the director in a CDC position, that address is interpreted as nonvalid and goes to intercept.

This leaves 20 letters available for CDCs. Consequently, subject to some further occasional and minor restrictions on the selective calling lines, a total of 400 different 2-letter codes is available for the system.

Referring now to Fig. 4, the multiple LTRS characters at the beginning and end are an aid to tape handling at the sending station transmitter. (Surplus LTRS characters at the end of a message are promptly discarded by the director.) The code LE cuts on the sending station so that a home copy is obtained while the message is being sent on the line. For an *83B2* line this is optional; on a TADS line the sending station CDC must be supplied. The code BY connects the *84A1* reperforator. The format in the OGL RT tape is shown in the second example of Fig. 4. The station codes are those used in the typical layout of Fig. 1 where the geographical relations may be seen.

On *83B2* lines, a further qualification is needed because of the *V* answerback used for circuit assurance. On all codes valid for the line, which include *LE* and *BY* in this illustration, the sending transmitter (at station *LE*) stops and waits for the return of a *V* from the called station. Such *V*s are returned from stations *LE* and *BY*. But *AD* is nonvalid for the sending line so that there will be no answerback after it. Here use is made of the letter *Y* in the RT cut-on code. This *Y*, combined with the following *V* (the answerback), operates a contact at every station on the line, including the particular station which happens to be sending, so that thereafter the transmitter will not stop, and no answerback is awaited. Thus the codes, nonvalid for the sending line but needed for the interline connections at the other side of the office, can be punched in the RT tape without unwanted system operations.

It follows that all intraline codes should be punched in the tape before the RT cut-on code. If one of them were added inadvertently after the RT code it would go on into the switching unit and appear at the director. Here, because of an "exclusion" feature which prevents a code from being sent back on the line from which it came, it would go to intercept. This would call the attention of the switching unit operator to the fact that a format error had been made, since he could see that the code ahead of the intercepted message was a valid code for one of the connecting lines.

Further, on *83B2* lines, it is necessary to prevent the *V* answerback after the RT CDC from being punched in the ICL RT tape. The circuit is so arranged that the reperforator is blinded until after the *V* has been received. Thereafter it is unblinded and the wanted crossoffice CDCs are punched in the tape.

Intercept

To a teletypewriter circuit designer, a lost message is one of the cardinal sins, and much design effort is expended to devise means to prevent this happening. One way is to provide an automatic means for intercepting messages which cannot be delivered because of a wrong or garbled address or because the receiving station is in trouble or out of service.

The *84A1* system is well provided with intercept features. In the first place, each connecting line has its own line intercept arrangement. Undeliverable messages addressed from one station to another on the same line are automatically intercepted. Incidentally, this feature makes possible the unattended operation of outlying stations with reduced chance of message delays resulting from undeliverable messages.

Second, the switching unit itself will intercept any messages with a CDC which the director does not recognize as a valid code. For a multiple-address message, the director will intercept only those codes which are nonvalid and will continue to process all valid codes to their normal outlets. Therefore, when all of the multiple-address crossoffice paths have been set up and the test of the message is sent, it goes to the intercept outlet as well as to the other correct outlets. The nonvalid code is sent to the intercept machine as an aid to the operator in identifying which intended station did not get the message.

The intercept machine may be a receiving-only typing reperforator (ROTR), which will deliver a readable punched tape for easy reintroduction into the system, or a printer if page copy is preferred.

The term "miscellaneous intercept" has come into general use for the automatic intercept of undeliverable messages. Another type of intercept, known as "willful intercept," takes place when an operator performs a manual operation to intercept deliberately messages for particular destinations. This might be used, for example, when an operator knows that a certain station is to be out of service for maintenance work.

The *84A1* switching unit has a key for each station on its satellite lines which when operated by an attendant diverts to intercept all crossoffice messages directed to that station. In addition there is a group of line keys, each of which will divert the traffic for all of the stations on a particular line.

Another provision for willful intercept is made at the incoming RT cabinet. By the operation of a key, designated FIGS H & INTCP, in conjunction with a BUSY key,

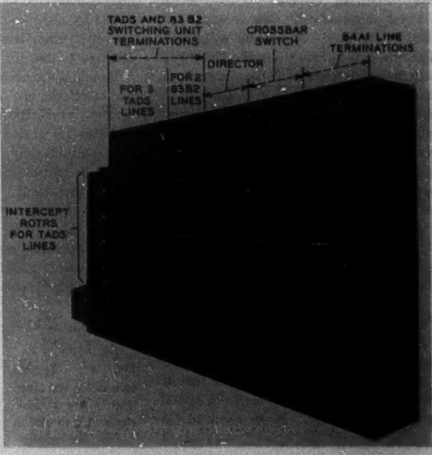

Fig. 5. The 84A1 switching unit with 83B2 and TADS line equipment

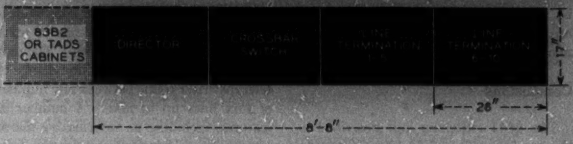

CABINET HEIGHT: 7 FEET

Fig. 6. Cabinet lineup for 84A1 switching unit

an operator may divert to intercept a message which is waiting in the ICL RT. This may be used to relieve a director tie-up caused by a busy OGL RT.

Director Operation on Nonvalid Letters and Function Characters

The director operations are performed in two fan circuits, called the first fan and the second fan. The normal operation of the director on CDCs (two valid characters plus one LTRS character) is to process the first character in the first fan, the second character in the second fan, and then to send through the LTRS character. In the case of nonvalid letters or function characters several different things may happen, depending on the circumstances.

If a LTRS character appears in the first fan it will be discarded. This is to dispose of the LTRS characters which may precede the CDCs and to assure that after these LTRS the CDCs will be in step, i.e., first CDC character to the first fan and second to the second fan. If a LTRS character should appear in the second fan, because of a malfunction which threw the CDCs out of step, the message would go to intercept.

Any of the following characters in either the first or the second fan are nonvalid as CDC characters and so will send the message to intercept: Blank *T*, *O*, *M*, *V*, FIGS, and Space.

Either CR or LF appearing in the first fan is recognized as end-of-address. The director is retired and does not process the following characters as CDCs. If CR or LF appeared first in the second fan, not having appeared in the first fan, the message would go to intercept.

These features increase the degree of protection provided in the switching unit against lost messages.

Alarms, Keys, and Lamps

The control panels in the *84A1* equipment cabinets have a number of alarm lamps and control keys designed so that an attendant may discover quickly the source of trouble and take steps to correct it. A common alarm lamp and bell, interlocked with the individual alarms, alerts the attendant in case of trouble anywhere in the switching center.

As an illustration, the excess-wait alarm in the director cabinet serves notice that the director has been waiting more than 2 minutes for a crossoffice connection to an outlet which it cannot reach because the outlet is busy. A lamp shows which outlet is causing the delay. There are two possible outcomes in this situation, depending on what the attendant does with the AP (automatic push to intercept) key. In the regular position of this key, the director continues to wait for the outlet; as soon as the outlet is free, the director makes the connection and the alarm is retired. When the key is in the AP position, the message which was waiting is automatically routed to intercept at the end of the 2-minute wait period, and the director is released to process the next incoming message. The excess-wait alarm does not appear in this case, but the intercept alarm tells the attendant that some action on the intercepted message is required.

A key is provided to stop the action of the director entirely, which may be needed to patch in the spare director or during maintenance operations.

A number of the alarms and controls are associated with reperforator-transmitters. Basic are the low-tape alarms, warning the attendant that the tape supply needs to be replenished. Another alarm warns if the tapes are torn or tangled. HOLD and BUSY keys are provided for the incoming and outgoing RTS to hold back messages during maintenance operations on any of the machines. If these keys are operated in the middle of a message, in most cases the action does not take place until the current message is completely sent or received. However, immediate stop can be had if needed.

Supplementing the switching unit alarms are the alarms normally provided with the conecting *83B2* and TADS lines. With the combination, there cannot be a major delay in system operations without a warning to the attendant.

Testing

A test cabinet and test bench for checking the circuits and for testing the machines, are offered as optional equipment with an *84A1* switching unit. The test cabinet contains line and equipment jacks for access to the line circuits, and trunks to the *84A1* switching unit equipment. The test position may be equipped with a monitoring printer, a transmitter-distributor for sending test messages from punched tape, and transmission measuring sets for examining the quality of signals.

The *84A1* switching unit cabinets, in addition to the trunks to the test cabinet, also have test panels behind the front covers normally available for use only by maintenance personnel. These contain various lamps and keys for use in testing the various switching unit components.

Spare Equipment

A spare director is provided in the director cabinet as insurance against lost time in case of trouble and to allow testing and maintenance work without service interruption. Convenient patch cords and connectors inside the cabinet permit easy and fast patching.

One spare line termination circuit is provided in the first line cabinet. It is expected that each switching unit would have some spare reperforator-transmitters to allow for maintenance work.

Equipment Arrangements

The control circuits of the *84A1* switching unit are mounted in four steel cabinets, three of which are shown in Fig. 5. The floor plan is shown in Fig. 6. For fast and easy installation, all connections between the *84A1* cabinets are made by plug-in connectors. Because of the lengths of the cords provided, the cabinets must be arranged in the order shown in Fig. 6.

Matching cabinets, which may be mounted in the same line as the *84A1* cabinets if space permits, contain the *83B2* and TADS switching unit terminations. Three of these are shown in Fig. 5.

The *14*-type reperforator-transmitters are mounted in the standard cabinets normally supplied for them. The ICL and OGL RTS for one line are both mounted in the same cabinet, with the incoming line connected to the upper level and the outgoing to the lower.

The test cabinet and test bench may

be in the same room or, if desired, in a separate room devoted to testing and maintenance.

Conclusions

The *84A1* switching unit described in this paper was designed to be a relatively inexpensive automatic teletypewriter message switching unit for businesses which need more automatic communications than can be given by one or more separate selective calling lines. The unit provides for the automatic interchange of teletypewriter traffic between any number of HDX lines up to nine. A number of features, including an informative alarm system, have been designed for the fast, smooth flow of traffic with a minimum of service interruptions.

Designs for Large Organic Reactor Power Plants

G. H. BOSWORTH
NONMEMBER AIEE

W. E. PARKINS
NONMEMBER AIEE

ONE of the types of nuclear reactors now under consideration for use in large central station plants makes use of an organic fluid as moderator and coolant. The organic fluid technology as applied to a nuclear reactor has been under development for several years. In addition, the Organic Moderated Reactor Experiment (OMRE) has been constructed and operated at the Nuclear Reactor Testing Station in Idaho. A number of preliminary designs have been prepared for organic reactor plants for the production of electric power as well as for the propulsion of merchant ships and the production of process steam for industry.

Perhaps the most suitable application, and certainly the one receiving the greatest present attention, is the use of organic reactors in central station power plants. The Atomic Energy Commission (AEC) recently approved a contract for the final design and construction of a small organic plant for the production of 11.4 net emw (electrical megawatts) for the city of Piqua, Ohio. This plant for Piqua, the OMRE, and the preliminary design for a 150-emw plant have been previously described.[1]

Recently the AEC sponsored a study by the Bechtel Corporation and Atomics International for a large, optimized organic-cooled reactor plant. The study was carried out simultaneously with similar studies by other organizations on the pressurized-water, boiling-water, and heavy-water-type reactor plant.

On the organic reactor project, an engineering survey was first conducted to determine which type of moderator showed the greatest promise for low cost power when used in a reactor cooled by an organic fluid. The survey, which is discussed in a subsequent section of this paper, indicated that a reactor moderated by the same organic fluid used as the coolant, possessed the greatest potential. An effort was then devoted to the preliminary design of a 300-emw-output plant with a secondary effort on the design of a similar plant for 75 emw. Finally, the preliminary design of a completely conventional 305-emw power station was prepared for a comparison of performance based upon identical site conditions. The results of these studies, together with a summary report on the work involving nuclear reactors, have been described in reports[2–6] now made available by the AEC. In this paper, some of the pertinent background technology for organic reactor systems is given, together with brief descriptions of the plant designs prepared and principal conclusions reached during the recent organic-cooled power reactor study.

Background Technology

Of the various organic fluids which have been considered for use in nuclear reactors, greatest attention has been devoted to commercial mixtures of the isomers of terphenyl. This material has been shown to be relatively stable at high temperatures and in the presence of radiation. It is available in large quantities at a cost of less than 20 cents per pound and is made by a process which uses benzene as the raw material. Most of the reactor design work has been based upon use of a terphenyl mixture known as Santowax-R, which boils at a temperature slightly above 700 F (degrees Fahrenheit) and melts over a range of temperatures from about 240 to 300 F.

The principal advantages of organics such as Santowax-R, when used in a nuclear reactor, are the relatively low vapor pressure and the negligible corrosive effect on nuclear fuels and on standard materials of construction. The principal disadvantages are relatively poor heat transfer properties and the gradual chemical decomposition which occurs in the presence of radiation. This decomposition requires purification of the coolant and the addition of fresh make-up material.

HEAT TRANSFER

Considerable experimental work has been carried out on many aspects of organic fluids, including the heat transfer rates attainable and the rates of radiation decomposition under practical reactor operating conditions. One of the important questions on the subject of heat transfer has been relative to changes in the heat transfer coefficient which might occur over long periods of time due to build up of any surface film from the organic fluid. Measurements in heat transfer loops and in the OMRE have demonstrated that relatively high temperatures, for example 850 F, may be employed at the heat transfer surface without significant long-time changes in the coefficient. The relatively low value of the coefficient itself, however, usually dictates the use of a high-temperature drive, perhaps 150 F, across the heat transfer film. Experiments have shown that in a practical reactor design the bulk organic can exit from the reactor at a

Paper 59-1132, recommended by the AIEE Nucleonics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted June 15, 1959; made available for printing July 28, 1959.

G. H. BOSWORTH is with the Bechtel Corporation, San Francisco, Calif.; W. E. PARKINS is with Atomics International, Canoga Park, Calif.

temperature in excess of 600 F, and that steam can be produced under superheat conditions in heat exchangers at temperatures of 600 F or somewhat above.

One of the heat transfer conditions which is being explored as a result of the recent organic-cooled power reactor study has been the use of subcooled nucleate boiling. Under this condition the heat transfer surface temperature operates above the boiling point of the fluid for the existing pressure, while the bulk fluid is at a temperature below the boiling point. Vapor is produced by boiling at the surface and it subsequently condenses in the bulk fluid. The advantage of this heat transfer mechanism is that good heat transfer rates can be achieved at low fluid velocities as compared with the velocities which would be required under nonboiling, or forced convection, conditions. This has the effect of reducing pressure drops in the organic circulating system and of lowering pumping power requirements. Experiments are presently in progress to establish the limiting conditions under which nucleate boiling heat transfer can be applied in a reactor core.

ORGANIC DECOMPOSITION

The operating conditions of current interest in organic-cooled power reactors are well below the temperature range where thermal, or purely pyrolytic, decomposition is appreciable. This pyrolytic decomposition is primarily related to the temperature of the bulk fluid, whereas the limiting conditions are presently being established by the temperature of the heat transfer surface.

The other type of decomposition, that which is due to the effects of radiation, is still present in any operating organic reactor. This decomposition results in the formation of volatile light hydrocarbons as well as in polymers, or high boilers, of lower vapor pressure than the organic feed material. The principal contributors to this radiation decomposition in an organic reactor core are gamma rays and energetic neutrons.

The radiation decomposition rates of organic fluids have been carefully measured in the OMRE as well as in separate in-pile experiments. This rate has been shown to decrease as the equilibrium high boiler content of the circulating organic increases. For this reason, as well as to reduce the rate of purification requirements in any practical organic reactor it is planned to operate with a high boiler content, in the neighborhood of 30%. Under such conditions the make-up requirement for the addition of fresh organic to the system amounts to approximately one pound per thermal megawatt-hour of operation. The cost contribution of this operational requirement amounts to approximately 0.6 mill/kwhr (per kilowatt-hour). It is expected that future reductions in the cost of the commercial organics and the eventual use of inhibitors in reducing radiation decomposition rates will appreciably lower this organic make-up expense.

REACTOR FUEL

Since the organic is a noncorrosive liquid, it is possible in principle to use any of the available nuclear fuels. It is, of course, desirable to clad the fuel material with some metal to prevent the escape of fission products into the coolant.

Previous designs of organic reactors have given principal emphasis to a fuel of uranium metal alloy clad with aluminum. An alloy consisting of uranium with 3.5% molybdenum and 0.1% aluminum has been recommended as one possessing good properties of stability for relatively high burn-up at the required operating temperatures. This material may be metallurgically bonded to aluminum cladding through a thin nickel-plated interface. To improve the heat transfer in the organic fluid, most designs have been based on an extruded aluminum cladding incorporating short fins to increase the surface area. Such a surface is arranged so that the fins are parallel to the direction of fluid flow, and in a practical case the fin configuration more than doubles the heat flux attainable from the fuel surface for given temperature conditions.

More recently, again as a part of the organic-cooled power reactor study a recommendation was made for the use of uranium dioxide (UO_2) as the fuel material. In this case the lack of strength of UO_2 itself led to the choice of APM (aluminum powdered metal, made by sintering aluminum and a small percentage of aluminum oxide) as the cladding material. A fuel rod made from these materials consists of a column of cylindrical pellets of UO_2 sealed with a helium gas atmosphere inside of a long tube of APM. Again, the design incorporates extruded longitudinal fins on the APM tube. The complete fuel element consists of a large number of the APM-clad UO_2 rods assembled into a box of square cross section through which the organic coolant flows.

The use of the APM-clad UO_2 is compatible with the high-temperature surface conditions desired. In addition, the UO_2 has been shown by a number of experiments to be a good stability fuel capable of achieving very high burn-up. The heat fluxes attainable from the UO_2 rod, as limited by the melting point of UO_2 at its center, are compatible with those which can be employed with the organic fluid.

Organic-Cooled Power Reactor Study

The study on a large organic-cooled power reactor plant by the Bechtel Corporation and Atomics International was initiated in December 1958. One of the guiding principles for this study was the objective of optimizing the size of the nuclear power station with regard to the anticipated growth of utility systems and to the production of minimum cost power. The plant was to be based on the most advanced technology available, consistent with a start of construction in July 1960.

REACTOR SELECTION

One of the first tasks was to select the moderator material leading to the design of highest over-all performance, when used in a large reactor cooled by an organic fluid. The moderating materials included in this evaluation were beryllium, beryllium oxide, zirconium hydride, heavy water, light water, graphite, and organic fluid. Survey nuclear and heat transfer calculations were conducted to determine the relative sizes for reactors utilizing these different moderators, and designs were prepared to assess the principal engineering problems.

Estimates of the differences in capital and operating and fuel costs were made to indicate differentials in the cost of power from the several systems examined. The reactor types were evaluated primarily from the point of view of incremental costs, although factors such as technical status, required development program, and feasibility from the standpoint of start of construction in July 1960 were necessarily considered.

Of the various concepts examined, the organic-moderated and cooled reactor system showed the lowest total power cost. In addition, this system resulted in the simplest design and required the least research and development effort. It was apparent that the organic-moderated type was also in a position to benefit the most from future anticipated reductions in coolant make-up cost. It was concluded, therefore, that the further design effort should be directed toward an advanced organic-moderated and cooled reactor plant, designated the OMCR.

The selection studies indicated the

second choice of moderator for an organic-cooled power reactor to be graphite. Such a graphite-moderated organic-cooled power reactor plant could be constructed in a large size and would produce power at costs approaching those from a reactor plant using organic fluid as the moderator. An attractive aspect of the graphite-moderated design is that, because of the use of externally manifolded fuel channels, this system offers a very promising future means of producing nuclear superheat. For this purpose certain of the outer fuel channels would be cooled by the steam produced in steam generators heated by the organic circulating through the other fuel channels.

Unit Capacity Selection

A unit rating of 300 emw net was selected as the size best meeting the various criteria stipulated by the AEC for the reference plant. The primary considerations leading to this selection were

1. Extensive discussions with turbine manufacturers revealed that, for the optimum steam conditions, a 300-emw unit would be the maximum size which could be made available, based on present and near-future turbine design technology.
2. Trends in the utility industry continue in the direction of constructing larger units, in line with the growth of markets and load centers. Units of 300-emw rating will be increasingly attractive in the future and are in the size range expected to constitute a significant fraction of the total new plant capacity to be constructed.
3. A single organic reactor installation is capable of supplying the required steam flow at suitable conditions for a 300-emw unit. Actually, a single reactor is capable of supplying much larger plants without imposed engineering limitations.
4. The emphasis on minimum generation cost logically leads to selection of large units to take advantage of economies inherent in large pieces of equipment and to distribute construction and operating costs over the maximum output of electrical power. The maximum size of available turbine essentially sets the plant size.

300-Emw OMCR Plant

The 300-emw OMCR plant is illustrated in Fig. 1. The reactor building is a 190-foot-diameter self-supporting hemispherical dome enclosing the reactor, primary coolant loops, steam generators, and fuel storage facilities. This building provides a low-pressure containment barrier to prevent any uncontrolled release of radioactivity to the environment. The low reactor building wing in front of the dome houses reactor and primary loop auxiliaries and is surmounted by the ventilation exhaust stack. The large building to the right of the dome houses more conventional equipment associated with the power generating facilities. A central control room, offices, shop, warehouse, and personnel facilities are located in the turbine building.

Reactor

A cutaway view of the reactor for the 300-emw OMCR is shown in Fig. 2. The reactor vessel is unclad and is fabricated of low-alloy steel. It is a cylindrical vessel 67 feet, 7 inches, in height with a welded dished head at the bottom and a removable dished head at the top. The upper section of the tank has an inside diameter of 17 feet and a wall thickness of 2 inches. The lower section, which contains the core, is 13 feet, 6 inches in inside diameter and has a wall thickness of $1^{1}/_{2}$ inches. The vessel is designed for 100 psig (pounds per square inch gage) at 750 F. Sixty-one cylindrical control rod thimbles penetrate the lower head and extend into the subpile room where the control-rod drive mechanisms are located.

The reactor core contains fuel element assemblies of APM-clad UO_2 rods. There are 376 fuel-element positions on a square lattice in the core. Active fuel elements occupy 352 locations with the remaining 24 occupied by 22 dummy elements and and 2 neutron sources. The core is surrounded by a steel inner thermal shield, which also serves as a core-supporting structure. Steel grid plates are used below and above the core with the upper grid containing the necessary provisions for routing in-core instrumentation thermocouple and tubing lines.

The organic coolant enters the core tank at a temperature of 550 F through four 30-inch-diameter inlet nozzles. It flows downward through the annulus between the reactor vessel wall and the inner thermal shield, mixes in the lower plenum, flows upward through the fuel element boxes, and from the upper plenum out through four 30-inch nozzles. Flow distribution through the fuel elements is controlled by individual orifices located at the lower end of each element. These orifices are sized to obtain a flow distribution which will result in a uniform coolant outlet temperature of approximately 675 F from all elements when the reactor is operating at full power. Heat transfer throughout the central region of the core is by means of subcooled nucleate boiling.

The reactor vessel is located within a cavity formed by the concrete walls of the biological shield. A steel outer thermal shield immediately surrounds the reactor vessel in the vicinity of the core, and a commercial thermal insulation occupies the remaining space between the core tank and the concrete wall of the cavity.

Sixty-one cruciform-shaped control elements are used in the reactor core to regulate power, to assist in adjusting the radial and axial core power distribution, and to serve as safety rods for any emergency shutdown. These elements are arranged in such a pattern that in the control region of the core there is one control element for every four fuel elements. Stainless steel is used as the cladding material for the cruciform sections, with the neutron-absorbing materials being Eu_2O_3 in some control elements and boron steel in others. The elements are actuated from the subpile room below the reactor vessel and are removed or replaced from above the core.

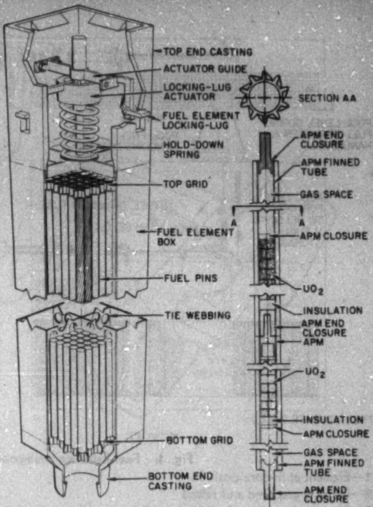

Fig. 3. Fuel element: 100 0.3-inch-diameter UO_2 fuel pins clad with APM in a stainless-steel box

Fuel

The UO_2 fuel is enriched to 2.5% U-235 and is clad with finned APM tubing. Each fuel element, as illustrated in Fig. 3, consists of 100 vertical fuel rods assembled in a long 0.035-inch-thick stainless-steel box measuring $5^1/_8$ inches on a side. The over-all length of the fuel-element assembly is approximately 15 feet, while the length containing fuel within the assembly is approximately 12 feet. Each fuel rod is made of two sections 7 feet long, sealed by APM end plugs. The UO_2 pellets are 0.3 inch in diameter and 0.6 inch long. The fins on the APM cladding tube are fabricated to have a slight helical pitch to prevent meshing and to assure proper spacing when assembled within the fuel element box.

To achieve the most efficient fuel utilization it is necessary to obtain the maximum possible burn-up for each fuel element in the reactor. By properly programing the replacement of fuel elements, it is possible to obtain an average fuel burn-up of 15,000 thermal mw-days per metric ton of uranium. This is based upon a fuel loading schedule which makes use of three annular zones of fuel elements. During refueling periods the fuel is moved from one zone to another with the new fuel loaded initially in the peripheral zone. The high burn-up fuel in the central region of the core assists in uniformizing the radial power distribution.

To remove fuel from the reactor vessel the handling arrangement shown in Fig. 4 is used. The reactor must be shut down, cooled to a lower temperature, depressurized, and the top head removed. A mechanism is provided which engages the upper end of any given fuel element, raises it within the pool of organic above the core, and tilts it to a horizontal position where the fuel element is discharged into a tube leading to the water storage pool. During the transfer to the water storage, separation between the two fluids is appropriately maintained by valves, and the element is cleaned through the action of a solvent wash. This under-liquid handling system has the advantage of maintaining the fuel element immersed, and hence adequately cooled, at all times during the transfer process.

Organic Coolant System

The coolant is specified as Santowax-R containing approximately 30% of high boiler compounds. This fluid is circulated in four parallel heat transfer loops located in separate compartments around the reactor vessel, see Figs. 5 and 6. All piping and components in the organic system are fabricated from low-carbon steel. Each loop is capable of being isolated from the remainder of the system by blocking valves. The pump in each loop is a vertical, 2-stage turbine-type unit rated at 31,200 gallons per minute and uses a 1,500-horsepower motor drive.

The organic liquid circulating in each loop gives up its heat in a U-shaped horizontal tubular steam generator and in a superheater of similar design located above the steam generator. The organic fluid flows in the shell side in the superheater, and in the tube side in the steam generator. At full capacity the four primary loops produce a total of 3,640,000 pounds of steam per hour at 600 psig and 650 F at the turbine throttle. For control of heat input to the steam generators at different power levels, each loop incorporates a valved bypass line around the steam generator and superheater combination.

Each of the four steam generators is provided with two power-operated relief valves, with each valve capable of removing approximately 120% of the steam-generator design steam flow. In addition, each steam generator is provided with safety valves as required by the American Society of Mechanical Engineers boiler code. The primary coolant loops are protected from any excess pressure which would result from rupture of a steam generator tube by a series of relief valves on the main coolant lines.

The plant is so designed that emergency decay heat removal from the core can be accomplished by natural convection circulation through any two of the four steam generators. To avoid dependence on availability of power during this period sufficient feedwater is delivered to the generators by small turbine-driven emergency feed pumps, taking suction from the condensate storage tank and utilizing a part of the steam generated by the decay heat.

Auxiliary equipment for the organic system provides for purification and degasification of the organic and means for disposing of the gases produced. The degasification system removes any water vapor, hydrogen, and light hydrocarbons in the organic by passing a small side stream of the fluid through a low-pressure tank. The purification system separates the reusable coolant from the high boiler material by passing a normally continuous side stream through a single stage of fractionation. New coolant make-up material is added at a rate to compensate for the removal of the high boiler and gaseous material. This make-up rate during full power operation is approximately 1,105 pounds per hour. Gases removed by the degasification system and by the purification system are appropriately filtered, diluted by the building ventilation air stream, and exhausted through the stack. Special equipment is provided to remove fission products from the gases in the event of fuel-element cladding failures. Any radioactive material removed with the high boiler reject is allowed to decay to safe levels for waste disposal by burning, through the use of storage tanks sized for a maximum of 106 days of storage during full-power operation.

TURBINE-GENERATOR AND ASSOCIATED EQUIPMENT

A flow diagram and heat balance for the steam system is given in Fig. 7. Nonradioactive superheated steam at 600 psig and 650 F drives a 300-emw (nameplate rating at 3.5 inches Hg [mercury] and 3% make-up) tandem-compound double-flow turbine-generator unit with a guaranteed throttle flow of 3,450,000 pounds per hour at 1,800 rpm. The gross and net outputs of the turbine-generator plant with 57 F river water and a condenser pressure of $1^1/_2$ inch Hg absolute are approximately 313 emw and 300 emw respectively. The gross heat rate is 10,414 Btu/kwhr. Exhaust steam from the turbine flows into a single-pass divided water box condenser located below the turbine. Screened river water is used to condense the steam which is reused in the system. The condensate is pumped through two low-pressure extraction steam heaters and a deaerating heater to increase its temperature. Boiler feed pumps taking suction from the deaerator force the feedwater through two high-pressure feedwater heaters and into the steam generators at a pressure of 635 psig and 400 F where it is again converted to steam, thus completing the cycle. Make-up requirements are met by evaporating treated river water in the auxiliary heating boilers and introducing the distillate into the deaerator.

Plant auxiliary equipment requiring heat removal is served by one of two systems. In the service water system, chlorinated river water is circulated through the generator hydrogen coolers, turbine lubricating oil coolers, and heat exchangers for other separate closed-loop systems. Buffered condensate is circulated through the cooling water system to the air compressors, air dryer, and heat exchangers for which river water is not suitable. This cooling water circulates in a closed system, losing its heat to the river through a heat exchanger in the service water system.

The generator is of the totally enclosed, nonsalient pole type, is rated at 384,000 kva, 0.85 power factor, 326,400 kw, 0.64 short-circuit ratio, and generates at 16,500 volts, Y-connected. The stator is a double-winding type with the windings terminating in 12 terminal bushings, 6 on each end of the generator at the bottom. The generator is hydrogen-cooled at 45 psig. Two motor-driven full-capacity (one spare) exciters are provided, rated 1,800 kw at 500 volts d-c. A motor-operated exciter field rheostat and voltage regulator of the magnetic amplifier type are provided.

The generator is connected through metal-enclosed bus to the terminals of the low-voltage delta winding of the main power transformer. The high-voltage windings of the main power transformer will be connected by an overhead line connection to a 230-kv switchyard. Taps are provided on the main generator bus for service to the two auxiliary transformers which step the generator voltage down from 16,500 volts to 4,160 volts to serve the main power auxiliaries. Service at 480 volts for intermediate power requirements for plant process systems and building facilities are provided through 480-volt unit substations and motor control centers.

Normal auxiliary power is provided from the generator bus through two 1/2-capacity transformers which step the voltage down to 4,160 volts to serve main power auxiliaries. A start-up transformer delivers outside power at the same voltage and can carry up to half the unit load during a generator outage.

A highly reliable emergency power system is provided as required for essential loads to protect equipment, maintain ability to restore generation quickly, or ultimately to permit safe shutdown of the unit. Two diesel generators are available to back up power on the 480-volt emergency bus which also feeds a 125-volt battery system through two battery-charging inverter-type motor-generating sets. Certain critical auxiliaries which must be maintained to insure a programed reactor shutdown on loss of load can be supplied by these motor-generator sets during the interval required for one

of the diesel generators to come on the line.

Control and Instrumentation

The reactor control and instrumentation system provides for automatic load following control in the power range and nonload following control during start-up and normal shutdown. In addition, it functions as the plant protective system providing automatic action to minimize or prevent damage as a result of misoperation or malfunction of equipment. There are instrumentation systems which furnish information on plant functioning and on the radiation levels in various areas. A diagram of the reactor plant control system is shown in Fig 8.

To provide the automatic load following control, system frequency regulates the throttle valve and voltage controls excitation. Feedwater control is assured by a conventional 3-element controller. Steam pressure ahead of the turbine throttle is used to control the flow of coolant by-passing the steam generators, thereby setting the rate of steam generation. The bulk temperature of the coolant from the reactor is used to control reactor power by automatic positioning of control elements. Up to 20% of the steam flow to the turbine can be manually bypassed to the condenser to facilitate start-up.

Emergency shutdown (scram) of the reactor is brought about by gravity insertion of all of the control elements into the reactor core. Scram, or power setback, wherein the control elements are driven at a controlled rate into the core, is automatically initiated by a number of signals. These are high or low coolant system pressure, high neutron flux, short neutron period in the start-up power range, high coolant outlet tempera-

ture, low coolant flow, low feedwater level, and loss of pumping power in two or more loops. In the event of a reactor scram, all of the bypass valves are trip-closed and the throttle valve tripped to an open position. This action minimizes thermal shock to the steam generator and automatically sets flow in the organic loops to the proper condition for decay heat removal by natural convection.

75-Emw OMCR Plant

The 75-emw OMCR was designed as an intermediate-size version of the larger plant just described. The 75-emw plant is based upon the same design criteria and incorporates essentially all of the same features as the 300-emw plant. Table I compares the specifications of the two plants.

There are two major design differences resulting from reduced size which merit mention. The 75-emw plant requires a much smaller primary system coolant flow; therefore, three loops of 24-inch-diameter pipe are used instead of four loops of 30-inch-diameter pipe as employed in the larger plant. Because the core height is less in the 75-emw reactor, the change in coolant temperature in passing through the reactor is 75 F instead of 125 F, where the outlet temperature has been maintained the same. This invites the use of 1,000-psig steam cycle, which has a lower steam rate, 9,822 Btu/kwhr, instead of 10,414 Btu/kwhr for the 300-emw plant.

Economics

The capital cost of engineering and construction of the entire plant for the first 300-emw unit has been estimated at $69,510,000, which is equivalent to $232 per net electrical kilowatt (ekw). Included in this total is the $300,000 which would be saved if no provisions were included for future plant expansion. These costs include escalation and interest during construction. For purposes of comparison with the reactor plant costs, as usually stated, the present-day cost excluding escalation and interest during construction is $184 per net ekw.

Several factors contribute to the relatively low cost of an organic reactor power plant. These are primarily related to the low vapor pressure of the coolant and the fact that it is noncorrosive. As a result, the reactor and its coolant system are designed for low operating pressures and are fabricated from low-carbon steel and other conventional materials. The use of the organic fluid as both the moderator and coolant adds to the simplicity of the system. In addition, the fact that the reactor is basically hydrogen moderated assures a compact core with resulting minimum costs for structure and shielding.

The estimated fuel cycle cost, at 80% plant capacity factor, varies from 2.67 mills/net kwhr (24.2 cents/million Btu) initially, to 2.45 mills/net kwhr (22.2 cents/million Btu) for the steady-state operation, based upon plant operation in the year 1963. Using an annual charge of 14% against the total plant investment, and adding the steady state fuel and other annual charges, the average cost of producing electric energy is estimated to be approximately 8.12 mills/kwhr at a plant capacitp factor of 80%.

Aside from further improvements in the design which may result in cost reductions, there are several areas in which substantial reductions in over-all power costs from an organic moderated and cooled reactor may be anticipated. These areas of potential improvement and their effect on the over-all cost for the 300-emw OMCR are as follows:

Table I. Comparison Between 300-Emw and 75-Emw OMCR Power Plants

	300 Emw	75 Emw
Turbine Plant:		
Turbine nameplate rating emw at $3\frac{1}{2}$ inches Hg	300	75
Electrical output (emw), gross/net, at $1\frac{1}{2}$ inches Hg	313.3/300.0	79.5/75.3
Gross plant heat rate (Btu/kilowatt-hour) at $1\frac{1}{2}$ inches Hg	10,414	9,822

Total	6.77	8.12	13.12
Possible future conditions, total	7.24†	7.2‡	12.2‡

* Coal at 35c/million Btu.
† Coal at 40c/million Btu.
‡ Realization of 0.9 mill/kwhr anticipated saving.

1. Reduction in the cost of the polyphenyl material from a present cost of 17 cents per pound appears likely for any substantial volume production. A price of 12 cents per pound for 100 million pounds per year has been estimated by a principal supplier. This would result in a decrease in power cost of 0.19 mill/kwhr. It is also possible that chemical additives will be found which can serve to reduce the rate of radiation decomposition.

2. Fuel preparation and fabrication costs are expected to be reduced by up to 40% by 5 years of development and some experience with plant operation. The resulting savings in power cost would be approximately 0.37 mill/kwhr.

3. It is believed that it will prove practical to utilize APM instead of stainless steel for the fuel element boxes in the core, with a resulting significant improvement in the neutron economy of the reactor. Such a substitution would save about 0.30 mill/kw-hr.

4. It is believed that it will be possible to extend average fuel lifetimes to as much as 20,000 mw-days per ton with a resulting saving of about 0.21 mill/kwhr in the power cost.

5. The reactor and the other plant components are designed with a margin of about 5% over the guaranteed steam flow of the turbine at design temperatures and pressures. If this design margin is realized, the actual full-load capability of the plant would be about 310 emw net under the expected average operating conditions. Such an increase in capacity would reduce the estimated power cost by about 0.16 mill/kwhr.

While the total of these savings is 1.23 mills/kwhr (which would reduce the power cost from 8.12 to 6.89 mills/kwhr), it is not probable that all of such reduction would be fully attained at once or at an early date. However, each of the reductions is considered to have a high degree of probability, and it would seem likely that a reduction in estimated costs approaching 0.90 mill/kwhr is a realistic expectation. The over-all power costs from the 300-emw plant would then be approximately 7.2 mills/kwhr.

Design and construction of a first single-unit 75-emw plant requires an estimated capital investment of $32,150,000, or $427/ekw net. The steady-state fuel-cycle cost for this plant is estimated to be 2.83 mills/kwhr. The addition of fixed, operating, maintenance, and organic make-up costs results in a total power cost of 13.12 mills/kwhr using the same criteria as specified for the larger plant. Since the anticipated cost reductions listed for the 300-emw plant also apply to the smaller plant, it is reasonable to expect that power costs for the 75-emw plant will approach 12.2 mills/kwhr.

COMPARISON WITH 305-EMW COAL-FIRED PLANT

In response to a request from the AEC the Bechtel Corporation compared the economics of a conventional fossil-fueled plant with the large OMCR plant. The study yielded the interesting results summarized in Table II. Power costs of the 75-emw plant are included to indicate the comparative economics of operating a smaller demonstration plant.

A striking observation obtained from comparing the detailed costs of the 300-mw plants is that the equipment costs for the nuclear and conventional plants are identical. The cost for structures is higher for the nuclear plant due almost entirely to the shielding and special building requirements. Indirect and engineering costs and contingencies for the nuclear plant are very much higher than for the conventional plant, reflecting the much less advanced state of the art. However, it is likely that further experience with large nuclear plants will assist in reducing these costs to what might be regarded as a normal level. When this is accomplished, the OMCR capital cost should approach that of a conventional coal-fired plant.

It was noted that the longer construction schedule and start-up time required for the nuclear plant led to significant increases in the cost of interest during construction. Further experience with nuclear plant construction and operation will result in these costs becoming more nearly comparable as well.

The cost of power generation by the conventional plant is very sensitive to the fuel cost on which it is based, since capital charges are relatively low. An increase from 35 cents/million Btu to 40 cents/million Btu, for example, results in an increase of the power generation cost to 7.24 mills/net kwhr. Additionally, an increase in plant factor from the 80% stipulated to 90%, which is typical of base-load operation, is more beneficial to the OMCR than to the conventional plant. When viewed in this light, and when consideration is given to the potential savings which can reasonably be expected in the OMCR fuel and operating cost as outlined above, it is reasonable to expect that, in areas of relatively high and increasing fossil fuel cost, a large OMCR-type unit operating as a base-load plant can become competitive shortly after start-up.

Summary

During the last several years the concept of a reactor plant moderated and cooled by an organic fluid has been established as a feasible approach to nuclear power. Tests at the OMRE and separate experiments have demonstrated that the radiation decomposition rate of the organic represents a nominal additional operating cost item. Measurements of heat transfer rates have shown that the organic fluid can be used under temperature and heat flux conditions of interest over long periods of time. The experimental work and the long-term operation of the OMRE have demonstrated the advantages and disclosed no unexpected difficulties in the potential use of the organic type reactor in central station plants.

Preliminary designs of organic reactor plants have been prepared for sizes ranging from 11.4 emw to 300 emw. A plant designed for 11.4 emw is now under contract for construction in the city of Piqua, Ohio. Other designs using similar operating conditions but for larger power outputs, have been previously prepared. Most recently, an engineering study was conducted by the Bechtel Corporation and Atomics International for the preliminary design of a large organic-cooled and moderated reactor (OMCR) power station. This work was carried out for a 300-emw installation and subsequently modified for a plant of 75-emw output.

The design of the OMCR was based on certain advanced features and operating conditions. Subcooled mucleate boiling was employed as the principal heat transfer mechanism in the core. The fuel elements consisted of assemblies of APM-clad UO_2 rods. The maximum temperature of the fuel rod surface was taken to be 850 F and the design used a relatively high temperature change for the organic passing through the reactor.

Estimates were made of the fuel cycle and capital cost of the 300-emw plant. With escalation and interest during construction, the net cost of power at 80% plant capacity factor was calculated to be 8.12 mills/kwhr. The equivalent figure for a 75-emw plant was 13.12 mills/kwhr. A design was also prepared for the same basic assumptions on a 305-emw coal-fired conventional plant. With fuel costing 35 cents/million Btu, the cost of power for the conventional plant was calculated 6.77 mills/kwhr

Based on the preliminary design of the 300-emw plant, it is apparent that the power cost from an OMCR has not yet reached a value achievable with conventional installations. However, the margin of power cost difference is small and there are a number of factors expected further to reduce the cost of power from the organic-type reactor plant in the future. Based on the present information, it appears that the potential use of this reactor type in central station power plants certainly holds sufficient promise to warrant the construction of prototype units as well as a continuing strong effort directed toward development of the organic reactor technology.

The Challenge of Universal Mobile Communications

ALAN F. CULBERTSON
MEMBER AIEE

PROCEEDINGS now under way before the Federal Communications Commission are again exploring the possibility that a large block of frequencies might be made available for extension of telephone service to moving vehicles on a large scale. If such an allocation is granted, universal mobile communications will become practically as well as technically feasible for the first time.

Operation of such a system will be a joint venture of some 4,100 operating telephone companies in the United States, of dozens of manufacturers who will supply the system components, and of the various laboratories which contribute long-range system planning for the telephone industry. A peculiarity of this type of service stems from the fact that roughly two-thirds of the territory to be covered by a universal mobile communications system is served by independent telephone companies. This means that a great deal more co-ordination between companies is going to be required than any previous program of similar scope. Thus it is appropriate at this stage to define some of the objectives of a universal mobile communications service and to consider some of the methods by which it can be accomplished.

Experience with the present limited types of 2-way dial mobile telephone service is beginning to uncover some of the more important problem areas which will need to be explored as the service becomes more and more universal in scope. This new approach, along with the "one-way" dial service which has been in operation for a number of years, is providing valuable experience both in the field of control and supervision and also in the field of transmission, where more and more information is being gained about the needs of a commercial grade of telephone service to be provided by radio.

Several important contrasts are immediately apparent between the field of 2-way radio and that of mobile telephone service. The principal difference is the matter of coverage and resulting transmission quality. Telephone subscribers cannot be forced to accept degraded transmission, the use of code words, and special operating procedures. Because of the different approach to coverage required in a universal mobile communications serv-

Paper 59-1148, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted June 12, 1959; made available for printing August 25, 1959.

Alan F. Culbertson is with Lenkurt Electric Company, Inc., San Carlos, Calif.

The author wishes to acknowledge the assistance of K. B. Breymayer in working out some of the material in the paper.

ice, it will undoubtedly be found that an altogether new approach in the field of transmission equipment will be required as well.

In order to approach the characteristics of the dial telephone, it will be necessary to find an adequate but inexpensive substitute for the physical wire connection between the conventional telephone and the central office. This physical path is now being made to handle certain essential low-information-content signals both simultaneously and sequentially with speech. These include on-hook and off-hook supervision, dial pulses and ringing current. Performing these same functions via radio is not quite as natural to the medium and considerable research may be required to reduce their cost before they can be applied to the mobile device.

Objectives

Performance Objectives

The objectives to be set for this type of service can be defined very simply; the universal mobile telephone must operate in a manner similar to the wired dial telephone as we know it today, plus any refinements which the dial phone may pick up along the way while the mobile system is under development. These features include the following:

1. Ready availability of dial tone.
2. "Wire-line" transmission standards
   a. Random noise on circuit
   b. Crosstalk
   c. Over-all circuit net loss
   d. Frequency response
   e. In-channel distortion
   f. Echo and singing limitations
3. Switch-hook supervision—on-hook and off-hook
4. Reliable transmission of dial signaling information
5. Positive method of subscriber identification
6. Fully selective signaling
7. Privacy of conversations (so far as party-line type sharing is concerned)
8. Access to direct-distance-dialing network
9. Full-duplex transmission (no push-to-talk button)

Finally, the system must have the ability to connect to the telephone described from any populated area or along any traveled highway.

Design Objectives

A large number of component and subsystem developments are required to meet the performance objectives. All of them must be directed towards a minimum-cost mobile unit. It must also be borne in mind that maintenance of the mobile units will be in the hands of those who now service the automotive broadcast receivers. The amount of extra training and know-how to be absorbed by these people must be kept to a minimum.

A first approximation of the over-all system objectives yields the following as a starting point.

1. Traffic Capacity. A system of 3–5 channels is probably the minimum to start service in any given area, with channel additions based upon an incremental range to be determined by further traffic studies.

2. Coverage Areas will have to be laid out conservatively to achieve the transmission objectives. In a uhf (ultrahigh frequency) system, satellite transmitters as well as receivers may be required for complete coverage. Cross-control of transmitters (similar to the "adjacent-transmitter-lockout" sometimes used in highway mobile service) will be needed to get maximum geographic sharing of the same channel.

3. Transmission Performance to equal "wired" telephone service will have to be along the following lines for at least 50% of the calls for the mobile system:

Frequency response: 300–2,800 cps (cycles per second), 3 db (decibels) points
Noise and crosstalk, combined:
  Toward subscriber: 40 dba (adjusted) maximum, 0 db transmission level
  Toward fixed plant: 35 dba maximum, 0 db transmission level
Subscriber loop loss: 8 db maximum, both directions
Spectrum shift: 20 cps maximum
In-channel distortion: 20% maximum (0 VU talker)

The Spectrum Stretcher

No matter how many channels may ultimately be available in a broadband system, spectrum conservation and principles of good service will demand more efficient channel usage than is possible with one-channel systems. A load-leveling "spectrum stretcher" will have to be used to apply traffic engineering principles to utilization of the radio-derived trunks.

The spectrum stretcher provides access to several different radio channels for each call and marks the specific idle channel in a group which will be used for the next call.

The manner in which the spectrum stretcher can increase the capacity of a group of channels is shown in a typical example; see Fig. 1. If a grade of service equivalent to a 75-subscriber single channel system is assumed, the capacity of 10 channels can be stretched from 750 subscribers in single-channel service to something on the order of 2,100 subscribers by multiple access.

The nominal party-line traffic engineering data from which these figures were originally derived will undoubtedly have to be reviewed in order to develop some ground rules which will apply to the mobile case. It is also certain that our initial objective will be to provide a better grade of service than that afforded by a 75-party line. However, these illustrations do serve to show how basic traffic engineering principles, long applied to the exchange switching problem, can be used to create 28 new channels in the spectrum where only 10 existed before.

Central Office Switching Arrangements

A universal service can be expected to grow until it is a factor to be considered at

every dial-switching exchange in the country. Thus mobile signaling arrangements must be planned to cause the least possible disruption to existing equipment arrangements.

This planning is complicated by the necessity of dealing with panel, crossbar and Strowger step-by-step exchanges as well as with various types of all-relay exchanges. The ultimate system must be able to work with electronic switching as well.

The simplest approach from the standpoint of the central office is the "line-level" arrangement which has been followed in most of the pioneer 2-way dial mobile systems. A block diagram is shown in Fig. 2(A). This equates one mobile station to one land station and assigns a standard directory number to each mobile. Such a system can be adapted to work on practically any type of line circuit available in the central office; 10-party, 4-party, 2-party, and straight lines. Fully-selective signaling the mobile can be achieved to the same extent practiced on the party lines.

Subscriber identification and charging can be accomplished with the line level approach in the same manner as it is for land subscribers. Various arrangements of Strowger Automatic Toll Ticketing (SATT) can be made to work on multi-party lines. Bell System automatic message accounting equipment (AMA) will work directly from one- or 2-party lines.

Widespread use of the spectrum stretcher will influence this picture to some extent. The spectrum stretcher will concentrate a large number of mobile stations into a relatively small number of channels. Thus some equipment savings are possible if no line circuits are provided at the central office. This "trunk-level" approach is illustrated in Fig. 2(B). In this case subscriber identification will have to be accomplished separately by the mobile signaling equipment, possibly as part of the spectrum stretcher.

With line-level termination, selection of the mobile subscriber line will immediately determine the mobile unit to be signaled. With a trunk-level arrangement at least a portion of the mobile subscriber's number will have to be repeated over the mobile service trunk and then translated by the mobile system signaling arrangement. This means more equipment in the mobile signaling portion, but it is common to a large number of mobile units and may have its cost offset by savings in line circuits and in cross connections.

The manner in which a call is placed to a mobile unit with a trunk-level arrangement is shown schematically in Fig. 3. If the mobile unit is associated with the "ROamer 1" central office, then this number might be ROamer 1-2345. Calls for this particular mobile would be directed to the ROamer 1 central office. Within the office, the digits "2345" would be used to select the 2300 trunk group and the last two digits, "45" would be stored.

Upon selection of the marked channel, channel A in the diagram, the digits 45 would be transmitted over it by the mobile signaling scheme. All mobile units in the *2300* group would be monitoring the marked channel, but only one will respond to the digits 45. All other mobiles will scan the remaining channels for the marking indication, and will lock on it to await future calls. The spectrum stretcher can handle only one call at a time for its particular channel group under this scheme, so it is important that the signaling be accomplished in a few milliseconds. It should be fairly easy to operate a high-speed signaling system with the good transmission envisioned for this system.

Mobile Signaling Arrangements

It is evident that a bold new approach to the mobile signaling problem is required to handle an ultimate system with millions

of subscribers. Obviously the signaling scheme must be uniform and co-ordinated on a nation-wide basis. To achieve a universal system, the various schemes now using 2-tone sequential, 2-tone simultaneous, 3-tone sequential/simultaneous, etc., will have to be phased out gradually.

With a universal system everyone must be considered a potential roving subscriber and must have a number assignment consistent with this concept.

Some of the attributes of the signaling scheme which will be needed are these:

1. Capacity at the mobile of about 10,000 combinations minimum, expandable on a building block basis to something on the order of 100 million combinations.
2. Signaling rate on the order of 200 bits per second in about a 2-kc bandwidth, or as fast as economically feasible over a channel with a signal-to-noise ratio of about 20 db or better.
3. Channel-marking to notify the mobile on which channel the next call may be expected. This marked channel will probably also be the one on which the next mobile-initiated call will be placed.
4. Lock-out to prevent two mobiles from seizing the same channel simultaneously, and also to prevent a mobile and a land call from being assigned to the same channel at once.
5. A translating scheme which conceivably may take several different forms:
   - a. Choice of the mobile subscriber to be signaled based upon which central office line is being rung. This option is applicable to line level terminations when 1- or 2-party lines are used.
   - b. A choice based upon the combination of the line circuit and the frequency or polarity of the ringing. This is applicable to line-level terminations in offices with multiparty harmonic, decimonic, synchromonic, or polarized fully-selective ringing.
   - c. A decoding of incoming pulses over the mobile service trunk. This option is applicable to trunk-level terminations where trunks with loop dialing or d-c key-pulsing are employed.
   - d. A decoding of incoming tones over the mobile service trunk. This option is applicable to trunk level terminations where trunks with multifrequency key pulsing are employed.
6. Subscriber identification of the mobile unit. For simplicity, it would be desirable to use the same signals in this direction as in the base-to-mobile direction.

The multifrequency key-pulsing arrangement now widely used over toll lines might be adapted to mobile signaling. This arrangement can be adapted to transmit one or a thousand decimal digits in sequence to suit local conditions. Such an arrangement is now being used in mobile dialing in the Lenkurt Mobiltel* automatic mobile dialing system, where two tones are used to transmit a single digit of a 20-digit code for selective signaling of one in 20 mobile units. A system transmitting decimal digits sequentially would be a fortunate combination of sequential and simultaneous signaling, and would coincide with the decimal system of directory numbers which is in use today.

Base Station Layouts

Operation at uhf means more base stations than at vhf to cover a given area. This brings up the problem of how to maintain continuity of conversation to a subscriber who drives across a base station boundary.

One possibility is illustrated in Fig. 4. This arrangement requires that odd-numbered channels normally be marked for use in the territory of base station no. *1*, with even-numbered channels normally used by base station no. *2*.

When a call is initiated while the subscriber is near station no. *1*, he will be placed on an odd-numbered channel; for example channel no. *1*. As he drives within range of receiver *R2*, it will pick up his channel *1* transmission along with *R1*.

After an appropriate time delay, if *R2* is still receiving continuous channel *1* transmission, the land connection can be switched from station *1* to station *2* to continue the conversation. A system such as this will undoubtedly need further refinement to prevent seizure by mobile units from more than one adjacent base station, for example, but it should be workable as a basic principle.

A fundamental problem will be advance determination of base station locations. Expensive field-strength and advance coverage surveys can be justified only in the most heavily populated areas. The equipment used will have to be very thoroughly engineered so that adjustments in coverage area can be made after installation. In a system of this sort the control arrangements which influence seizure of the mobile and marking of the next usable channel will have a decided effect on coverage. Thus adjustments of these functions can possibly have almost as much influence as antenna heights and transmission line losses in a well laid-out system.

It is assumed that all base transmitters will be multiplexed in some form or other. Thus simultaneous multichannel trans-

---

Vol.
Pt. 1
1959

mission can be accomplished without excessive interchannel crosstalk.

A system of this sort must be planned around a very lower power output from the mobile unit. Thus receiver spacing must be very conservative. A commercial grade of signal should be obtained with a power output from the mobile unit on the order of 1–10 watts.

Roving Subscribers

The most feasible means of handling roving subscribers seems to be to assign them to a small group of separate channels, which would be manually selected by the subscriber as he leaves his home coverage area. The size such a channel group needs to be will have to be determined by actual experience in the field.

Possible arrangement for a roving mobile unit is illustrated in Fig. 5. In this arrangement a mobile unit with the full directory number of 201-ROamer 1-2345 is assumed.

Local channels to which this mobile is assigned all terminate in the ROamer 1 central office in the 201 numbering plan area. Thus when the mobile is operating on local channels, the local call selector can be permitted to respond to any call which transmits the digits 2345.

When the subscriber switches manually to the roving channel group, he increases the discrimination of his selector by cutting in ahead of it a device which will only connect through calls in which the first digits are 201-RO1.

In case there are subscribers who have no use for the roving feature, the roving call selector should be designed so that it can be added to the mobile unit on a building block basis. In large metropolitan areas a selector may be required which will respond to 7 digits even though the subscriber does not roam far enough to require the total of 10 digits. For this application, the *RO1* section should be made available separately from the *201* section.

The mobile unit will have to be arranged to transmit its complete 10-digit identification for all calls it initiates, both local and roving. The following conditions are possible:

1. Local subscribers' calls placed over local channels: mobile identification equipment will verify that the first 6 digits correspond to the local area, and then absorb them. AMA or SATT equipment records only the last four digits, adequate for billing purposes to local mobile subscribers.

2. Calls from foreign mobiles over roving channels: roving channels come into special ticketing equipment which must be arranged to record all 10 digits. Bills are directed to the home area of the foreign mobile subscriber, as in a credit-card call.

3. Calls from foreign mobiles over local channels: because of geographical channel sharing, this situation is bound to exist unless some method is adopted to prevent it. Ticketing equipment on local channels will not normally be arranged to record more than four digits, particularly where line-level terminations are used.

To handle this situation, the subscriber identification equipment on local channels will check the first six digits as mentioned in the foregoing. Where the wrong digits are transmitted, the calling subscriber will be unable to get dial tone until he switches to his roving channels.

Subscriber identification must be furnished at the beginning and end of each transmission. This will provide additional verification in case of fades or other interruptions to transmission. With the high signaling speeds contemplated, channel time occupied by this procedure will be negligible.

Roving Subscriber Location

Initially, it will be up to the toll operators to locate the roving subscriber, based upon suggestions from the calling party. As the system progresses automatic location of roving subscribers will be practicable. The first requisite for this feature is automatic reporting-in by each mobile unit.

It should be possible to design the mobile unit so that it would automatically transmit its complete telephone number at periods not to exceed about 10 minutes whenever the selector switch is in the "Roving" position.

The base receiver picking up such trans-

missions will record them in its identifier register and will feed it to a "roving mobile register" a high-speed memory device, as shown in Fig. 6.

Calls for roving mobiles are then dialed into a "Zone Director" which is associated with the roving mobile register. The zone director would then complete the call through the base station from which the mobile unit was last reported. The roving mobile register will erase all entries stored in it after 10 minutes have elapsed. If the mobile unit is not heard from again, it will be assumed to have gone back to local channel operation or to have left the zone.

Area registers, as shown in Fig. 7, will eventually have to be added to correlate information on out-of-zone mobiles which will be relayed by the zone directors. Ultimately, a national director can be added and no assistance should be required from either the operator or the calling subscriber to locate a mobile telephone anywhere in the country.

Light Traffic Areas

Many of the features previously described will be of little or no value in light traffic areas, where revenue from this service will probably be inadequate to justify their cost.

In order to accommodate this requirement, a standard "core package" will have to be devised which can be mass-produced and applied on a random basis to areas needing coverage but having little traffic to justify it.

Such a package will probably be equipped with a minimum number of channels, which may be all from the roving group. Because of the light traffic density, complex cross-control features can be eliminated. Subscriber identification information can possibly be trunked back to the nearest large office. A standardized light-traffic arrangement can also be designed so that engineering and installation costs can be held to a minimum.

Transitional Arrangements

The system contemplated is a far cry from the type of service now being operated by any branch of the mobile communications industry. Evidently considerable experimentation and testing of principles will be necessary before such a system can be ultimately achieved. A number of transitional stages will be necessary in development, and some of them must be tried operationally.

The financial structure of a mass communications industry dictates that new services integrate as smoothly as possible on a planned evolutionary basis. Thus existing plant can be amortized in an orderly fashion without undue penalty to the new service.

Unfortunately, the nature of frequency allocations is such that if a universal service is to be provided, it is almost certain to be in a band which will require a five-to-one jump in frequency for most of the sets now in use. There can be no gradual transition for radio equipment under these conditions, and entire systems will have to be cut over abruptly when the new equipment goes in service.

There is much about the control equipment which can be reused from one system to another. Our objectives at this stage should be to think of control equipment now under design as being adaptable as the first stage in the trend towards a universal mobile communications service.

It is certainly premature at this stage to attempt to predict in detail the precise characteristics of a signaling system or of a supervision system. It is almost certain, however, that the method now being used in most manual mobile telephone service will have to be succeeded by a system which is more economical of channel time and capable of many more possible combinations.

At this time, at least five different development organizations have designed versions of 2-way dial mobile telephone systems which are being used in various telephone applications. From such developments there is a great deal to be learned about the eventual possibilities of a universal mobile system. Ultimately, of course, one standard will have to be agreed upon and the universal system will have to be organized.

Conclusion

Many dramatic achievements have been credited to the field of electrical communications over the past few years. Radio receivers and transmitters have been miniaturized to an amazing degree. Transistors have reduced power consumption in portable equipment to the point where it is a relatively unimportant problem. Selectivity and stability of radio equipment has been advanced steady so that frequency spectrum requirements per channel are considerably less than they were a few years ago.

In the telephone field, switching and transmission accomplishments have made direct-distance-dialing ultimately possible on a nationwide basis. Even today from a large number of our present 65 million telephones, many other telephones in the country can be reached in a matter of seconds with just a few pulls on the dial.

Table I. Total Number of Subscribers Served per Trunk Group

The high standards of performance required from both people and equipment to permit this accomplishment are staggering to contemplate. Telephone service of this type demands a degree of reliability unheard of in other applications of electronics. The problem of transmission between any random pair of telephones is much more challenging than any specific point-to-point communications problem.

Growth of the wired telephone system to this point has been dependent upon obtaining a right-of-way for the poles, wires and cables which comprise the fixed transmission paths between subscribers. Growth of the unwired telephone service can begin as soon as an adequate right-of-way is obtained through the frequency spectrum to reach the subscribers whose telephones can not be anchored in place.

Appendix I. Traffic Engineering Considerations

By applying standard formulas used in the planning of dial central offices,[1] one may derive various values for the number of trunks needed to handle a given number of subscribers. If traffic in a certain office is known to have an average holding time of 100 seconds, and it is engineered to an average delay of 25 seconds, the figures in first column of Table I indicate the total number of subscribers that can be served by using from one to ten trunks.

The figures in the second column give the same information if the holding time is assumed to be 80 seconds and it is engineered to an average delay of 5 seconds.

It is known that mobile service today is based upon common sharing of a channel by as many as 75 subscribers. In private systems the figure will run much higher than 75. Therefore as a starting point it is appropriate to speculate about the service

Vol.
Pt. 1
1959

capabilities based upon performance no worse than that obtained today with single-channel systems. Fitting a curve to the figures of the first and second columns yields the figures in the third column. These figures are plotted in Fig. 1 of the main body of this paper.

It is quite likely that these heavy subscriber densities will upset the previous rules. There is certain to be a "mobile traffic factor" of some kind which reflects the smaller percentage of time that the subscriber spends in his vehicle, the possibility that he has driven out of the area, and the possibility that the telephone has been turned off. Only time and experience will determine the proper criteria to follow for this type of service.

Relation Between Permanent Magnet Configuration and Performance

P. P. CIOFFI
MEMBER AIEE

THE NECESSITY for minimizing magnet weight has raised questions regarding the most efficient permanent-magnet shape for the magnetic circuit of air-borne magnetrons. The bowl-shaped permanent magnet was introduced, presumably because of its greater efficiency, to replace the conventional U-type permanent magnet.[1] As far as is known, however, no direct evidence has been presented to support this view, and the purpose of this investigation was to determine by magnetic-circuit analysis the relative merits of the two permanent-magnet configurations.

The permanent-magnet structure in question consists of two bowl-shaped Alnico V magnets with their brims in contact and with axial cylindrical pole faces in contact with the magnetron cylindrical pole pieces; see Fig. 1(A). In this manner the volume of the permanent magnet is circularly distributed except for an open wedge for bringing out the output waveguide. The magnet path length is the distance measured along the mean flux path from pole to pole and is determined by the mmf (magnetomotive force) necessary to develop the required air-gap field.

The more common permanent-magnet structure consists of two U shapes about oppositely disposed faces of the magnetron pole pieces; see Fig. 1(B).

The volume of permanent-magnet material and its performance in the magnetic circuit are compared for the two configurations. However, an appreciable part of the total weight of the magnetic-circuit assembly, which must be kept as small as possible for air-borne applications, is in the provision for the cooling and packaging of the magnetron with the permanent magnet. This must also include a nonmagnetic cover to protect the permanent magnet against possible contact with magnetic material and consequent degradation of air-gap field. The excess weight of the magnetic circuit will be determined, in part, by the surface area of the permanent-magnet configuration.

The Magnetic Circuit

The permanent magnet must be proportioned to develop an mmf across its pole faces equivalent to the drop in mmf in the air-gap and pole pieces. A magnet operating at the maximum energy-product point $(\mathbf{B}_m,\mathbf{H}_m)$ on the demagnetization curve, develops the mmf $\mathbf{H}_m,L_m$ with a length L_m and area at the neutral section given by

$$A_m=(\mathbf{H}_mL_m)P/\mathbf{B}_m \qquad (1)$$

where P, the magnetic-circuit permeance, is equal to the sum of the air-gap permeance P_g and the pole piece and permanent magnet surface leakage permeances P_p and P_m respectively.

Because of surface leakage along the axis of magnetization, a corresponding variation of sectional area is necessary to obtain constant flux density operation over the entire magnet volume. The variation of sectional area A, with distance l from the neutral section, for this condition of operation, is illustrated in Fig. 2 for both the U- and bowl magnets which were examined in this study. If f is the average height under the curves of Fig. 2, the average sectional area is fA_m and the magnet volume is

$$V_m=(\mathbf{H}_mL_m)^2fP/\mathbf{B}_m\mathbf{H}_m \qquad (2)$$

The quantity (fP) represents average magnet circuit permeance P_a.

Due to restrictions in magnetron design which fix the pole piece dimensions and presumably also P_g and P_p, minimum permanent-magnet volume is determined by the magnet configuration which minimizes either $P_m/\mathbf{B}_m\mathbf{H}_m$ or $P_a/\mathbf{B}_m\mathbf{H}_m$. Alnico V, the material with the highest energy product commercially available, satisfies one condition for minimum magnet volume. Since surface leakage permeance is proportional to surface area, a magnet configuration with circular cross sections, Fig. 3, and hence minimum surface area, would satisfy the second condition.

The concept presented here, however, is that permeance and energy product are mutually dependent and that least permeance and maximum energy product are incompatible except in ellipsoids of revolution of appropriate dimensional ratio. For any other configuration, the optimum magnet will be determined by a balance of permeance against energy product, which minimizes their ratio. The magnetron magnet is an illustrative example of the dependence of the two factors which determine magnet efficiency. If the relatively long magnet required were disposed as a single curved shape between coplanar faces of the pole pieces, as shown in Fig. 3,

Vol.
Pt. 1
1959

due to unequal flux paths measured from the pole piece equipotential surfaces, the permanent-magnet material would be nonuniformly magnetized and the greater the magnet thickness the greater would be the degree of nonuniformity of magnetization. Assuming operation of the axial path at the optimum point on the demagnetization curve, material on either side would operate above or below this point, i.e., at lower energy product, and average operation below maximum would depend upon the degree of nonuniformity of magnetization.

With a single magnet of circular sectional areas, the condition for minimum surface permeance, the greatest degree of nonuniform magnetization would prevail and operation would be substantially below optimum. By distributing the permanent-magnet material between two magnets, energy product operation would improve as a result of the decrease in radial thickness and consequent increase in uniformity of magnetization. The maximum degree of uniformity of magnetization would be obtained by distributing as much as possible of the permanent-magnet material about the pole piece axis, as in the bowl magnet configuration. The expediency of redistributing magnet volume to improve energy product operation is accompanied, however, by an increase in surface area and leakage permeance.

Magnetic Measurements

To arrive at some assessment of the relative performances of the two types of magnetic circuits for the same practical application, detailed measurements were made on a sample of each type; these data are given in Table I. In this comparison, the magnet volumes differ by only 1.4% and the pole pieces are dimensionally alike except that the contact surfaces with the magnet pole faces are either cylindrical, Fig. 1(A), or rectangular, Fig. 1(B). With comparable permanent-magnet material volumes and pole piece dimensions, differences in magnetic-circuit behavior can be ascribed mainly to differences in configuration of permanent-magnet material.

Magnetic measurements were made with the recording fluxmeter with an estimated error of less than 0.5%.[2] The flux through various sections of the magnet was measured with a single-turn search coil. Measurements on the U-magnet configuration were made by slipping the coil from a given section of one magnet to the corresponding section on the second magnet. Measurements on the bowl magnet were made by removing the coil from the magnet after disassembly of the circuit. No error is introduced by the relatively long interval required for measurements because of the very large time constant of the fluxmeter. The curves of Fig. 2 were derived from these results.

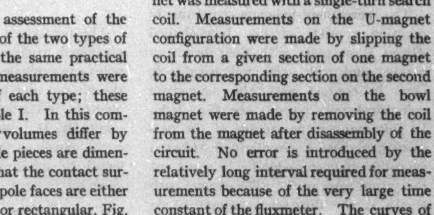

Fig. 3. Magnetic circuit with single magnet of circular cross sections and minimum surface

Table I. Comparison of Magnet Configurations

Cm = centimeters.

Measurements of magnetic-circuit mmf and field intensity in the permanent-magnet material were made with Chattock potentiometer coils.[3,4] Permeances were determined from mmf and flux measurements and average energy product operation of the permanent magnet was determined from equation 2.

The air-gap field $\mathbf{H}_g$ was measured with a small search coil midway between the inner and outer radii of the pole pieces at the center of the air gap. The inconsistency between air-gap field and mmf in these measurements is due to a small discrepancy in air-gap length between the two magnetic circuits. This is evident as an inequality in apparent air gap, given by $\mathbf{H}_mL_m/\mathbf{H}_g$. The apparent air gap is appreciably larger than the nominal dimension because of magnetic saturation in regions of the pole pieces.

Discussion of Results

The striking observation in the results presented in Table I is that the total magnetic-circuit permeance P is only 5% greater for the bowl magnet configuration, and the significant difference between the two magnetic circuits is in the division of permeance between the magnet and pole piece surfaces. The pole piece surface leakage permeance P_p is 33% higher for the U-magnet configuration because the relatively smaller contact surface with the magnet pole faces leaves large exposed areas at full magnetic potential difference. On the other hand, the bowl magnet configuration has 35% greater magnet surface leakage permeance P_m because of its greater surface area, especially in the regions of maximum potential difference. These results indicate that total magnetic-circuit permeance is, for all practical purposes, independent of permanent-magnet configuration and only its division between magnet and pole pieces is affected by configuration. This is to be expected since the major contribution to permeance derives from the polar regions, and the magnet configuration determines whether the predominance of this surface resides in the magnet or in the pole pieces.

The second point of comparison is energy product operation of the permanent-magnet material. The U-magnet configuration operates with approximately 8% higher energy product but, since average permeance is also slightly greater, the ratio $P_a/B_m\mathbf{H}_m$ is not very dissimilar for the two configurations. Average energy product operation, however, is substantially below the characteristic value of 5×10^6 gauss-oe (oersteds) for Alnico V in both configurations. This can be accounted for in the bowl shape by incomplete development of anisotropic characteristics in the direction of final magnetization because of inadequate processing. The behavior of the U-magnet, on the other hand, can be accounted for by nonuniform magnetization and consequent operation at a level of energy product below the intrinsic value. An indication of the relative degree of uniformity of magnetization in the two magnet configurations is illustrated by the difference in field intensity between the outer and inner magnet edges, ranging from approximately 2% to 12% in the bowl magnet, Fig. 1(A), and 8% to 60% in the U-magnet, Fig. 1(B).

The anisotropic characteristics of Alnico V are developed by cooling, after heat treatment, at a controlled rate through the Curie temperature in a magnetic field of appropriate intensity applied in the direction of actual magnetization of the magnet in its magnetic circuit. A misalignment of the processing field will prevent the development of maximum permanent-magnet capability in the direction of magnetization. The processing field for bowl shapes is developed with pancake coils, and inaccurate field shaping by this method may account for the characteristics observed. The U-magnet configuration, however, is better adapted for processing because the magnetic field can be accurately directed with a solenoid of appropriate shape around the magnet. The relatively high average energy product actually obtained, compared with the maximum possible, is indicative of the effectiveness of processing in this shape.

Since magnetic-circuit permeance is practically independent of magnet configuration, energy product operation is the predominant factor in magnetic-circuit efficiency. The U-magnet configuration is potentially capable of operating with the optimum characteristics of the permanent-magnet material but this capability is not realized when the radial thickness is large because of nonuniform magnetization and consequent average operation substantially below optimum energy product. However, since total magnetic-circuit permeance is independent of magnet surface area, the magnet thickness can be made as small as necessary to take advantage of uniform magnetization and maximum utilization of the permanent-magnet characteristics.

Discussion

M. J. Schindler (Radio Corporation of America, Harrison, N. J.): When Faraday introduced the concept of closed lines of induction, he predetermined the evolution of magnetic engineering up to the present. In spite of the fact that the induction **B** has no physical meaning, while the magnetization (or intrinsic induction) **I** does, we still insist on using the former and not the latter. The field in a magnetic object is given by the sum of the external field and the demagnetizing field, which is a function of the magnetization **I** and not of the induction **B**. Therefore, the use of a **B-H** plane in the presence of external fields will even yield incorrect results.

In the case discussed by Mr. Cioffi, use of the **I-H** concept would simplify the issue inasmuch as the distinction between pole piece and magnet stray flux disappears. A given configuration with a given distribution of surface potential will create a certain field configuration and the local magnitude of this field will determine the local operating point of the magnet. Such a static concept of permanent-magnet devices will not, of course, permit thinking in terms of an electrodynamic analogy and therefore it does away with load lines, lumped permeances, magnetic "circuits" and, generally, "Ohm's law of magnetism." On the other hand, it indicates the usability of electrolytic tanks, resistance paper and similar procedures of field analysis, and should provide the design engineer not only with a better understanding of the problem, but also with a more accurate solution.

Recently, I conducted some experiments related to the design of periodic magnetic focusing stacks for traveling-wave tubes. They clearly indicated the superiority of the static concept over the generally used "electrodynamic" design approach, yielding very accurate results.

P. P. Cioffi: Although Dr. Schindler's remarks are thought-provoking, it should be pointed out that no ambiguity will arise in the solution of magnetic-circuit problems if the distinction and relationship between **I** and **B** are kept clearly in mind. An important aspect of problems of this kind, for instance, is the relationship between energy stored in the air gap and the energy product developed by the permanent-magnet material. This is most conveniently expressed in terms of the product of the **B** and **H** co-ordinates of the operating point of the material on the demagnetization curve. While the static concept and the use of the electrolytic tank and similar design aids are useful in magnetic-circuit problem investigations, such methods are of dubious value in the analysis of actual magnetic-circuit configurations compared with the direct method presented in this paper.

Use of High-Speed Digital Computers to Study Performance of Complex Switching Networks Incorporating Time Delays

Y. N. CHANG
ASSOCIATE MEMBER AIEE

O. M. GEORGE
NONMEMBER AIEE

THE two-valued characteristic of a switching network (i.e., the "make" or "break" of a contact, the presence or absence of a voltage at a node, or the activation or deactivation of an electric or mechanical control element) makes it possible to apply the principles of Boolean algebra, an algebra of logic, to the design and analysis of the network. The first important contribution to switching algebra was made by Shannon in 1938.[1] The fundamental concepts, postulates, and theorems of switching algebra are well treated in many books; consequently they will not be presented in this report. Most of the terminology used in this presentation can be found in reference 2. The concept of transmission was chosen for this report on the application of a high-speed digital computer to the analysis of switching networks, although the concept of hindrance could be used equally well.

Switching algebra has been applied to the design and analysis of static switching networks, but sequential switching networks incorporate make and break time delays that introduce hazards if the sequence of events is not properly controlled. The bookkeeping involved in maintaining a time history of each logical element makes calculation very laborious, time consuming, and subject to error. The modern electronic digital computer has three advantages over the engineer in this phase of the problem: (1) it has an accurate memory, (2) it does arithmetic at a fantastic rate, and (3) it has no aversion to tedious and repetitious computations. An extension of the switching algebra notation has been developed by the authors to facilitate the analysis of sequential switching networks on a digital computer. The computer program described in this paper enables the engineer to study the dynamic performance of a complex switching network by including the actual time delays of the logical elements. Therefore, he can check performance, improve the design, and discover sneak circuits caused by improper timing, relay racing, and incompatible conditions, without having to construct and activate the system.

The high-speed digital computer will tabulate a complete time history of a switching network comprising hundreds of logical elements in a minute or less. Thus the engineer can explore the switching network efficiently for input combinations which may not have been considered in the original design. A complex switching network usually consists of several seemingly independent parts. With the aid of a computer, a combined system performance study becomes feasible and economical.

Mechanization of Switching Network for Digital Computer Programing

ELEMENTS, VARIABLES, AND STATES

Digit *1* is used to represent the "1" state (on, closed, energized, activated, etc.), and digit *0* represents the opposite "0" state. In a network, any physical element which has two states is defined as a "logical element." An on-off switch, a relay, the presence or absence of voltage on a control bus or node, an open-and-shut valve, or any other 2-state device is a logical element. A device which has more than two states must be resolved into *n* logical elements. For example, if the device is an *n*-position switch, each of the *n* logical elements is in state *1* when the switch makes contact at its own position, and state *0* when the switch is not making contact at this position. Additional examples are given in Appendix I. A system comprising logical elements is a logical system (reference 2, page 7). To permit the use of a digital computer to study a complex system, all the logical elements in the system are identified by numbers.

Input elements are those logical elements whose states are independent of other elements. Their states are assigned by the investigator from time to time as conditions of system operation.

Dependent elements are those logical elements whose states are to be determined from a Boolean function of other elements. These other elements are called variables. A variable is given the same identification number as its associated

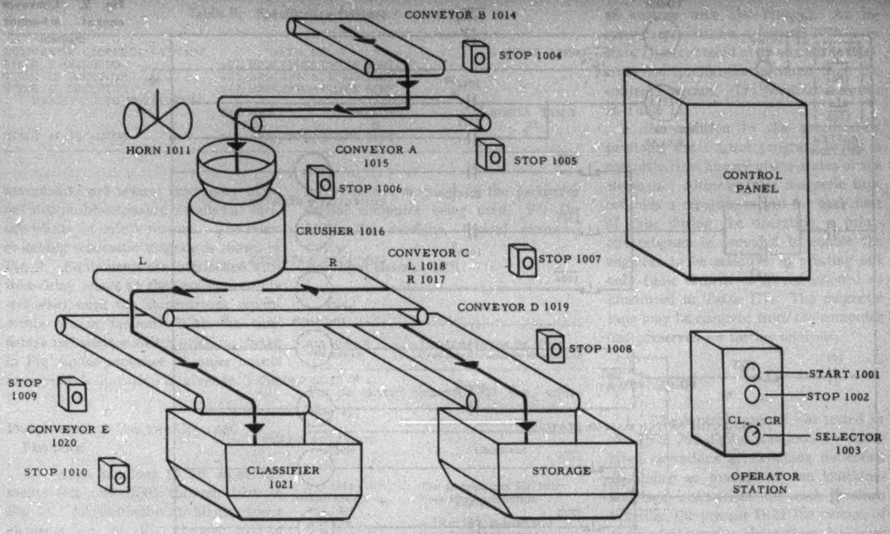

Fig. 1. Conveyor system diagram

logical element. For instance, a transmission function from control voltage to ground for a relay coil may be used to determine the state of this element. When this function becomes *1*, the element is energized; when this function becomes 0, the element is de-energized. However, the contacts of this relay are variables, because they appear in the transmission functions of other dependent elements.

A complemented variable assumes the opposite state of its associated element. A good example of this is a normally closed contact of a relay. When the relay is energized, state *1*, the contact is open, state *0*, and conversely. The complementation is represented by a bar over the number designation of the element. A bar is also used over an expression to represent the complementation of that expression as in conventional Boolean algebra.

Time-Delay Elements

In addition to the sequential nature of the input conditions of a logical system, the elements themselves are frequently the cause of sequential events. Two notations are introduced here to represent time delays of an element: the α-delay is written as a numerical superscript and the β-delay as a numerical subscript on the right-hand side of the number designation of the variable. Each variable may have its own set of α and β values, although the variables are associated with a common element (e.g., a relay may have several different time-delay contacts).

The α-delay is defined as the integer units of time delay between a change of state from *0* to *1* of the element and the change from *0* to *1* of the variable, or *1* to *0* for a complemented variable. The β-delay is similarly defined as the time between a change of state from *1* to *0* of the element and the change of state of the variable. The omission of α and β implies that the change of state of the variable occurs instantaneously with that of the element (i.e., no time delay). The unit of time may be minutes, seconds, milliseconds or any other convenient unit as long as α and β are integers.

An example of the mechanization of a system is given following the description of the digital computer control program.

Functional Description of Digital Computer Program

Control Program

A basic control program was written for the International Business Machines Corporation (IBM) *704* digital computer to check the compatibility of a switching network and the sequence of events directed by (1) input conditions entered at intervals during the simulated operation, and (2) the time delays of the elements.

The program essentially solves a set of simultaneous Boolean equations which describe the logical system by expressing each dependent element as a function of other variables so that the state of each logical element is determined at any time. At the option of the engineer, the state is compared with a specification (the expected state at that time entered as data) and the results of the comparison are printed. If the specification is met, the control program advances a time counter one unit and continues the simulated operation. The engineer may direct the program to continue if the specification is not met; otherwise it stops. At the termination time, entered as data by the engineer, the history of the states of the elements has been written on a magnetic tape, one record for each unit of time. Provision is made for entering a brief description of the conditions of the operation. This description is written at the beginning of the magnetic tape to identify the performance tape when it is removed from the computer and stored for subsequent study.

The simulated operation of a system starts at *0* time. The control program determines the equilibrium state of each logical element by an iterative solution of

Fig. 2. Conveyor control schematic diagram

the set of Boolean equations, and records the time and state. A time counter location is increased by one unit and the equilibrium states are redetermined. At each time, the program checks for new input conditions; thus, the states of input elements remain constant until the engineer enters new data. A time-delay subroutine applies the α- and β-delays of a variable to the recorded time of change of state of the associated element to determine the effective state of the variable at each unit of time. Debugging routines print diagnostic comments for indeterminate and incompatible states, or the improper entry of input states and specifications, and stop the simulated operation.

Boolean Equations Program

The set of Boolean equations for the dependent elements of the network are coded for the digital computer and then assembled in machine language to form a subprogram compatible with the basic control program. The control program is permanent; only the Boolean program need be reassembled for a new network. Since the Boolean program is assembled in relocatable form, the equations may be changed directly in machine language without reassembling. If extensive additions are made to the network, it is preferable to reassemble the Boolean program.

Performance Print Program

At the conclusion of the simulated operation, the print deck may be loaded to print selected records from the performance tape, or the tape may be removed and stored for subsequent printing. The print program prints the system description stored on the tape. Then it searches the tape and prints the states of all the input and dependent elements at each time selected by the engineer and entered as data.

Application of Program to a Simplified System

The following example was chosen to illustrate the procedures for using the control program and to show the input data and the printed results of the analysis of a switching network.

Description of the System

The physical arrangement of the system is shown in Fig. 1. Conveyor *B* transports ore from a loading area to the plant site. Conveyor *A* transfers rough ore from conveyor *B* to the crusher. After being crushed, the fine ore can either be directed through conveyors *C* and *D* to a storage bin or through *C* and *E* to a classifier where the ore is separated according to size. Start and stop pushbuttons and a selector switch, which selects one of the two modes of operation, are provided at the master station. A horn warns workers off the conveyors prior to their

movement, and several emergency lockout stop pushbuttons are installed at various points for safety reasons. The relay switching schematic diagram is shown in Fig. 2. Equipments are interlocked with time-delay relays so that no equipments will start until the downstream equipments are in motion. With the time delays and selector switch positions shown in Fig. 2, the sequence of major events for a possible operation is given in Table I.

PROCEDURES TO USE THE CONTROL PROGRAM

1. Assign numbers to all input elements (e.g., no. 1001 through 1010 of Fig. 1). Assign numbers to all dependent elements (e.g., no. 1011 through 1021 of Fig. 1), and write their transmission functions as illustrated in equations 1 through 11.

$$F_{1011}=[(1001)+(1012)](\overline{1012_0^5}) \tag{1}$$

$$F_{1012}=[(1001)+(1012)](\overline{1012_0^{15}}) \tag{2}$$

$$F_{1013}=(\overline{1002})[(1013)+(\overline{1012_0^{10}})] \tag{3}$$

$$F_{1014}=(1013)[(1017_3^5)+(1018_3^5)](\overline{1004})(1015_3^5) \tag{4}$$

$$F_{1015}=(1013)[(1017_3^5)+(1018_3^5)](\overline{1005})\quad(1016_3^5) \tag{5}$$

$$F_{1016}=(1013)[(1017_3^5)+(1018_3^5)](\overline{1006}) \tag{6}$$

$$F_{1017}=(1013)(\overline{1007})(\overline{1003})(1019_3^5) \tag{7}$$

$$F_{1018}=(1013)(\overline{1007})(1003)(1020_3^5) \tag{8}$$

$$F_{1019}=(1013)(\overline{1003})(\overline{1008}) \tag{9}$$

$$F_{1020}=(1013)(1003)(\overline{1009})(1021_3^5) \tag{10}$$

$$F_{1021}=(1013)(1003)(\overline{1010}) \tag{11}$$

2. Code the input elements and the Boolean functions for the dependent elements in the language of the particular digital computer being used. For the IBM *704* machine, typical examples follow.

For input element 1001:

```
Code                    Comment

PZE 1001,, 2........Two instructions for 1001
TSX INVAR, 4.......Uses input variable subroutine
```

For dependent element 1011 (i.e., equation 1):

```
Code                    Comment

PZE 1011,, 10.......Ten instructions for 1011
TSX DELAY, 4.......Uses delay subroutine
PZE 1012
PZE 5,, 0...........α-delay is 5, β-delay is 0
COM.................Complement the state
STO T...............Save temporarily
CLA 1012
ORA 1001............OR
ANA T...............AND
TRA STATE.........Transfer to control program
```

3. Assemble the code to produce a machine-language program that is compatible with, and will be combined with, the machine-language control program.

4. Punch data cards for the sequential input conditions and specifications for the time duration of the operation. Also enter the total number of elements and the total time of the operation. Provision is made for entering a brief title which may specify the date and conditions of the operation. This description is printed out and also preserved on the magnetic tape that contains the time history of the system.

For the example shown in Fig. 2 and Table I, input conditions were entered at times 0, 1, 41, and 48 seconds. The specifications in Table I at times 5, 25, and 48 seconds were also entered. An incorrect specification (element 1015 is in state *1*) was entered at 45 seconds to illustrate the specification printout from the control program. The printout is shown in Table II.

5. In addition to the specification printout, the control program writes a complete time history of the states of the elements. Although this magnetic tape contains a separate record for each unit of time during the operation, a printout program is provided to enable the engineer to be selective in printing out only those records of special interest as illustrated in Table III. The magnetic tape may be removed from the computer and preserved for further analysis.

Conclusions

1. The control program was tested on the IBM *704* digital computer by simulated operations of switching networks. Assuming an average of ten machine-language instructions for each Boolean function, the present IBM *704* version of the control program determines the states of dependent elements at the rate of about 7,000 per minute. With a 32,768-word IBM *704*, a network of about 3,000 elements can be solved at the high speed.

2. The use of Boolean algebra to describe the transmission of each element in a system provides a better understanding of the relationship of the element to the system. Therefore, the effort to mechanize a system for a simulated operation on a digital computer is well compensated by the advantages of a better designed system.

3. Since time delays are incorporated in the transmission functions written for the control program, most of the relay racing problems in a system can be detected by simulated operation on the digital computer. Also, the required tolerance specifications for the relays can be determined similarly at very low cost because of the high speed operation of the computer.

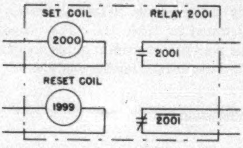

Fig. 4. Mechanical latching relay

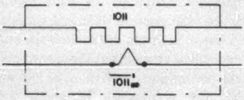

Fig. 5. Detonator or fuse

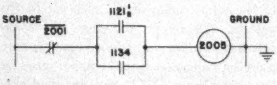

Fig. 6. Permanently grounded relay circuit

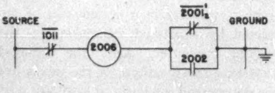

Fig. 7. Ungrounded relay circuit

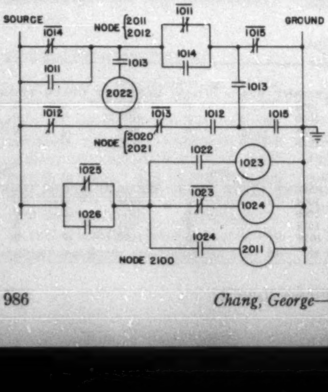

Fig. 8. Relay circuit to illustrate nodal method

4. If adjustable time-delay elements are used in the system, a simulated operation provides the best information for setting the delays for optimum operation of the system.

5. Once the system is coded as a digital program, the performance of the system can be obtained quickly and with very little labor. Therefore, the engineer can afford to analyze the system for all possible input conditions, even those which seldom occur normally.

6. The digital program may be used for systems other than relay and switching if the system can be described by Boolean equations. Therefore, complete systems, including hydraulic and pneumatic equipment, can be tested at high speed and low cost.

Appendix I. Examples of Logical Elements for Common Devices

Stepping Switch

A 6-position rotary-type stepping switch is used for the illustration (see Fig. 3). Each time the coil numbered 1200 receives a pulse, the switch advances its contact one position higher than its previous position. The contacts numbered from 1201 to 1206 are treated as dependent elements of the coil. Their functions are

$$F_{1201}=(1201)(\overline{1200})+(1200)(1206)$$

$$F_{1202}=(1202)(\overline{1200})+(1200)(1201)$$

$$F_{1203}=(1203)(\overline{1200})+(1200)(1202)$$

$$F_{1204}=(1204)(\overline{1200})+(1200)(1203)$$

$$F_{1205}=(1205)(\overline{1200})+(1200)(1204)$$

$$F_{1206}=(1206)(\overline{1200})+(1200)(1205)$$

The first term of the functions indicates that the switch contact remains at its own position, when the coil is not energized. The second term indicates that the switch advances the contact position by one, whenever the coil is energized.

Switching Flip-Flop

A mechanical latching relay is shown symbolically in Fig. 4. The relay numbered 2001 is treated as a dependent element to the set coil 2000 and reset coil 1999. There are two cases possible:

1. Set coil overrides reset coil when both are energized. The function of the relay is

$$F_{2001}=(2001)(\overline{2000})(\overline{1999})+(2000)$$

The Veitch diagram for F_{2001} is

	$F_{1999}=0$	$F_{1999}=1$
$F_{2000}=0$	Unchanged	0
$F_{2000}=1$	1	1

2. Reset coil overrides set coil when both are energized.

$$F_{2001}=\overline{(\overline{2001})(\overline{2000}(\overline{1999})+(1999)}$$

The Veitch diagram for F_{2001} is

	$F_{1999}=0$	$F_{1999}=1$
$F_{2000}=0$	Unchanged	0
$F_{2000}=1$	1	0

Detonator or Fuse

When the heater element 1011 in Fig. 5 is energized, the fuse is assumed to ignite after 1 second. Once the fuse ignites, the circuit in series with the fuse will open indefinitely. With an α-delay of 1 second and β-delay of some time longer than the total simulation time of system operation, this device can be represented in the digital computer program.

Appendix II. Techniques in Writing Transmission Functions

Permanently Grounded Element

The transmission function of the element is the transmission to its source. This theorem is illustrated in Fig. 6 and the transmission function of the relay is

$$F_{2005}=(\overline{2000})[(1121_2{}^1)+(1134)]$$

Ungrounded Element

The transmission function of the element is the AND product of the source transmission and ground transmission. This theorem is illustrated in Fig. 7.

Source transmission $T_s=\overline{1011}$

Ground transmission $T_g=(\overline{2001_2{}^1})+(2002)$

Therefore, the transmission function of the relay is

$$F_{2006}=T_sT_g=(\overline{1011})[(\overline{2001_2{}^1})+(2002)]$$

Nodal Method in Writing Transmission Functions

For a large system, it may be more convenient to write the transmission function of an element from one node to another node instead of tracing the circuit to the source or ground. Since a node can be either connected or disconnected to a source or a ground, the node actually possesses four states. To overcome this difficulty, two numbers may be assigned to a node (i.e., it is resolved into two logical elements). However, if the node cannot be grounded, then one number is sufficient to represent the node. The example in Fig. 8 illustrates an element numbered 2022 in a bridge circuit and the use of the nodal method. Elements 2022, 1023, 1024, and 2011 are voltage coils of their associated relays. Voltage coils are considered to be open-circuit devices, while current coils are short-circuit devices. Transmission functions for the nodes and relays are

$F_{2100}=(\overline{1025})+(1026)$ single number node

$$F_{2011}=[(1011)+(\overline{1014})]+[(\overline{1011})+(1014)](1013)(1012)(\overline{1013})(\overline{1012})$$

But $(1013)(\overline{1013})$ is always zero, then

$F_{2011}=(1011)+(\overline{1014})$; source node

$F_{2012}=[(\overline{1011})+(1014)][(\overline{1015})+(1013)(1015)]$; ground node

$$F_{2020}=(\overline{1012})+(\overline{1013})(1012)(1013)[(\overline{1011})+(1014)][(1011)+(\overline{1014})]$$

$=(\overline{1012})$; source node

$F_{2021}=(\overline{1013})(1012)[(1015)+(1013)(\overline{1015})]$

$=(\overline{1013})(1012)(1015)$; ground node

With the above node transmission functions established, the transmission functions for the relays are extremely simple.

$F_{1023}=(2100)(1022)$

$F_{1024}=(2100)(\overline{1023})$

$F_{2011}=(2100)(1024)$

$F_{2022}=(2011)(2021)(1013)+(2020)(2012)(1013)$

Transistorized Multifrequency Ringing Generator

J. F. KOSTELICH

B. W. HOWALD
ASSOCIATE MEMBER AIEE

THE selective telephone party-line ringing system using mechanically tuned bells is relatively well known. A 5-party line, for example, may have phones with bells tuned to 20, 30, 40, 50, and 60-cycles, respectively. Introducing a 40-cycle ringing voltage to this party line will cause only the 40-cycle bell to ring.

Several types of ringing voltage generators may be used to supply the required frequencies for a telephone central office. Both a-c and d-c driven motor-generator sets, vibrator-type inverters, magnetic frequency changers, and electronic-tube-type generators are in use today. The reasons for developing still another type of ringing voltage generator can be best explained by outlining the requirements of the ideal generator, together with the basis for each requirement.

Some of these requirements are as follows:

1. The output frequency of the generator should be stable and capable of precise adjustment to the required frequency. The sharp mechanical and electrical resonance curves of the selective ringer dictates that the ringing frequency should not shift more than 1/2 cycle from its initial value under any normal operating condition. Preferably, the shift should be kept within ±1/4 cycle with varying load, ambient temperature, input voltage, and age. In addition, the frequency setting must be precise because in most installations two generators will be installed, one for normal and one for stand-by use, and the performance of the system should not change when transferring from normal to stand-by operation. The normal and stand-by generators must thus be adjusted to the same frequency.

2. The output voltage of the generator should be nearly free of harmonics. There are two reasons for this requirement: the elimination of cross-ring and the elimination of noise and crosstalk in the telephone system.

Three series of ringing frequencies are now in common use: the harmonic series, using $16^2/_3$, 25, $33^1/_3$, 50, and $66^2/_3$ cycles; the synchromonic series, using 20 (or 16), 30, 42, 54, and 66 cycles; and the decimonic series, using 20, 30, 40, 50, and 60 cycles. In two of these three series the second and third harmonics of the lower frequencies can cross-ring the bells of the higher frequencies. The amount of voltage required to produce an objectionable cross-ring, or tinkle of the ringer, which should remain silent, is less than 10 volts with some ringers. Since the ringing voltages of the lower frequencies are about 100 volts, the second and third harmonics in the lower frequencies must be kept well below 10%.

Fig. 1 shows the selectivity curves of typical telephone ringers. With 60 volts applied, the 20-cycle and 40-cycle ringers are frequency selective within 3 cycles. Although the bell selectivity curves appear to be broad, it must be kept in mind that on occasion bells are tuned in the field, and the setting selected may be just inside the selectivity curve limits. Thus the ringing generator frequency must be stable, as a significant frequency shift in ringing voltage may cause a ringing failure in these field-tuned bells. Note that 15 volts of second harmonic voltage in the 20-cycle ringing voltage would be sufficient to energize the 40-cycle ringer.

The harmonics in the higher audio range are also objectionable as they produce noise

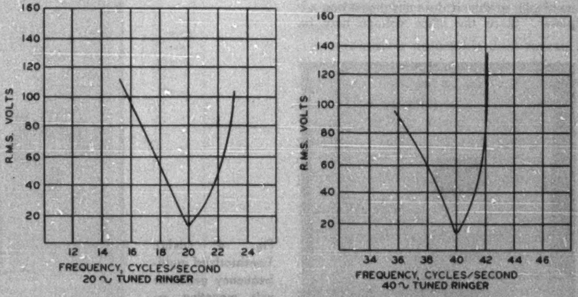

Fig. 1. Frequency selectivity curves for typical tuned ringers

Paper 59-1175, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted June 9, 1959; made available for printing August 17, 1959.

J. F. KOSTELICH and B. W. HOWALD are with Lorain Products Corporation, Lorain, Ohio.

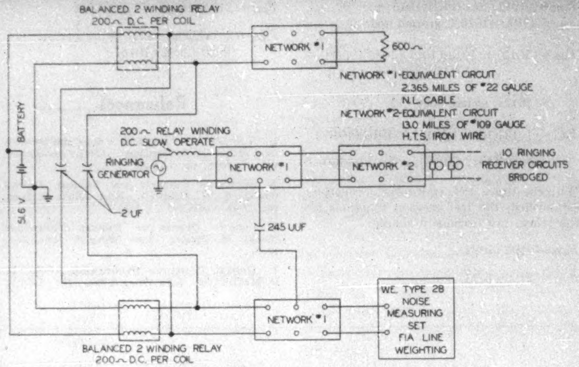

Fig. 2. Crosstalk noise-measurement test circuit

or crosstalk in the adjacent pairs in the telephone cable. The Rural Electrification Administration (REA) requirement is that the noise measured on an equivalent cable circuit, as shown in Fig. 2, must not exceed 25 dba (decibels adjusted) as measured with the Western Electric *2B* noise measuring set (*F1A* line weighting).

3. The generator should be dependable and not require frequent maintenance or adjustment. Ideally, it should not have any moving or expendable parts, and all components should have anticipated life of the order of 50,000 hours or more. If maintenance is required, it should be simple in nature, so that a unit which is out of service can be replaced or repaired in a very few minutes.

4. The generator should be self-protecting in case of overloads or short circuits so that it will not be damaged by ringing into short-circuited lines or by faulty interrupters or accidental short circuits placed across it during maintenance operations in the office. Preferably, the protection should not be in the nature of fusing as the replacement of fuses in an unattended office can be a serious nuisance.

5. The generator preferably should operate on the telephone office battery (50 volts d-c nominal), so that it does not depend on a-c power. Since the office voltage may be anywhere between 44 and 56 volts, the generator must operate satisfactorily and not be damaged by operation over this range of voltage.

6. The generator should have good voltage regulation so that satisfactory ringing will be obtained under all load conditions. On long, heavily loaded lines, where not all the ringers are of the same type, it is sometimes difficult to get satisfactory ringing on all phones. In these cases, well-regulated ringing voltage is important, so that ringer adjustments, made under one load condition, are still correct when the load is considerably different, or when the office battery voltage drops during an a-c power failure or rises while the batteries are being equalized. For ideal operation, the ringing voltage should not change with the load or with changes in input voltage.

7. The power consumption of the ringing generator should be as small as possible, especially if it operates from the office battery. The no-load drain is important as the generator may operate for considerable periods with little or no load. Since start-stop operation is frequently employed, the voltage and frequency should not shift appreciably during the warm-up period.

It is the purpose of this paper to describe a transistorized multifrequency ringing generator, which may be the proper approach to this idealized source of ringing voltage.

Fig. 3 shows the transistorized ringing generator to be described. This unit mounts on a 19-inch relay rack, requires 17½ inches of vertical space, and is 13⅝ inches deep. Fig. 4 shows the slide mounting arrangement of the units. The five frequency generators are identical and interchangeable, while the sixth unit, in the lower right-hand corner, contains the battery filter, a reverting tone generator, and remote control features.

Fig. 5 is a block diagram of the 5-frequency ringing machine. Power input into the generators is supplied through a battery filter and remote start relay in the common unit. The remote start relay can be energized remotely by applying (positive) ground to the start terminal. The identical ringing generators are shown with their output ringing voltage appearing on the terminal block as indicated.

The output of the audible ringback tone generator appears on the terminal block. The tone generator output is 420 cycles with 40-cycle amplitude modulation, which is the industry standard for reverting tone.

Fig. 7. Schematic diagram of a single-frequency generator unit

Circuit Performance

A block diagram of a transistorized frequency generator circuit is shown in Fig. 6 while Fig. 7 shows a partial schematic diagram of the generator unit.

Voltage Regulator

A simple voltage regulator, comprised of a Zener diode and a power transistor, provides a constant 12-volt direct current to the oscillator and driver-amplifier stages. The regulator is required to keep the output alternating voltages of the oscillator and driver stages constant during battery voltage variations (44 to 56 volts d-c).

Oscillator

The oscillator is a tuned collector oscillator. The frequency is determined by an *L-C* tank circuit, which can be adjusted readily from 15 to 66²/₃ inches. Coarse tuning is accomplished by capacitor tap selection. The two capacitors in the circuit are used singly, or they are used in parallel. The fine tuning is done by a screwdriver adjustment on the variable gap inductor. The a-c output voltage of the oscillator is constant at all frequencies to which the oscillator is tuned.

Two 250-milliwatt transistors work in push-pull, with a common base configuration being used to minimize the effect of transistor parameter variations.

Driver-Amplifier

The driver-amplifier stage is transformer-coupled to the oscillator. This stage is a common-collector current-amplifier circuit. The regulation of this stage must be good, so that the drive voltage supplied to the next stage will not decrease with increased load requirements. This high-gain stage requires little power from the oscillator, so that the oscillator is effectively isolated from the power amplifier by the driver amplifier stage.

A screwdriver adjustable dual resistor varies the input drive to the driver-amplifier. This is a fine adjustment providing approximately 15% adjust variation for the output voltage of the generator. Included in this stage is part of the cutoff circuitry for short-circuit protection of the generator as a whole.

Power Amplifier

The power stage, transformer-coupled to the driver-amplifier stage, is comprised of a 4-transistor bridge, output transformer, and current transformer.

The power transistors operate class *B*,

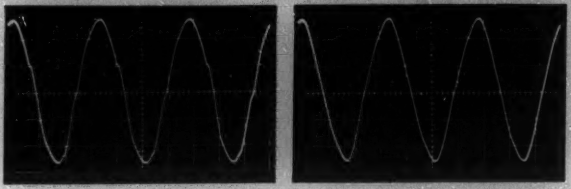

Fig. 8. Output waveshape, 50 cycles at 125 volts full load (left) and no load (right)

producing a sine-wave output voltage. Each transistor has a separate drive winding on the driver amplifier output transformer. Inverse feedback windings on the power transformer, in conjunction with the drive windings, provide a constant drive voltage on the power transistors. To compensate for circuit losses and decreasing current gain in the power transistors at higher generator load levels, a positive current feedback winding is also used in the power transistor drive circuit.

The adjustable positive current feedback feature allows setting the output voltage at nearly flat regulation from no load to full load on the generator.

The constant drive voltage results in good output voltage regulation with wide variations in input battery voltage. With a 20% change in battery voltage (44–56 volts d-c), the change in a-c output voltage is about ±5%.

To promote maximum efficiency in the power stage, the drive voltage is set at a maximum value that will allow a sine-wave output and yet not produce clipping of the output wave at low battery levels or high load conditions. In this way transistor heat dissipation is kept to a minimum. Adequate heat sink area has been used to maintain transistor junction temperature to a safe value at all ambient and load conditions.

The output transformer design is such that pulses of direct current (tripping battery) in the output winding will not distort the output waveshape. The sine-wave output is also maintained with reactive loads down to 70% power factor.

CUTOFF CIRCUIT

The cutoff circuit in this generator is a current-sensitive device. At a prescribed current overload level (approximately 75–100% overload), a cutoff voltage is fed back to the amplifier and oscillator stages, causing them to drop their output sharply. The output current is maintained at a low level at short circuit, and will remain at this safe low level for the duration of the short circuit or overload.

The generator recovers as sharply as it had dropped when the load condition is reduced to about 175% load.

Performance Data

Fig. 8 shows the output wave shape of a frequency generator set at 125 volts, 50 cycles, at no load and full load. A reasonably good sine wave is produced, whose third harmonic content averages very low, at about 5.2%.

Fig. 9 illustrates the output regulation curves for this 5-frequency generator at nominal battery (48 volts). The cutoff overload point is indicated by the dotted line at end of each curve.

Fig. 10 shows the regulation of one generator at nominal, maximum, and minimum battery levels. The change in output voltage is only about ±5% with approximately 20% variation (44–56 volts) in battery voltage.

Conclusions

Several methods of generating multifrequency ringing voltages have been outlined, and the ideal generator would incorporate the advantages of all these methods.

The various data presented in this paper have been concerned with describing the circuitry and performance of a commercially available transistorized multifrequency ringing generator. The initial and the operating costs of the equipment described are generally less than those of magnetic frequency changers and motor-generator sets, which are considered compared in reliability to the transistorized equipment. A review shows that this unit meets the outlined performance requirements for the ideal generator:

1. The frequencies of this generator can be set precisely to the frequency desired by a screwdriver adjustment of the tuning inductor. Because the oscillator operates from regulated voltage and is effectively isolated from the power stage, the oscillator (and thus the generator) shows less than 1/10-cycle variation due to battery voltage changes (44–56 volts d-c) or load conditions on the ringing generator. This performance is well within the 1/2-cycle maximum frequency shift requirement.

2. The output voltage is a sine wave. The harmonic content averages 5.2%, which is not enough to cause cross-ring difficulty. Laboratory checks were made for crosstalk noise, using the network indicated in Fig. 2. A maximum noise level of 15 dba was registered using a generator adjusted for 66 cycles at 140 volts a-c output. This maximum noise level is far less than the maximum allowable noise level (25 dba).

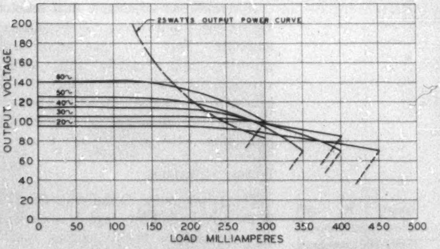

Fig. 9. Output voltage regulation curves for multifrequency generator

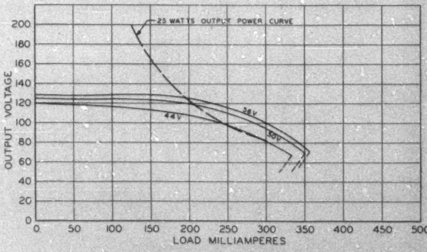

Fig. 10. Output voltage regulation curve for 50-cycle generator with different input battery voltages

3. One of the original multifrequency generators has been installed on field trial in a local 4,000-line telephone office for 20 months. To date, there has been no opertional difficulty or need for maintenance reported by the telephone operating personnel. Conservative electrical design regarding component ratings indicates that many years of troublefree performance under normal operating conditions can be anticipated. A spare unit is on hand, however, and can be quickly adjusted to replace any frequency generator if service is required.

4. The generator is self-protecting in case of overloads or short circuits on the generator output.

5. The generator operates from telephone office battery (50 volts d-c nominal), eliminating its dependence on a-c power.

6. The voltage regulation of the generator can be adjusted to less than a 5-volt variation in output voltage from no-load to full-load conditions. Changes in battery voltage (44–56 volts d-c) have a small effect on output voltage regulation, as shown in Fig. 10.

7. The power consumption per frequency generator is 100 milliamperes at no load, and about 1 ampere at full load (25 watts). The over-all efficiency of the multifrequency generator is about 55% at full load.

Input battery filtering is provided in the common unit. With full load on the multifrequency generator, battery noise of 18 dba maximum was read with a Western Electric *2B* noise measuring set (*F1A* line weighting). The filtering is adequate to keep the battery noise level well below the maximum level of 32 dba.

The General Form of Some Common Network Theorems

COLIN ADAMSON
MEMBER AIEE

S. M. EL-SOBKI
NONMEMBER AIEE

WHEREAS network theorems are widely used for the reduction and simplification of networks of a substantial degree of complexity, they tend to be neglected when complex systems are to be solved on a network analyzer. The network analyzer has proved to be a very satisfactory tool for power network analysis, but a review of the situation is profitable for cases of large problems which may exceed the number of impedance units available. There are two main general aspects to the use of network theorems:

1. The use of theorems for the specific investigation of a portion of a network, or the relationship between two portions of a network, e.g., Thévenin's, or the compensation, theorem.
2. The use of techniques of successive reduction, e.g., mesh-to-star transformation.

The most significant application of the reduction techniques of category (2) is the generalized mesh-to-star transformation; in this case there are numerous conditions to be satisfied before reduction can be accomplished if a plain star without mutual impedances is finally required. It can be shown that during the stages of preparing a problem for solution, a network analyzer may be used to obtain the necessary conditions.

In the case of the theorems of category (1), they also behave as theorems of reduction in their most profitable applications. These are the concern of this paper, and it is of interest to note that there is a common thread to all the theorems in this category, and that they, and their derivatives, may all be deduced directly from the equations obtained by applying the network laws of Ohm and Kirchoff to electric circuits. Premier places in the hierarchy of theroems are occupied by those of Thévenin and Norton;[1] the relationship of the theorems of Millman,[2] and of Starr,[3] to Thévenin's and Norton's theorems have recently been discussed.[4] In this paper further relationships to the work of Ataka,[5] Zepler,[6] and Tasny-Tschiassny,[7] are considered, together with the compensation theorem. The common threads of all the network theorems in category 1 are thus exposed, together with the methods to be adopted to obtain network reduction in a practical manner; illustrative practical examples are quoted in the Appendix.

Definitive Mesh and Nodal Relationships

For a mesh network with *m* meshes:

$$\|e_m\| = \|z_{mm}\| \times \|i_m\| \quad (1)$$

where

$\|e_m\|$ denotes impressed mesh voltages.
$\|i_m\|$ denotes response currents in the meshes.
$\|z_{mm}\|$ defines the impedance matrix of the network viewed from its *m* meshes.

From equation 1 solving for $\|i_m\|$ yields

$$\|i_m\| = \|z_{mm}\|^{-1} \times \|e_m\| \quad 1(A)$$

where $\|z_{mm}\|^{-1} = \|a_{mm}\|$, the admittance matrix viewed from the *m* meshes. The elements $a_{11}, a_{21} \ldots$, etc., of a_{mm} may be obtained readily on the network analyzer.[8]

If the same network is considered, the number of node pairs being *n*, the performance equation of the network is

$$\|I_n\| = \|Y_{nn}\| \times \|V_n\| \quad (2)$$

where

$\|I_n\|$ denotes current through the *n* node pairs.
$\|V_n\|$ denotes voltage across the pairs of nodes.
$\|Y_{nn}\|$ is the admittance matrix viewed from the *n* node pairs.

The practical method of obtaining the elements Y_{11}, Y_{21}, etc, of $\|Y_{nn}\|$ is demonstrated later.

Thévenin's Theorem

The generalization of Thévenin theorem has been discussed recently;[4] the main points of interest in this discussion were the relationship of the theorem with the technique of "tearing" advocated by Kron,[9] and the inclusion in the general body of the theorem of the special cases of Millman and Starr. Thévenin's theorem will be treated here briefly by matrix methods to illustrate, first, its relationship to the work of Ataka, Tasny-Tschiassny, and Zepler, and to the compensation theorem.

Fig. 1 shows a general network having *m* meshes, with mesh currents i_{m1}, i_{m2}, etc., and *n* accessible node pairs across which there are voltages $V_1, V_2, \ldots, V_q\ V_r, V_k$, etc. If the accessible node pairs are traced through to an external circuit, lying to the right of, but not shown in, Fig. 1 and connected to the same *n* node pairs, then *n* meshes are added to the original networks; this is equivalent to considering the network of Fig. 1 as containing $(m+n)$ meshes. It should be noted that the additional of the external circuit to give an additional *n* meshes,

Paper 59-1180, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted July 24, 1958; made available for printing August 11, 1959.

COLIN ADAMSON and S. M. EL-SOBKI are with Manchester College of Science and Technology, Manchester, England.

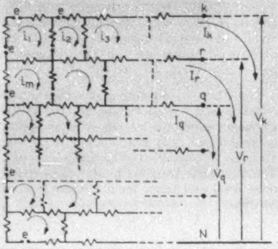

Fig. 1. General network with m meshes and n node pairs

makes the n mesh currents the same as the n currents flowing in the n independent node pairs; thus $i_n = I_n$. The technique may be better appreciated by reference to Fig. 2, where e_k' is the sum of all sources of emf (electromotive force) encountered within the mesh k; here the kth mesh containing terminal k has been considered and the cumulative mesh emf has been obtained by traversing the mesh in a positive direction and summating all the emf including the terminal voltage. Thus $e_k = e_k' - V_k$.

Obviously, the relationship between mesh voltages (of the $m+n$ meshes), the matrix impedance of the complete network, and the mesh currents is

$$\|e\| = \|z\| \times \|i\| \tag{3}$$

Equation 3 may be partitioned along the m and n meshes, the latter being those which contain the accessible terminals:

$$\begin{Vmatrix} e_m \\ e_n \end{Vmatrix} = \begin{Vmatrix} z_{mm} & z_{mn} \\ z_{nm} & {}_{n\ n} \end{Vmatrix} \times \begin{Vmatrix} i_m \\ I_n \end{Vmatrix} \tag{3(A)}$$

or

$$\|e_m\| = \|z_{mm}\| \times \|i_m\| + \|z_{mn}\| \times \|I_n\| \tag{3(B)}$$
$$\|e_n\| = \|z_{nm}\| \times \|i_m\| + \|z_{nn}\| \times \|I_n\|$$

where

$$\|e_n\| = \|e_n'\| - \|V_n\| \tag{3(C)}$$

and represents the total of equations such as the one, $e_k = e_k' - V_k$ obtained from the kth node pair.

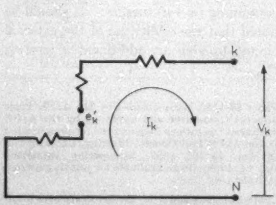

Fig. 2. The kth mesh of the general network

There are two cases of major interest when these equations are solved:

1. The relationship between $\|I_n\|$ and $\|V_n\|$, i.e., the conditions at the terminals; this is Thévenin's theorem.
2. The relationship between $\|i_m\|$ and $\|V_n\|$ i.e., the effect of terminal conditions on the network, which is useful when the effect of connecting loads on load flow and losses are being considered.

For case (1), eliminating $\|i_m\|$ yields

$$\|V_n\| = \|e_n'\| - \|z_{nm}\| \times \|z_{mm}\|^{-1} \times \|e_m\| - \{\|z_{nn}\| - \|z_{nm}\| \times \|z_{mm}\|^{-1} \times \|z_{mn}\|\} \times \|I_n\| \tag{4}$$

Equating $\|I_n\|$ to zero to give the open-circuit conditions at the nodes yields

$$\|V_n\|_{oc} = \|e_n'\| - \|z_{nm}\| \times \|z_{mm}\|^{-1} \times \|e_m\| \tag{5}$$

Equating all the mesh emfs to zero, i.e.,

$\|e_n'\| = \|e_m\| = 0$, yields

$$\|V_n\| \times \|I_n\|^{-1} = \|z_{nn}\| - \|z_{nm}\| \times \|z_{mm}\|^{-1} \times \|z_{mn}\| = \|Z_{nn}\| \tag{6}$$

where $\|Z_{nn}\|$ represents the impedance of the network viewed from its n node pairs. Therefore

$$\|V_n\| = \|V_n\|_{oc} - \|Z_{nn}\| \times \|I_n\|$$

Also, $\|V_n\| = \|Z_{nn}'\| \times \|I_n\|$ where $\|Z_{nn}'\|$ is the load impedance. Therefore

$$\|V_n\| = \{\|Z_{nn}'\| + \|Z_{nn}\|\} \times \|I_n\| \tag{7}$$

which is a general statement of Thévenin's theorem.

For case (2), the relationship between $\|i_m\|$ and $\|V_n\|$ may be obtained as follows. By applying voltages $\|e_n''\|$, each of one pu (per unit) value, between each node and the reference node, equations 3(B) become

$$\|e_m\| = \|z_{mm}\| \times \|i_m\| + \|z_{mn}\| \times \|I_n\|$$
$$\|e_n'\| - (\|V_n\| + \|e_n''\|) = \|z_{nm}\| \times \|i_m\| + \|z_{nn}\| \times \|I_n\|$$

By equating the original sources of emf in the network, $\|e_m\|$ and $\|e_n'\|$, to zero, and solving for $\|i_m\|$, the following expression is obtained:

$$-[\|z_{mm}\| - \|z_{mn}\| \times (\|Z_{nn}'\| + \|z_{nn}\|)^{-1} \times \|z_{nm}\|]^{-1} \times \|z_{mm}\| \times (\|Z_{nn}'\| + \|z_{nn}\|)^{-1} \times \|e_n''\| = \|i_m\| \tag{8}$$

The mesh circulating currents $\|i_m\|$ represent the transfer admittances in pu between the n node-pairs and the m meshes.

Also, rewriting equation 3(A) yields

$$\|e_m\| = \|z_{mm}\| \times \|i_m\| + \|z_{mn}\| \times \|I_n\|$$
$$\|e_n'\| = \|z_{nm}\| \times \|i_m\| + (\|Z_{nn}'\| + \|z_{nn}\|) \times \|I_n\| \tag{9}$$

Eliminating $\|I_n\|$ and solving for $\|i_m\|$ in terms of $\|V_n\|_{oo}$ and $\|i_m\|_o$

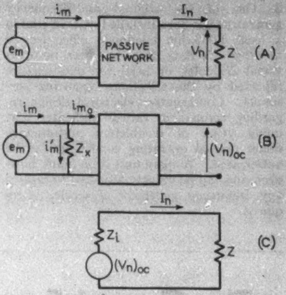

Fig. 3. A—Linear network with m=1 and n=1. B—Zepler's equivalent representation of (A). C—Thévenin equivalent of (A) and (B)

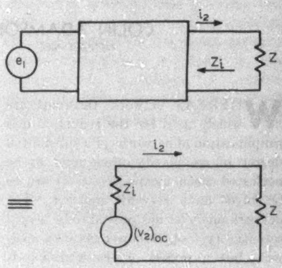

Fig. 4. Equivalent circuit for obtaining Y_t

which is the current in the meshes when $\|I_n\| = 0$, yields

$$\|i_m\| = \|i_m\|_o + \|Y_t\| \times \|V_n\|_{oc} \tag{10}$$

where $\|Y_t\|$ is the transfer admittance between the n node-pairs and m meshes as given in equation 8; then the change in mesh current (or branch current) due to load connection is given as follows: $\|Y_t\| \times \|Y_n\|_{oc}$.

Similar reasoning gives the dual of this relationship: the nodal voltage due to load connection at the nodes is

$$\|V_m\| = \|V_m\|_{sc} + \|Z_t\| \times \|I_n\|_{sc} \tag{11}$$

where $|V_m|_{sc}$ is the voltage at the m node pairs when the n node pairs are short-circuited, and where $|Z_t|$ is the mutual impedance between the m node pairs and the n node pairs, and $\|I_n\|_{sc}$ is the short-circuit current at the n node pairs.

Some General Cases

The foregoing derivations include many special cases which have received special formulation; two of these, the theorems of Millman and Starr, have been discussed

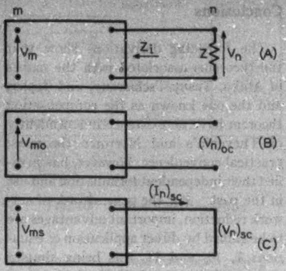

Fig. 5. A—Linear active netork with m=1 and n=1. B—Network of (A) with open-circuit conditions at node pair n. C—Network of (A) with short-circuit conditions at node-pair n

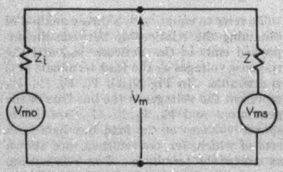

Fig. 6. Tasny-Tschiassny's equivalent circuit of Fig. 5(A) for obtaining V_m

recently, and shown to have no existence independently either of Thévenin's theorem or steps leading to the formulation of Thévenin's theorem: thus, for example, equation 7 for the case of $n=3$ gives Starr's theorem. The four other cases of note are discussed in the following sections.

ZEPLER'S THEOREM

Zepler's network theorem, formulated in 1952, evaluated for a generator connected between two nodes, the effect of connecting a static load between two other nodes. This is thus a special case of Thévenin's theorem but with a limitation in that it is inapplicable to active networks.

It states that in a linear network containing a generator e_m, an impedance Z may be replaced, without changing the effect on the generator, by another impedance Z_z connected in parallel with the generator, where

$$Z_z=\left(\frac{e_m}{(V_n)_{oc}}\right)^2\times(Z_t+Z) \tag{12}$$

where Z_t and $(V_n)_{oc}$ are the two quantities which specify the Thévenin equivalent circuit viewed from the load side; Fig. 3.

Writing $\|i_m'\|$ for the product $\|Y_t\|\times\|V_n\|_{oc}$ in equation 10 yields

$$\|i_m\|=\|i_m\|_0+\|i_m'\| \tag{10A}$$

where $\|i_m'\|$ are the currents resulting from the connection of impedances $\|Z_{nn}\|$.

Applying equation 10(A) to Fig. 3(A) (a circuit with only one pair of nodes and one mesh of interest) yields

$$i_m=i_{m0}+i_m' \tag{10B}$$

where i_m' is the current in the equivalent network, Fig. 3(B), which results from the connection of the load impedance Z. To obtain i_m', Y_t must be obtained, as follows.

Referring to Fig. 4,

$$Y_t=\frac{i_2}{e_1}=\frac{(v_2)_{oc}}{(Z_t+Z)}\times\frac{1}{e_1} \tag{13}$$

Thus

$$i_m'=\frac{(v_2)_{oc}}{e_1(Z_t+Z)}\times(V_n)_{oc} \tag{14}$$

If the network is passive and has only one source of emf, then $e_1=e_m$; $(v_2)_{oc}=(V_n)_{oc}$, and equation 14 becomes

$$i_m'=\frac{(V_n)_{oc}^2}{e_m(Z_t+Z)}$$

$$=\left(\frac{(V_n)_{oc}}{e_m}\right)^2\times\frac{e_m}{Z_t+Z}=\frac{e_m}{Z_z}$$

where Z_z is the impedance given by Zepler's theorem. It can thus be seen that the theorem is a special case of equation 10.

It is interesting to note that there is no general formulation of Zepler's theorem for cases of more than one pair of nodes and more than one internal mesh of salient interest. An equivalent system may, however, be created which follows directly from equation 10, the load impedance being replaced in the meshes which are of interest by currents injected from external current sources.

TASNY-TSCHIASSNY'S THEOREM

The Tasny-Tschiassny theorem has been regarded by its originator as a useful extension of Thévenin theorem and is as follows; see Figs. 5 and 6:

> If an impedance Z is connected between two terminals of a network, the potential difference between any second pair of terminals will be equal to that between the common terminals of two generators connected in parallel and having emfs equal to the voltages across the second pair of terminals when $Z=\infty$ and when $Z=0$ and internal impedance equal to the Thévenin impedance, Z_t, of the network viewed from the first pair of terminals and to Z, respectively.

Thus, from Figs. 5 and 6

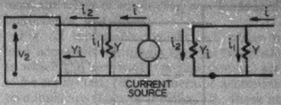

Fig. 7. Relation between Y_t and Y_t'

$$V_m=V_{ms}+(V_{m0}-V_{ms})\times\frac{Z}{Z_t+Z} \tag{15}$$

$$=V_{m0}+(V_{ms}-V_{m0})\times\frac{Z_t}{Z_t+Z}$$

These relationships may be derived from equation 11 for the case when $m=1$ and $n=1$, i.e.,

$$V_m=V_{ms}+Z_t\times(I_n)_{SC} \tag{11A}$$

Referring to Fig. 7 and applying a current source across the pair of nodes n, and measuring the voltage v_2 at the other node-pair m yields

$$Z_t=\frac{v_2}{i}\text{ and }Z_t'=\frac{v_2}{i_2}$$

where Z_t' is the mutual impedance when the load impedance $Z=\infty$, i.e.,

$$Z_t'=\frac{v_2}{i}\times\frac{Y_t+Y}{Y_t}$$

$$=Z_t\times\left(\frac{Z+Z_t}{Z}\right)$$

Applying equation 11(A), when $Z=\infty$, yields

$$V_{m0}=V_{ms}+Z_t'\times(I_n)_{SC}$$

$$V_{m0}=V_{ms}+Z_t\times\frac{(Z+Z_t)}{Z}\times(I_n)_{SC}$$

Therefore

$$Z_t\times(I_n)_{SC}=(V_{m0}-V_{ms})\times\frac{Z}{(Z+Z_t)}$$

By substituting in equation 11(A) the Tasny-Tschiassny equations can be obtained, i.e.,

$$V_m=V_{ms}+(V_{m0}-V_{ms})\times\frac{Z}{(Z+Z_t)}$$

and

$$V_m=V_{m0}+(V_{ms}-V_{m0})\times\frac{Z_t}{(Z+Z_t)}$$

and an alternative form

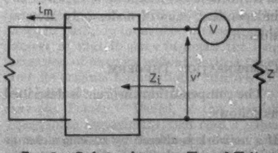

Fig. 8. Relation between Z_t and Z_t''

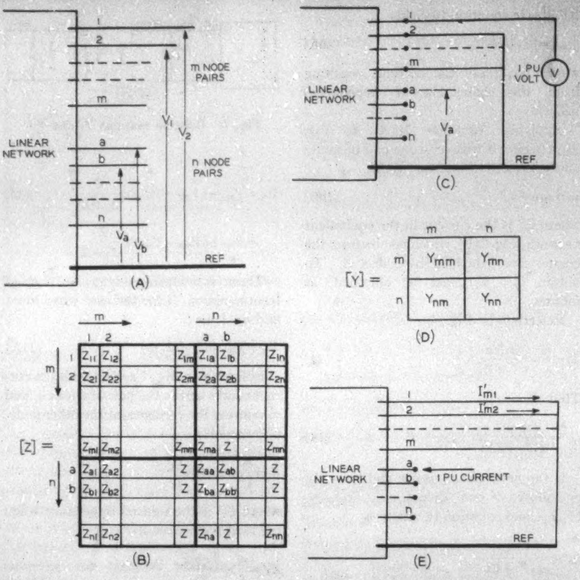

Fig. 9. A—Linear network with m generator node-pairs, and n load node-pairs. B—Matrix impedance of (A). C—Arrangements for obtaining the voltage distribution factor for (A). D—Matrix admittance of (A). E—Arrangements for obtaining the current distribution factor of (E)

$$V_m = V_{m0} - (V_n)_{\mathrm{oc}} \times \frac{Z_t'}{Z+Z_t}$$

Thus this theorem is a special case of equation 11, for $m=1$ and $n=1$, i.e., two independent pairs of nodes only.

ATAKA'S THEOREM

Ataka's theorem has also been formulated as an extension of Thévenin's theorem, as follows:[5]

> A current i_m through any branch m, say, is equal to the sum of a current i_{m0} through the branch m, when any other branch n, say, is open-circuited and a current i_m' through the branch m when an open-circuited emf V_{n0} acts in the branch n and all other emfs are replaced by their internal impedances.

$$i_m = i_{m0} + \frac{(V_n)_{\mathrm{oc}}}{Z_t}$$

It can be readily seen that this theorem is a special case of equation 10 when two independent pairs of nodes only are considered.

COMPENSATION THEOREM

The compensation theorem is described as follows.

> If a network is altered by making a change ΔZ in the impedance Z of a branch, the change in the currents in all other branches is that which woud be produced by an emf of value $-i \times \Delta Z$ acting in series with the modified branch, where i is the current in Z.

As the theorem stands in this form it cannot represent the effect of changing Z from ∞ to Z but, with the use of equation 10, the change in the current in any branch m, say, due to change of impedance of another branch n, say, from Z_1 to Z_2 is given by

$$I_{m1} - I_{m2} = \frac{Z_t}{Z_t''} \times (V_n)_{\mathrm{oc}} \times \left(\frac{1}{Z_t+Z_1} - \frac{1}{Z_t+Z_2}\right) \quad (10B)$$

This equation covers the whole range of change of Z from 0 to $\pm\infty$; Z_t'' represents the transfer impedance between branch m and branch n, when Z (of branch n) $=0$.

To relate Z_t'' to Z_t, consider Fig. 8:

$$Z_t = \frac{v}{i_m}$$

$$Z_t'' = \frac{v'}{i_m} = \frac{v}{i_m}\left(\frac{Z_t}{Z_t+Z}\right)$$

$$Z_t'' = Z_t \times \frac{Z_t}{(Z_t+Z)}$$

Conclusions

The foregoing derivations show that the theorems associated with the names of Ataka, Tasny-Tschiassny, and Zepler, and the one known as the compensation theorem have no existence independently of Thévenin's and Norton's theorems; practical convenience, however, has justified their independent formulation and use in the past. For the general task of network reduction, important advantages are to be gained by direct application of equations 7, 10, and 11, this being simpler than applying the individual theorems independently.

Appendix

Voltage Distribution Factor

To refer to equation 4, a direct method of obtaining the relationship between the impressed emfs in the network $|e_m|$ and the response voltages at the load terminals $|V_n|$ is desirable. In Fig. 9(A), V_1, V_2, ... V_m represent the voltages at the bus bars of the generators, and V_a, V_b, ... V_n, are the response voltages at the load bus bars both sets of which, for convenience, are shown as accessible terminals. The relationship between the two sets of voltages may be obtained as follows.

By impressing 1 pu current at each accessible generator terminal in turn, the values of the response voltages across the various pairs of load terminals will give the pu values of the elements of $|Z_{nm}|$, where this impedance is the bottom left-hand section of Fig. 9(B), i.e.,

$$\|V_n\| = \|Z_{nm}\| \times \|I_m\|$$

but

$$\|I_m\| = \|Z_{mm}\|^{-1} \times \|V_m\|$$

where $|Z_{mm}|$ is obtained in the same manner, and is the upper left-hand section of Fig. 9(B). Thus

$$\|V_n\| = \|Z_{nm}\| \times \|Z_{mm}\|^{-1} \times \|V_m\|$$

The relationship between $|V_m|$ and $|V_n|$, i.e., $|Z_{nm}||Z_{mm}|^{-1}$ is thus obtained directly, as shown in Fig. 9(C), by short-circuiting $(m-1)$ generator nodes to neutral in turn and measuring the voltages $|V_n|$ with 1-pu voltage applied between the generator node and neutral. In the event of loads being connected to the generator bus bars, this procedure still holds, provided that the loads are correctly represented at terminals 1, 2, etc., but are still contained within the "box" shown in Fig. 9(C).

Current Distribution Factor

In the case of the current distribution factor, the relationship between the load current $|I_n|$ and the currents at the generator terminals $|I_m'|$, due to the flow of current $|I_n|$, can be evaluated as follows: By impressing 1-pu voltage between the load terminals n and the neutral, in turn (all other terminals being short-circuited), and

Fig. 10. System interconnection

values of the response currents at the generator terminals give the pu values of the elements of $|Y_{mn}|$, where $|Y_{mn}|$ is the upper right-hand section of Fig. 9(D), i.e.,

$$\|I_m'\| = \|Y_{mn}\| \times \|V_n\|$$

but

$$\|V_n\| = \|Z_{nn}\| \times \|I_n\|$$

where $|Z_{nn}|$ is obtained in the same manner as $|Z_{mm}|$ of the previous section, but disregarding the connection of loads. Therefore $|I_m'| = |Y_{mn}| \times Z_{nn}| \times |I_n|$.

This factor $|Y_{mn}| \times |Z_{nn}|$, can be obtained directly, as shown in Fig. 9(E), by short-circuiting the m generator nodes to neutral and impressing 1-pu current to the load nodes in turn (the other $(n-1)$ load nodes being open-circuited), and measuring $|I_m'|$ at the generator bus bars.

Additional Losses

Additional losses in a system may be due to the connection of more loads, or to connection to another existing system. Fig. 10 shows a system with a number of accessible terminals, to which additional loads (or another system) are to be connected. It can be shown, assuming negligible change at the generator bus bars due to regulation, that the losses in the original system will increase (or decrease) in accordance with the following relationship. The change in losses in the original system is

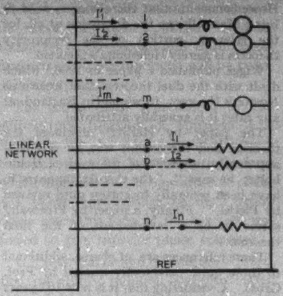

Fig. 11. Effect of load currents on the equivalent circuit of Fig. 9(A).

$$\Delta P = (\|Z_{nn}\| \times \|I_n\|)^* \times \|I_n\|$$

where the asterisk denotes a conjugated quantity, and where $|Z_{nn}|$ is the internal impedance of the original network viewed from the n accessible terminals. It should be noted that the currents through the accessible terminals $|I_n|$ may be positive or negative. The relationship is clearly true since the initial values of $|I_n|$ were zero.

The main point of interest is the case with which the generalization of Thévenin's theorem is applied to give $|I_n|$, since the currents through the terminals 1, 2, .. n are equal to $(|Z_{nn}'| + |Z_{nn}|)^{-1} \times |V_n|_{\mathrm{OC}}$.

This assumption is valid if the generators are not equipped with regulators, and provided the series impedances of the generators are regarded as integral parts of the transmission system, thereby contributing to the losses. However, from the point of view of voltage regulation at the generator bus bars, the effect of connecting new loads is of importance, as follows:

Fig. 11 represents the network where n load accessible terminals are the terminals to which the new loads (or new system) are to be connected; the m generator accessible terminals are those of interest, i.e., those at which the regulation is to be determined. The other generators in the circuit are not of prime interest and are included within the box. Now, as shown above, the current distribution factor $|Y_{mn}| \times |Z_{nn}|$ is measured for the box, thus, $|I_m'| = |Y_{mn}| \times |Z_{nn}| \times |I_n|$. With $|I_m'|$ known, and with the internal impedance matrix of the generators known, the bus-bar voltages may be evaluated.

Discussion

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.): Since the authors deal with a number of useful network theorems, it may be of interest to add a few historical comments: The "Thévenin" theorem was made known 4 years before L. Thévenin (1857–1926) was born; the "principle of the equivalent generator" was first formulated in 1853 by Helmholtz (1821–1894), but never given his name because it must have been considered a minor contribution of this famous physicist. Even if Thévenin did not know of Helmholtz's earlier work when he wrote his article 30 years later, in 1883, those in this country who "discovered" Thévenin some 40 to 50 years ago would have found from a study of the history of circuit theorems, as contained in many European textbooks, who really originated what they then named "Thévenin's" theorem.

Thévenin published his total findings, a dry statement of five paragraphs, without any proofs, in 1883; this paper gives nothing but the procedure of establishing the equivalent generator (see reference 1 of the paper). Helmholtz' paper, however, is a comprehensive analytical investigation which includes the rigorous proof.[1]

The "useful network theorem" given in the authors' reference 2) is also contained in an earlier work, published in 1921 by Willheim[2] in very general form and including the consideration of an electrical center of gravity. This theorem was later used by many authors, and restated by Willheim in two subsequent publications.[3,4]

Colin Adamson and **S. M. El-Sobki**: The authors are grateful to Prof. Gross for emphasizing that the theorem attributed to Thévenin, was, in fact, formulated by Helmholtz in 1853. It may be of interest to note that the question of the credit due to Helmholtz was dealt with, with finality by Howe in 1943,[1] in an article of considerable interest in that it gives in detail the long succession of authors who at various times after its original formulation, "discovered" the Helmholtz (Thévenin) theorem; see, for example, Pomey.[2] Pleijel, of the Swedish Telegraphic Department, had read a paper at the International Conference of Post and Telegraphs in Paris in September 1910, and

Pomey states that Pleijel has used Thévenin's theorem together with a lemma of his own. Howe points out that the lemma is unnecessary as it follows directly from Helmholtz's theorem.

Chapman applied Thévenin's theorem to alternating current networks in 1923.[3] No references were given for earlier papers on the subject. In 1927, Wenner,[4] published a paper, reprinted with documents from a Scientific paper of the United States Bureau of Standards, which restated Helmholtz's theorem and supplied a great many references, including Helmholz but not Thévenin.

The theorem of Helmholtz (Thévenin) was further described in 1928 by V. Jenkin in the pages of *Revue Generale de l'Électricité*. A further statement of the same theorem was made in 1933 by J. G. Brainard in the *Proceedings* of the Institute of Radio Engineers: Brainard called the theorem Thévenin's but added, "Sometimes called Pollard's theorem."

A more substantial contribution was published in 1935 by Van den Meersche.[5] Howe comments that there was no need to bring Maxwell into the discussion at all, for the relevant portion of the reciprocity theorem is merely Helmholtz's theorem.

Wigge published a paper in 1936,[6] which dealt with the duel theorem that known as Norton's theorem, to whom (in England, at any rate) it is generally attributed.

The paper by Herlitz[7] discusses the theorem and the author was, in this case apparently, unaware of the work of Helmholtz; he says "...the theorem appears to have been generally forgotten until revived by Pleijel." Finally, a paper by Freeman,[8] seems to be a restatement of the dual theorem.

These references are, of course, additional to those quite pertinently quoted by Prof. Gross. Considering that it is now 107 years since Helmholtz first formulated the theorem which does not usually bear his name, it is high time that this situation was corrected. It is unfortunate, indeed, that the theorem is nearly always known as Thévenin's theorem by practicing engineers.

Ripple-Type Time-Delay Networks Using Elliptic Functions

J. R. KISEDA

D. J. FORD
ASSOCIATE MEMBER AIEE

ONE METHOD for simulating the approximate effect of transport delay or time delay is through the use of active networks containing electronic operational amplifiers. It is necessary that such networks be used in the field of analog computers so that adequate simulation of problems involving time-delay phenomena can be solved. The thermal and hydraulic problems involved in the design of nuclear reactor power plants form an important class of present-day problems which require such networks.

The purpose of this paper is to present the methods whereby time-delay networks may be designed on the basis of a criterion set up in the frequency domain. The network is selected to have a gain magnitude characteristic which is constant with frequency and a group-delay characteristic (the first derivative of the phase angle with respect to angular frequency) which ripples about the ideal constant value in a prescribed manner. The design methods permit the group delay to assume virtually any ripple-type function. As an example, an elliptic-type function will be studied. Since the ripples are to be considered small in relative magnitude, the phase angle may be assumed to possess a ripple characteristic similar to the group delay.

Historical Background

A number of recent investigators have developed analog computer networks to approximate an ideal time delay or the ideal transport lag. Two studies with which the present work is to be compared are those of Stubbs and Single[1] and Fox.[2] Stubbs and Single produced networks which could be developed from cascaded second-order networks, each of which would have a ripple-type phase characteristic. Their approach was a semigraphical one whereby the variation in the ripple magnitude was considered as certain parameters were varied. The networks of Stubbs and Single produced a phase characteristic which rippled in a somewhat undefined way; the resulting configurations did produce large phase shifts for a given maximum specified phase error. Fox developed circuits with a linear type of "maximally-flat" phase characteristic. These circuits maintained extremely small phase errors in the low-frequency range, with a smooth non-ripple-type phase characteristics throughout the useful frequency range.

Basic Theory

The transfer function of the ideal time-delay device is taken to be $\exp(-sT_d)$ in which s is the complex Laplace transform variable, and T_d is the magnitude of the time delay, or transport delay. For steady-state sinusoidal conditions, this becomes $\exp(-j\omega T_d)$. Appendix I gives a brief proof that the quotient of two infinite-order polynomials represents exactly this ideal steady-state transfer function, provided that the restrictions on the n coefficients implied by equations 21, 23, and 25 are satisfied. If the two series of 21 are terminated at a finite number of terms, then the resulting quotient will approximate the ideal transfer function in a manner dependent upon the restrictions placed on the finite number of A_n, B_n coefficients. Appendix II shows that if the numerator and denominator polynomials are terminated at $n=N$, and if the steady-state gain magnitude is specified as unity for the infinite-frequency range, then the numerator and denominator coefficients must be related as indicated in equation 1.

$$A_{2n}=B_{2n},\ n=0,1,2,\ldots \qquad (1)$$

$$A_{2n-1}=-B_{2n-1},\ n=1,2,3,\ldots$$

When these restrictions are applied to

Paper 59-1193, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted March 23, 1959; made available for printing August 11, 1959.

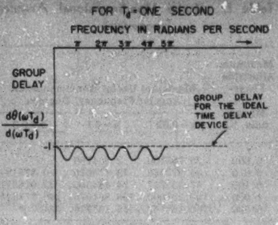

Fig. 1. Ripple-type group delay, curve an elliptic-type function

equation 21, it may be written in the form:

$$e^{-j\omega T_d} \approx \frac{\sum_{n=0}^{N} \cos\left(\frac{n\pi}{2}\right) A_n(\omega T_d)^n - j\sum_{n=0}^{N} \sin\left(\frac{n\pi}{2}\right) A_n(\omega T_d)^n}{\sum_{n=0}^{N} \cos\left(\frac{n\pi}{2}\right) A_n(\omega T_d)^n + j\sum_{n=0}^{N} \sin\left(\frac{n\pi}{2}\right) A_n(\omega T_d)^n} \qquad (2)$$

A magnitude response of unity for all frequencies is typical of all-pass structures, hence equation 2 may be thought of as representing that class of networks.

The object of this paper is to present a general method by which the A_n coefficients of equation 2 can be selected so as to produce a prescribed ripple-type group delay characteristic. This is accomplished by setting an exact (or approximate) form of the desired ripple function equal to the group delay calculated from the right-hand side of equation 2.

In doing this, it is assumed that the magnitude of the ripple is relatively small, so that there will be a somewhat similar ripple in the phase characteristic. The exact shape of the ripple in the phase characteristic is not treated as a design quantity directly, since it was found more convenient to manipulate the group-delay characteristic.

Three main types of ripple functions could be classified as: 1. an equal ripple and periodic function; 2. an equal ripple and nonperiodic function; and 3. a nonequal ripple and nonperiodic function. The function chosen to exhibit the first classification was an elliptic-type function. If $\theta(\omega T_d)$ is the phase angle of the right-hand side of equation 2, the group delay can be set equal to an elliptic-type function in the following manner:

$$\frac{d\theta(\omega T_d)}{d(\omega T_d)} = \frac{-1}{\sqrt{1-k^2 \sin^2 \omega T_d}} \qquad (3)$$

where k controls the maximum value of the curve's deviation from the -1 value. Examples of the second and third classifications of ripple functions will be given in a later paper.

The group delay represented by the elliptic-type function of equation 3 is shown in Fig. 1. This form of the function was selected in preference to the form which oscillates on the opposite side of the -1 value representing the ideal group delay since this form of the function was found to give superior phase response.

In the actual design techniques utilized, the true elliptic function is approximated by a finite number of terms of its binomial expansion. The resulting phase characteristic ripples about the ideal linear-phase characteristic in a manner which produces both positive and negative phase errors. (The phase error is defined as the difference between the phase response of the ideal time-delay transfer function and the calculated theoretical values of the approximation.)

Second-Order Ripple-Phase Approximation

Let N take on the value 2 in equation 2. The resulting transfer function will be a a second-order approximation to the ideal time-delay transfer function, exp$(-j\omega T_d)$. If the A_0 coefficient is factored out of the numerator and the denominator of equation 2, the remaining coefficients could be designed A_1' and A_2'. If A_1' is set equal to KA_2' and the primes are dropped for convenience, the resulting second-order approximation function can be written as:

$$e^{j\omega T} \approx \frac{1-jKA_2(\omega T_a)-A_2(\omega T_a)^2}{1+jKA_2(\omega T_d)-A_2(\omega T_a)^2} \qquad (4)$$

The magnitude of the right-hand side of equation 4 is unity for all real frequencies in a manner typical of all-pass network structures. The phase angle of the right-hand side of equation 4 can be shown to be:

$$\theta(\omega T_d) = -2\tan^{-1}\left[\frac{KA_2(\omega T_d)}{1-A_2(\omega T_d)^2}\right] \qquad (5)$$

while the corresponding group delay becomes:

$$\frac{d\theta(\omega T_d)}{d(\omega T_d)} = -2\times \left[\frac{KA_2+KA_2^2(\omega T_d)}{1+(K^2A_2^2-2A_2)(\omega T_d)^2+A_2^2(\omega T_d)^4}\right] \qquad (6)$$

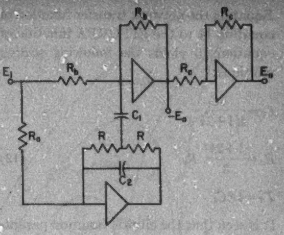

Fig. 2. Second-order ripple-phase circuit

In order to require that the group delay assume an elliptic function form, equation 6 is set equal to equation 3. Comparing these equations, it does not seem possible to require the group delay of the second-order system to fit the elliptic function exactly. Expanding the denominator of the elliptic function in a binomial series and retaining only the first three terms (which requires that k be preferably much less than unity for a reasonably accurate approximation), equations 3 and 6 can be combined to show that:

$$-1 = \left[\frac{-2KA_2+(k^2KA_2-2KA_2^2)(\omega T_d)^2+\left(k^2KA_2^2-\frac{k^2KA_2}{3}\right)(\omega T_d)^4}{1+(KA_2^2-2A_2)(\omega T_d)^2+A_2^2(\omega T_d)^4}\right] \qquad (7)$$

from which the parameters A_2 and K can be determined in terms of the elliptic function parameter k as:

$$A_2 = \frac{1+2k^2}{12} \qquad (8)$$

$$K = \frac{6}{1+2k^2} \qquad (9)$$

This provides the means whereby the elliptic function second-order ripple-phase approximation (EFSORPA) transfer function can be written as:

$$e^{-j\omega T_d} \approx \frac{1-j\frac{1}{2}(\omega T_d)-\left(\frac{1+2k^2}{12}\right)(\omega T_d)^2}{1+j\frac{1}{2}(\omega T_d)-\left(\frac{1+2k^2}{12}\right)(\omega T_d)^2} \qquad (10)$$

Equation 10 completes the mathematical development of the transfer function for the second-order approximation.

One method for physically realizing the transfer function of equation 10 is through use of the analog computer circuit given in Fig. 2. The transfer function of the network in terms of its parameters can be shown to be:

$$\frac{\vec{E}_o}{\vec{E}_i} = \frac{1+j\omega\left(2RC_2-\frac{RR_bC_1}{R_a}\right)-\omega^2R^2C_1C_2}{1+j2\omega RC_2-\omega^2R^2C_1C_2} \qquad (11)$$

Equating the network transfer function of equation 11 to the EFSORPA function of equation 10 yields the following scaling relations:

$$C_2=\frac{3C_1}{4(1+2k^2)}$$

$$R_a=\frac{1+2k^2}{3}\,R_b \qquad (12)$$

$$T_d=4RC_2$$

It is seen that the elliptic function parameter k fixes the ratio of C_1 to C_2 and R_a to R_b. The selection of C_2 allows the time delay T_d to be a linear function of the resistance R.

A set of curves giving the magnitude of the phase error as a function of the nondimensional angular frequency, ωT_d, for various values of k is drawn to semilog coordinates as Fig. 3. The curves of Fig. 3 possess a characteristic which could be termed a bandwidth. This bandwidth could be defined as the frequency range from zero to the highest value for which the per-cent phase-error magnitude equals the value attained at the "hump" or first peak in the curve. By changing the elliptic function parameter k, the bandwidth can be increased or decreased, though the maximum error within the bandwidth varies correspondingly.

For each value of the per-cent phase-error magnitude, there exists a maximum frequency range over which the error is equal to or less than this value. This frequency range varies with the elliptic function k, for a given per-cent phase-error magnitude. Table I gives some calculated values in the relationship between the per-cent phase-error magnitude and the maximum useful frequency range for this error for three different values of k.

It can be shown that the maximum possible phase angle of the EFSORPA function (and the equivalent analog computer network of Fig. 2) ripples slowly about the ideal curve until the maximum usable frequency is reached. Beyond this point the phase angle departs appreciably from the ideal curve and approaches its maximum value of 2π asymptotically.

Experimental Results for EFSORPA Network

To test the feasibility and accuracy of the EFSORPA function development, a set of sinusoidal magnitude and phase-shift tests were conducted on the network of Fig. 2. The measuring equipment available at the time of these tests required that the frequency range be restricted to 20 cps (cycles per second) and above. Some preliminary runs indicated that the useful frequency range for 1% error was about 140 degrees. With this information, a phase shift of 90 degrees was set at 60 cps, and the time delay T_d fixed accordingly. The other parameter values were determined by the scaling relationships of equation 12 and by the selection of arbitrary reasonable values for the small-size analog computer equipment available. The calculated values for the tests are:

$T_d=4.16667\times10^{-3}$ seconds
$C_1=1.0\times10^{-7}$ farads
$R_b=1.0\times10^{6}$ ohms

k	C_2, Farads	R, Ohms	R_a, Ohms
0.02	7.494×10^{-8}	13,900	333,600
0.10	7.353×10^{-8}	14,167	340,000
0.20	6.944×10^{-8}	15,000	360,000

The input and output voltages for the operational amplifier network were measured in the usual way by vacuum-tube

Table I. Useful Nondimensional Angular Frequency*

Maximum Allowable Phase-Error Magnitude, %	Maximum Useful Nondimensional Angular Frequency, Degrees

voltmeters which were calibrated to an accuracy of approximately ±1%. The gain magnitude was unity throughout the frequency range tested. The phase shift between input and output was measured by the 3-voltmeter method.

The experimental phase-shift data is given in the curves of Fig. 4 by the series of *x* marks. As can be seen, the measured values agree very well with the calculated curve. The maximum deviation was 1.3%, which occurred at 60 cps, and was probably due to hum voltage pickup within the circuit. Only the data for *k* equal to 0.2 is given, since the data for the other values of *k* agreed with the calculated values within the same accuracy limits.

Fourth-Order Ripple-Phase Approximation

To develop a fourth-order ripple-phase approximation, the *N* of equation 2 is set equal to four. The general procedure beyond this point is basically the same as in the second-order approximation. However, one or two slight variations on the fundamental method are possible. It might seem desirable to cascade two identical second-order linear-phase approximation networks to form a fourth-order network. This would double the phase angle at each frequency, but it would also double the error, so that the percentage error at each frequency would remain the same as in the second-order case. If one considers a fixed time delay, T_d, this is equivalent to saying that a fourth-order approximation formed in this way would produce precisely twice the useful frequency range, for a given magnitude phase error that the second-order approximation would produce. If, on the other hand, one considers cascading two different second-order ripple-phase approximation functions, it is possible to obtain more than twice the useful frequency range for a given magnitude phase error. This method will be illustrated in the following.

Let the basic polynomial approximation function of equation 2, with *N* equal to four, be broken into two different second-order factors as:

$$\epsilon^{-j\omega T_d} \approx \frac{A_0 - jA_1(\omega T_d) - A_2(\omega T_d)^2}{A_0 + jA_1(\omega T_d) - A_2(\omega T_d)^2} \times \frac{B_0 - jB_1(\omega T_d) - B_2(\omega T_d)^2}{B_0 + jB_1(\omega T_d) - B_2(\omega T_d)^2} \quad (13)$$

Dividing by the leading coefficient and defining new coefficients and constants in the same manner as in the second-order approximation gives:

$$\epsilon^{-j\omega T_d} \approx \frac{1 - jKA_2(\omega T_d) - A_2(\omega T_d)^2}{1 + jKA_2(\omega T_d) - A_2(\omega T_d)^2} \times \frac{1 - jLMA_2(\omega T_d) - MA_2(\omega T_d)^2}{1 + jLMA_2(\omega T_d) - MA_2(\omega T_d)^2} \quad (14)$$

From this, the group delay can be shown to be:

$$\frac{d\theta(\omega T_d)}{d(\omega T_d)} = -2A_2 \times \left[\frac{\begin{array}{l}(K+LM)+\\ (\omega T_d)^2(A_2)(K^2LMA_2+KL^2M^2A_2-\\ \quad 2KM+K+LM^2-2LM)+\\ (\omega T_d)^4(A_2^2M)(K^2LMA_2+KL^2MA_2-\\ \quad 2K+KM+L-2LM)+\\ \quad (\omega T_d)^6(A_2^3M^2)(K+L)\end{array}}{\begin{array}{l}1+(\omega T_d)^2(A_2)(K^2A_2-\\ \quad 2+L^2M^2A_2-2M)+\\ (\omega T_d)^4(A_2^2)(K^2L^2M^2A_2^2-2L^2M^2A_2-\\ \quad 2K^2MA_2+M^2+4M+1)+\\ \quad (\omega T_d)^6(A_2^3M)(K^2MA_2+L^2MA_2-\\ \quad 2M-2)+(\omega T_d)^8(M^2A_2^4)\end{array}}\right] \quad (15)$$

This group delay is set equal to the desired elliptic function (see equation 3), the denominator of which is expanded in a binomial series as before. Retaining the first five terms of this expansion gives:

$$\frac{d\theta(\omega T_d)}{d(\omega T_d)} = \frac{1}{1 - \frac{k^2}{2}\left[(\omega T_d)^2 - \frac{(\omega T_d)^4}{3} + \frac{2}{45}(\omega T_d)^6 - \frac{(\omega T_d)^8}{315}\right]} \quad (16)$$

Thus equating equation 16 to equation 15 gives implicitly the required relationship between the coefficient parameters of the general time-delay approximation function, A_2, *K*, *L*, *M*, and the *k* parameter of the elliptic function. This set of equations can be written as:

$$0 = KA + LMA - 1/2$$

$$0 = K^2A^2 - 3KA + L^2M^2A^2 - 3LM^2A + \frac{k^2}{2}(K+LM)$$

$$\begin{aligned}0 = {} & K^2L^2M^2A^4 + K^2L^2M^3A^4 - 2K^2MA^3 - 3K^2LM^2A^3 - \\ & 3KL^2M^2A^3 + 6KMA^2 + KA^2 - 2L^2M^2A^3 + LM^3A^2 + 6LM^2A^2 - \\ & \frac{k^2}{6}(K+LM) + \frac{k^2}{2}[(K^2LMA^2 + KL^2M^2A^2 - 2KMA + \\ & KA + LM^2A - 2LMA)]\end{aligned}$$

$$\begin{aligned}0=\;&K^2M^2A^4+K^2LM^2A^4+\\&KL^2M^2A^4-3KM^2A^3-2KMA^3+\\&L^2M^2A^4-2LM^2A^3-3LM^2A^3+\\&3KM^2A^4+3LM^2A^4-\\&\frac{k^2}{10}[K^2LMA+KL^2MA^2-\\&2KMA+KA+LM^2A-2LMA]+\\&\frac{11k^2}{630}\,[K+LM]-\frac{3k^2}{2}\times\\&[KM^2A^3+LM^2A^3]\end{aligned}\qquad(17)$$

where the 2 subscript on the A has been dropped for convenience in notation.

Solution of the four simultaneous nonlinear algebraic equations 17 was performed by use of the Newton-Raphson method with Fortran programming techniques applied to an IBM (International Business Machines Corporation) *704* digital computer. Solutions for k equal to 0.02, 0.03, 0.04, and 0.05 were determined. These are given as:

	Elliptic Parameter k			
	0.02	0.03	0.04	0.05
K	10.888727	10.382075	9.917709	9.480453
L	7.812266	7.131397	6.304980	5.368634
M	0.712903	0.668802	0.644128	0.637577
A	0.030380	0.033000	0.035768	0.038750

The substitution of any set of these values into equation 14 yields the final form of the elliptic function fourth-order ripple-phase approximation, or EFFORPA, function for a given k. For $k=0.02$, this can be written as:

$$\epsilon^{-j\omega T_d}\approx\left[\frac{1-j0.330800(\omega T_d)-0.030380(\omega T_d)^2}{1+j0.330800(\omega T_d)-0.030380(\omega T_d)^2}\right]\times\left[\frac{1-j0.169198(\omega T_d)-0.021658(\omega T_d)^2}{1+j0.169198(\omega T_d)-0.021658(\omega T_d)^2}\right]\qquad(18)$$

When k was increased above 0.05, it was found to be impossible to solve the the set of equations 17 with K, L, M, and A restricted to real values.

An analog computer circuit which will realize the transfer function given in equation 14 is shown in Fig. 5. The transfer function of this circuit is:

$$\frac{\vec{E}_0}{\vec{E}_i}=\left[\frac{1+j\omega\bigg(2RC_2-\dfrac{RR_bC_1}{R_a}-\omega^2R^2C_1C_2}{1+j^2\omega RC_2-\omega^2R^2C_1C_2}\right]\times\left[\frac{1+j\omega\left(2R_1C_4-\dfrac{R_1R_dC_3}{R_c}\right)-\omega^2R_1{}^2C_3C_4}{1+j2\omega R_1C_4-\omega^2R_1{}^2C_3C_4}\right]\qquad(19)$$

Since a general solution to the set of equations 17 could not be found, a general set of scaling relationships in terms of k could not be developed either. In a specific case, these can be evaluated. For $k=0.02$, the following can be shown to be true:

$$\begin{aligned}T_d&=6.045949RC_2\\C_2&=0.277623R_b\\C_4&=0.33045C_3\\R_c&=0.756532R_d\end{aligned}\qquad(20)$$

The calculated phase-shift error magnitude in per cent is given in Fig. 6 as a function of nondimensional angular frequency ωT_d. Table II gives the maximum usable nondimensional angular frequency for several values of the phase error magnitude for the data shown in Fig. 6. Comparison of this table with Table I shows that the maximum useful frequency range of the fourth-order network is appreciably more than twice that attainable for the second-order network for the same k. For example, if the phase error is restricted to 1% or less, the maximum usable frequency range of the fourth-order network is 3.25 times that attainable with the second-order configuration for the same k value of 0.02.

The fact that the physical realization of the fourth-order configuration requires only four operational amplifiers as compared to the three amplifiers which were required in the second-order network seems to make the fourth-order network even more attractive. Other physical realizations of the defining equations may be possible which would render this comparison apparently less favorable. Stubbs and Single were able to produce a fourth-order network using only three operational amplifiers and a number of additional components. Questions of convenience in operation and adjustment might make the 4-amplifier configuration presented herein superior to the 3-amplifier configuration of Stubbs and Single.

A comparison of the maximum useful frequency ranges for specified phase-error magnitudes for the Stubbs and Single network, the Fox maximally flat phase-response network, and the elliptic-type ripple-phase function networks is made in Table III. For the extremely low values of phase-error magnitude, the Fox circuit is superior to all other types while for the larger values of phase-error magnitude, the Stubbs and Single circuit gives from 5 to 10% larger useful frequency range than the particular EFFORPA cases calculated. Since the EFFORPA network response changes markedly with the parameter k, it is felt that larger useful frequency ranges could be obtained through further calculations. This is perhaps more evident from Table II and Fig. 6. For example, it is felt that an optimum value for the useful frequency range at a phase-error magnitude of 5% could be found for a k value in the vicinity of 0.035. It is further believed that this optimum value would compare favorably with the range attained by the Stubbs and Single network. By varying k, the optimum useful frequency range could be obtained for each value of phase-error magnitude of interest. A chart or set of curves could be drawn to portray this information easily. Experimentally, a similar set of data could be obtained by varying the resistance and capacitance values of Fig. 5 to obtain a variation in k. The lack of a general solution for k in terms of the network parameters would hamper this method, but the ranges of

values to be investigated is made reasonably narrow by the solutions presented in the foregoing.

From a partical viewpoint, only those frequency ranges, in the vicinity of the 0.10, 1, and 5% phase-error magnitude values of Table III would probably be significant. For the EFFORPA network, the variation in the frequency range with k for these phase-error values again points to the wide range of characteristics obtainable.

Experimental Results for EFFORPA Network

The EFFORPA network with k equal to 0.02 was tested experimentally by the same methods as those used to test the EFSORPA network. The time delay was selected by setting the 60 cps phase shift at 180 degrees. The scaling relations were developed in a manner similar to that indicated for the EFSORPA case. The numerical values used are given as:

$T_d=8.33333\times10^{-3}$ seconds
$C_1=1.0\times10^{-7}$ farads
$C_2=9.005\times10^{-8}$ farads
$C_3=1.0\times10^{-7}$ farads
$C_4=3.3045\times10^{-7}$ farads
$R_a=277{,}623$ ohms
$R_b=1{,}000{,}000$ ohms
$R_c=756{,}432$ ohms
$R_d=1{,}000{,}000$ ohms
$R=15{,}306$ ohms
$R_1=21{,}334$ ohms

The experimental phase-shift points are given in Fig. 7. The same very close agreement of the experimental points with the calculated curves was obtained in this case as was found for the EFSORPA network. The magnitude ratio was constant at unity through out the frequency range tested.

Conclusions

A method of designing approximate time-delay simulation network in the frequency domain has been presented. The method utilizes an expansion of the steady-state sinusoidal transfer function of an ideal time-delay device into the quotient of two polynomials in ωT_d. By taking a finite number of terms of the expansion, an approximation to the ideal time-delay device is obtained. If the corresponding coefficients in the numerator and denominator are set equal (except for the signs of some terms), the quotient will possess first, a constant unity-gain for all positive frequencies which is characteristic of all-pass structures, and second, a phase characteristic which may be adjusted at will. By setting the group-delay equal to a desired ripple-type function, it is possible to cause the phase characteristic to ripple about the ideal linear-phase curve. The details of the development were illustrated for an elliptic-type ripple function in second- and fourth-order transfer-function configurations. The method has been applied to other ripple-type functions but the results were not presented here.

No attempt was made to obtain the maximum possible usable frequency range for the elliptic-type ripple-function approximation networks under conditions of various specified phase-error magnitudes. The general range of k for this optimum condition was indicated for the 1 and 5% phase-error magnitude cases in the calculated data. One calculated case indicated that it was possible to obtain considerably more than twice the usable frequency range with a fourth-order approximation network, than was possible with a second-order network for a given phase-error magnitude and a given elliptic-function parameter value.

It is believed that the design methods presented in this paper give a methodical way of developing a large class of ripple-type time-delay simulation networks.

Appendix I. Validity of Approximation for $e^{-j\omega T_d}$

The expansion chosen for the ideal time-delay transfer function in this paper is

$$\epsilon^{-j\omega T_d}=\frac{\sum_{n=0}^{\infty}(-j)^nA_n(\omega T_d)^n}{\sum_{n=0}^{\infty}(-j)^nB_n(\omega T_d)^n} \tag{21}$$

which could be expanded to:

$$\epsilon^{-j\omega T_d}=\frac{A_0-jA_1(\omega T_d)-A_2(\omega T_d)^2+jA_3(\omega T_d)^3+A_4(\omega T_d)^4+\ldots}{B_0-jB_1(\omega T_d)-B_2(\omega T_d)^2+jB_3(\omega T_d)^3+B_4(\omega T_d)^4+\ldots} \tag{22}$$

A judicious choice of the coefficients of $(\omega T_d)^n$ in equation 22 would permit it to be expressed as:

$$\epsilon^{-j\omega T_d}=\lim_{n\to\infty}\left[\frac{1-\frac{ja_1}{n}(\omega T_d)-\frac{a_2}{n^2}(\omega T_d)^2}{1-\frac{jb_1}{n}(\omega T_d)-\frac{b_2}{n^2}(\omega T_d)^2}\right]^n \tag{23}$$

It can be shown that

$$\lim_{n\to\infty}\left[\frac{1-\frac{ja_1}{n}(\omega T_d)-\frac{a_2}{n^2}(\omega T_d)^2}{1-\frac{jb_1}{n}(\omega T_d)-\frac{b_2}{n^2}(\omega T_d)^2}\right]^n=\epsilon^{-j(a_1+b_1)(\omega T_d)} \tag{24}$$

If a_1 and b_1 were restricted by the following relationship:

$$a_1+b_1=1 \tag{25}$$

then:

$$\lim_{n\to\infty}\left[\frac{1-\frac{ja_1}{n}(\omega T_d)-\frac{a_2}{n^2}(\omega T_d)^2}{1-\frac{jb_1}{n}(\omega T_d)-\frac{b_2}{n^2}(\omega T_d)^2}\right]^n=\epsilon^{-j\omega T_d} \tag{26}$$

Thus it has been shown that

$$\epsilon^{-j\omega T_d}=\frac{\sum_{n=0}^{\infty}(-j)^nA_n(\omega T_d)^n}{\sum_{n=0}^{\infty}(-j)^nB_n(\omega T_d)^n} \tag{27}$$

provided that the restrictions imposed on the coefficients of equation 21 by equations 23 and 25 are satisfied.

It is to be noted this illustrates that the correct choice of the A_n and B_n coefficients of the right-hand side of equation 21 allows one to say that this quotient of two infinite-order polynomials becomes exactly the exponential function, exp $(-j\omega T_d)$. Since the angle of exp $(-j\omega T_d)$ is ωT_d, a completely linear function of ω, the correct choice of A_n, B_n in equation 21 will produce precisely this phase characteristic. The objective of this paper is to show that by using a truncated form of the right-hand side of equation 21 and by setting slightly different restrictions upon the (finite number of) A_n, B_n coefficients, a phase characteristic can be produced which will ripple about this exact phase characteristic, exp $(-j\omega T_d)$ in a prescribed way over a finite-frequency range while the magnitude characteristic can be made to be precisely constant at unity for this same finite-frequency range (as well as, incidently, the entire infinite-frequency range).

Appendix II. Restrictions on Coefficients of All-Pass Network Transfer Function Approximation to Ideal Time Delay

It has been shown in Appendix I that:

$$\epsilon^{-j\omega T_d} = \frac{A_0 - jA_1(\omega T_d) - A_2(\omega T_d)^2 + jA_3(\omega T_d)^3 + A_4(\omega T_d)^4 + \ldots}{B_0 - jB_1(\omega T_d) - B_2(\omega T_d)^2 + jB_3(\omega T_d)^3 + B_4(\omega T_d)^4 + \ldots} \qquad (28)$$

was a valid approximation for $\epsilon^{-j\omega T_d}$ provided that the restrictions imposed on the coefficients of $(\omega T_d)^n$ of equation 28 by equatious 23 and 25 were satisfied. Equation 28 can be written in the following equivalent form:

$$\epsilon^{-j\omega T_d} = \frac{\sum_{n=0}^{\infty} \cos\left(\frac{n\pi}{2}\right) A_n(\omega T_d)^n - j\sum_{n=0}^{\infty} \sin\left(\frac{n\pi}{2}\right) A_n(\omega T_d)^n}{\sum_{n=0}^{\infty} \cos\left(\frac{n\pi}{2}\right) B_n(\omega T_d)^n - j\sum_{n=0}^{\infty} \sin\left(\frac{n\pi}{2}\right) B_n(\omega T_d)^n} \qquad (29)$$

To form an approximate expression for exp $(-j\omega T_d)$, a finite number of terms of equation 28 is selected, say $N-1$ terms. Then equation 28 becomes:

$$\epsilon^{-j\omega C_d} \approx \left| \frac{\sum_{n=0}^{N} \cos\left(\frac{n\pi}{2}\right) A_n(\omega T_d)^n - j\sum_{n=0}^{N} \sin\left(\frac{n\pi}{2}\right) A_n(\omega T_d)^n}{\sum_{n=0}^{N} \cos\left(\frac{n\pi}{2}\right) B_n(\omega T_d)^n - j\sum_{n=0}^{N} \sin\left(\frac{n\pi}{2}\right) B_n(\omega T_d)^n} \right. \qquad (30)$$

If the magnitude of equation 30 is set equal to unity for all frequencies, then:

$$\left\{ \frac{\left[\sum_{n=1}^{N} \cos\left(\frac{n\pi}{2}\right) A_n(\omega T_d)^n\right]^2 + \left[\sum_{n=0}^{N} \sin\left(\frac{n\pi}{2}\right) A_n(\omega T_d)^h\right]^2}{\left[\sum_{n=1}^{N} \cos\left(\frac{n\pi}{2}\right) B_n(\omega T_d)^n\right]^2 + \left[\sum_{n=1}^{N} \sin\left(\frac{n\pi}{2}\right) B_n(\omega T_a)^n\right]^2} \right\}^{1/2} = 1 \qquad (31)$$

Equation 31 will be satisfied when the A_n, B_n are chosen such that:

$$A_{2n} = B_{2n},\ n = 0,1,2,\ldots$$

$$A_{2n-1} = -B_{2n-1},\ n = 1,2,3,\ldots \qquad (32)$$

If equation 32 is inserted into equation 30, the right-hand side of 30 will be in the form of the transfer function for an all-pass network structure. Selection of the A_n coefficients will then specify the phase characteristic of the network. In this paper, the A_n are selected so as to produce a ripple-type group delay and thus a ripple-type phase characteristic.

Subarea Determination of the Capacitance of Cocentric Annular-Plate Capacitors

DANIEL K. REITAN
MEMBER AIEE

THOMAS J. HIGGINS
FELLOW AIEE

Synopsis: The basic theory of calculation of the capacitance of a capacitor comprised of two cocentric annular plates by the method of (annular) subareas is advanced. Confirming the theory, excellent agreement results between the several available experimentally determined (by electrolytic tank) values for specifically dimensioned capacitors and corresponding calculated values. A family of universal curves is constructed. These afford, by inspection, values of capacitance over the range of geometry of interest in practice.

IN A SERIES of recent papers Aikawa, Oshiyama, Sano, Nakaya,[1–3] Sato, and Ataka[4–6] discuss the capacitance of a capacitor consisting of two cocentric circular annular plates, relative to the use of this configuration in the important industrial problem of determining moisture content of various materials by measuring their "effective" dielectric constants. In addition, this problem is of other than purely electrical interest. Knowledge of a parameter analogous to the capacitance is required, for example, in the hydrodynamic or aerodynamic problems associated with the irrotational flow of a fluid through cocentric annular orifices in an infinite barrier,[7] or of the irrotational flow of a fluid around a thin cocentric annular plate,[8] or of a thin cocentric annular plate moving in a viscous fluid in the direction of its normal.[9]

Exact determination of the capacitance of (and such associated aspects as the charge density over) a stated finite plane area is a problem of such analytical difficulty that exact solutions in terms of tabulated functions have been effected to date only for the circular and elliptic discs.[10,11] In consequence it is to be expected that known solutions for a capacitor composed of two finite plane areas would be both more restricted in geometry and more difficult to effect in analysis. Such is actually the case. It would seem that solutions are known only for capacitors composed of two coaxial[12–23] or two coplanar[24] identical circular plates,

as obtained by quite intricate analysis. Thus, Kobayashi's[24] solution, the only one available, for coplanar disks enfolds a very complicated analysis based on use of double hypergeometric series.

At the conclusion of his solution Kobayashi mentions the desirability of determining the capacitance of a capacitor consisting of coplanar circular-annular plates, remarks on the corresponding greater difficulties that would attend solution, and conjectures that this problem is intractable to rigorous analytic solution. Such is also the recent opinion of Aikawa. Lacking an equation enabling calculation of the capacitance of a cocentric annular-plate capacitor, Aikawa, Sato, and Ataka determined the several values of the capacitance needed in their investigation by analogous measurements effected in an electrolytic tank.[25] The capacitance of this biplate capacitor can, however, be obtained analytically to any desired degree of precision and over any desired range of geometry by the method of subareas developed earlier by the present authors in determining the capacitances of several single-plate capacitors.[26–29]

Accordingly, the prime purpose of this paper is to advance, as determined by the method of subareas, a set of curves which afford the capacitance of a coplanar annular-plate capacitor of specified dimensions over the range of geometry to be encountered in practice.

Fig. 2. Potentials at a point r in the plane of a uniformly charged subannulus

Recasting the Computations

The basic course of procedure, somewhat different from that used in earlier papers,[26–29] is summarized as follows. Consider each of the two plates as comprised of subannuli, numbered $(i=1, \ldots, n)$ for one plate and $(i=n+1, \ldots, n+n')$ for the other. As in Fig. 1 therefore $n=6$ and $n'=4$. In view of angular symmetry, the charge density is a function of only the radial co-ordinate. Accordingly, consider each subannulus S_i as of essentially uniform, but different, charge density q_i and of essentially constant potential V_i. If V_{1i} denotes the potential at the midpoint of subannulus S_1 produced by the subannulus S_i of charge density q_i, the total potential V_1 of subannulus S_1 of charge density q_1 is

$$V_1=\sum_{i=1}^{n+n'} V_{1i} \qquad (1)$$

A similar equation expresses the potential

Table I. Capacitance as a Function of k_1r and k_2r ($k_3r=6$)

5.5	5.5	7.99	12
5.75	5.75	7.21	12
6	6	0	

of each of the other subannuli. Hence the resulting set of $n+n'$ equations is to be expressed generally by

$$V_j=\sum_{i=1}^{n+n'} V_{ji} \quad (j=1,\ldots,n+n') \tag{2}$$

where each of the V_{ji} are furnished by appropriate use of the equations of Fig. 2, which have been developed in reference 27, equations 7, 8, 9.

Imposing next the conditions, stemming from the fact that in exact solution each plate is an equipotential surface, $V_0=V_j(j=1,\ \ldots,n)$ and $V_0'=V_j(j=n+1,\ldots,n+n')$, and subtracting in turn each equation (furnished by $j=2,\ \ldots,n+n'$) from the first yields a set of $(n+n'-1)$ equations for the q_i. Of this the constant member on the right-hand side of each equation is either zero or (V_0-V_0'). An additional equation stems from the condition that in exact solution the plates have equal but opposite charges, hence the sum of the charges on the $n+n'$ subannuli is zero. Thus,

$$\sum_{i=1}^{n+n'} Q_i=\sum_{i=1}^{n+n'} A_iq_i=0 \tag{3}$$

A_i designates the area of the subannulus S_i. Solution of the complete set of $(n+n')$ equations 2 and 3 yields expression of the q_i in terms of (V_0-V_0').

Finally, as in previous solutions,[26-29] approximation of the value of the capacitance C follows from

$$C=Q/(V_0-V_0')=\left[\sum_{i=1}^{n} A_iq_i\right]\Big/(V_0-V_0') \tag{4}$$

The term (V_0-V_0') cancels on effecting the division indicated in equation 4. In addition, the values of the q_i afford approximation to the charge density distribution over the plates.

In conclusion, it is to be noted that determination of C and $q(r)$ can be effected to increasingly good degrees of precision by an increase of n and n'. As indicated in the following section, excellent approximations are afforded by use of relatively small values of n and n'.

An Illustrative Example

Fig. 1 shows one quadrant of a specifically dimensioned annular capacitor (of radii 1 and 4 cm (centimeter) and 5 and 6 cm) divided into 10 subannuli. Evaluating the V_{ji} in equation 2 by use of the equations tabulated in Fig. 2 and the Q_i in equation 3 yields a set of 10 equations in terms of the 10 unknown q_i. Solution yields values of q_i as noted on Fig. 1. Hence

$$Q_{\text{total}}=\sum_{i=6}^{10} A_iq_i=3.353(V_0-V_0') \tag{5}$$

Equations 4 and 5 furnish $C=Q/(V_0-V_0')=3.353(V_0-V_0')/(V_0-V_0')=3.353$ electrostatic units $=3.726$ μμf (micromicrofarad), as plotted at the point ($k_1=4$, $k_2=5$) on Fig. 3.

Universal Curves for Capacitance

A series of computations, effected as in the preceding section, where the values of $r=1$ cm and $k_3=6$ cm are maintained and k_1 and k_2 are suitably varied between 1 and 6, yields the data of Table I.

As in the electrostatic units set of units, the primary dimensions of C are centimeters; and as in virtue of angular symmetry the capacitance of a coplanar annular-plate capacitor is a function of the four radial dimensions alone, it follows from Buckingham's Π-Theorem[30] that C/r is dimensionless and is a function of the three dimensioned quantities k_1, k_2, and k_3. If, then, k_3 is held constant and a family of curves of C/r versus k_1 is plotted for a range of values of k_2, the resulting set of curves affords the capacitance of any coplanar annular-plate capacitor having this fixed k_3. Fig. 3, plotted from the data of Table I, comprises this family of universal curves. The value of $r=1$ shown on Fig. 1 is one of convenience in the solution for the normalized curves of Fig. 3; any arbitrary value r_0 of r could be chosen. Thus, taking $r_4=6r_0$, whence k_3 yet equals 6, yields the same set of C/r curves.

The values of $C/r=0$ at the points ($k_1=1$, $1\leq k_2\leq 6$) and the corresponding values of $C/r=0$ at the points ($1\leq k_1\leq 6$, $k_2=6$) are for points where the inner and outer annuli, respectively, degenerate to circular lines, for which $C=0$: which is always the case for a capacitor comprised of two "plates" where one plate is a finite surface and the other plate degenerates to a finite line segment.

Finally, a plot of a similar set of curves for a desired range of values for k_3 would yield a portfolio of universal curve sheets from which could be obtained, by means of suitable interpolation, the capacitance of any specifically dimensioned capacitor.

Experimental Confirmation

For the annular capacitor defined by ($r=0$, $k_1=5/2$, $k_2=3$, $k_3=6$) Aikawa found (Fig. 5 of reference 3) by electrolytic tank measurements that $C\cong 2.75$ μμf. For the same k_i ($i=1, 2, 3$) but $r=1.0$, Fig. 3 yields, in good agreement, $C\cong 2.63$ μμf. The slightly higher value given by Aikawa is to be expected: for his inner plate encompasses a complete circular disk ($r=0$) rather than an annulus ($r=1$). The center holes in the configuration of the annuli act to reduce the capacitance slightly, how much depending upon the magnitude of k_1/r_1: as predicted by the well-known theorem in electrostatics that the capacitance of any portion of a capacitor is less than the capacitance of the complete capacitor.

It is of interest to note that Aikawa's electrolytic tank measurements tend to a final value of $C=\infty$ as the radial separation between the plates approaches zero (the edge-effect becoming the predominant factor); such results from the necessary use of plates of finite, even though very thin, thickness. However, such is not the case for the indefinitely thin plates of this paper. Thus in Fig. 3 for the limiting case of $k_1=k_2=3$, the capacitance approaches $C\cong 4.25$ μμf, whereas Aikawa's "corresponding" value approaches $C=\infty$. Changing Aikawa's curve to a final value of $C\cong 4.25$ μμf (assuming $r=0$) would not significantly change his curve in the working range pertinent to the geometry to be expected in practice: whence it is to be inferred that his electrolytic tank measurements provide substantial confirmation of the accuracy of the calculated curves of Fig. 3.

Summary

The basic theory of determination of the capacitance of a coplanar annular-plate capacitor by the method of subareas (subannuli) is outlined and application is illustrated by detail of calculation for a specifically dimensioned capacitor. Corroboratively, this value is found to be in good agreement with corresponding experimental values determined by electrolytic tank measurement.

A family of universal curves is advanced, which yields the capacitances of annular capacitors over the range of radial geometry of essential interest in practice.

Detection of Transmission Errors in 5-Level Punched Tape

R. STEENECK
NONMEMBER AIEE

H. F. CALEY
ASSOCIATE MEMBER AIEE

BUSINESS CONCERNS in this age of automation are making steadily increasing use of their leased telegraph systems for the transmission of data in 5-level tape form. The number of errors introduced in the data by transmission over high-grade facilities is relatively small and can be tolerated in many business applications. In some situations, however, the error frequency must be reduced to the lowest possible rate. For these situations the telegraph company has developed equipment which will incorporate redundant check characters in the data at the transmitting end of the circuit and perform the check and delete the check characters at the receiving end.

Error-Checking Principle

The first problem which must be resolved in the design of an error-detecting system is which of the many possible error-detecting codes will be used. As this system had to be compatible with conventional 5-level telegraph switching equipment, use of any of the simple vertical parity checks was ruled out because they require at least six levels. In addition, extensive tests showed that vertical parity checks are relatively ineffective when the bits making up a character are transmitted serially as they are on a telegraph circuit. Approximately 10% of the errors encountered in telegraphic communications affect two bits in the same character and the resulting errors are not detected by the simple vertical odd or even parity check. The information which can be transmitted in any given time is also reduced by $16^{2}/_{3}\%$. More complex vertical parity checks have been devised which lower the 10% undetected error rate but they further decrease the rate of transmission.

Attention was therefore directed to the horizontal-type checks and tests were made of the effectiveness of a single horizontal parity character at the end of each line (maximum of 72 characters) and a two-character binary total at the end of each line. Both of these checks proved superior to the vertical parity checks with the two-character binary total being the more effective of the two. It had the further advantage of reducing transmitted information per unit time by less

than 5%. Accordingly, this system was adopted.

Figs. 1 and 2 illustrate the basic features of the 2-character binary total-error detection system. Each character is considered a 5-digit binary number with levels 1–5 having weights 1, 2, 4, 8, and 16 respectively. The characters in a variable-length line which does not exceed 72 characters are totalled up to and including the "carriage return."

The simple computer used has 8 stages and can therefore total from 0 to 255. As the total for a line of 72 characters can be as high as 2,232 the counter will cycle a number of times in totaling an average line. This raises the possibility that equipment troubles in switching centers such as sticking pins on transmitters will consistently add or drop a number of pulses in one of the levels which may be sufficient to exactly cycle the counter and cause the errors to be undetected. This cannot occur in levels 1 and 2 when block length is limited to 72 characters because 256 pulses must be lost or gained in level 1 and 128 pulses lost or gained in level 2. However, the possibility does exist in levels 3, 4, and 5 where gaining or losing 64, 32, and 16 pulses, respectively, will cycle the counter.

A simple modification which causes the computer to cycle on a count of 255 instead of 256 greatly improves this situation and requires that 255 pulses be added or lost in anyone of the 5 levels before a computer cycle can be gained or lost. This, of course, cannot occur in 72-character groups.

At the end of the group the complement of the 8-digit binary total in the computer is punched in the tape as levels 1, 2, 4, and 5 in two characters. The third level of each of these characters is always punched to avoid the formation of control-character combinations such as *Figs*, *H* and *CR*, *CR* used in switching systems.

The checking process at the receiving station consists of again totaling the characters in the group in a computer very similar to the one in the sending unit. The 8 binary digits in the two check characters are also totalled and if no errors were introduced in transmission this results in all eight stages of the computer being set on 1. The binary additions in Table I illustrate the processes taking place in the sending and receiving computers for the short blocks of data shown on Figs. 1 and 2.

If any of the bits in the block were reversed during transmission it can be seen that the foregoing process would result in at least one of the stages in the receiving computer being set on zero.

With this checking system errors occurring in one character can be compensated for by equal and opposite errors in the same level in another character in the same block of data. This condition, fortunately, is quite rare on high-grade land lines. Much more frequent is the mutilation of several successive bits by one "hit" on the line or the shifting of a marking bit from one level to the next and this system prevents such errors from being compensating.

System Design

Both sending and receiving units operate at 200 wpm (words per minute) and are, therefore, capable of handling up to three 65-wpm transmission circuits.

The equipment can be packaged in different ways depending on whether data will flow in only one direction or in both directions. The simplest system for checking data flowing in one direction will be described but it will be noticed that sending and receiving station equipments are very similar and with only minor additions and modifications could serve both functions.

The checking equipment at the sending station is illustrated in Fig. 3 and a block diagram is shown in Fig. 4.

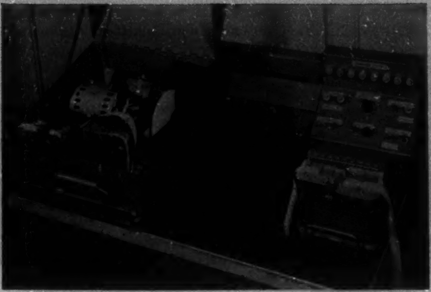

Fig. 3. Sending station equipment

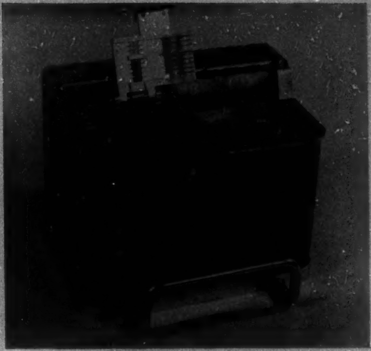

Fig. 5. Dual-reading tape transmitter

Sending Station Operation

The sending-end equipment is primarily designed to produce from the data tape a new tape incorporating check characters at the end of each line of data. To start this process the selector switch is set to the "Generate Tape" position and the data tape without check characters which has been prepared on a *Type 19* set, or other tape producing equipment, is fed through the special dual-reading transmitter; see Fig. 5. This transmitter has two sets of reading pins 0.1 inch apart which is the distance between characters on the tape. The first set feeds the computer and the second set feeds the reperforator through the check character switch and the character-reading matrix. Routing information at the beginning of the tape for the control of switching centers is transmitted to the reperforator, but is not sent to the computer which is turned off at this time. At the end of the routing information, a special 3-character code which has been inserted in data preparation is read indicating the beginning of the data. At this point the computer is turned on automatically and set to zero count. In the block diagram the starting 3-character code is shown as *Figs, A, Ltrs;* however, any combination could be used.

The entire first block of data ending with *CR* is sent to both the reperforator and the computer. When *CR* is read by the matrix the transmitter is stopped, the two check characters are transmitted from the computer to the reperforator and the computer is reset to zero. This process is repeated for the next data block beginning with *LF* and ending with *CR* and for succeeding data blocks until the *end-of-data* characters *Figs, A, F, Ltrs* are read. This combination turns off the computer and allows the message terminating characters to be transmitted only to the reperforator. By using two sets of reading pins in the transmitter, one to transmit to the computer and one to the reperforator, the possibility of reading errors being undetected is practically eliminated. The possibility of both sets of pins making the same error is extremely small and any difference will be detected in the check at the receiving station.

Fig. 4. Block diagram of sending station

The tape that has been produced in the reperforator contains check characters for each block of data and may be transmitted over any conventional switching system or leased circuit.

If it is desired to check the tape locally transmitting it the selector switch is thrown to "Check Tape" which disconnects the reperforator and connects checking units. The tape is fed through the dual-pin transmitter and each block is checked for punching errors in a manner which will be described in succeeding sections covering the receiving station unit. If an error is detected an alarm is sounded and the tape stops until the "Reset" switch is operated which silences the alarm and causes checking to continue.

Receiving

At the receiving station the data tape with check characters is received on a reperforator and is fed to the transmitter on the error-checking unit, shown in Fig. 6. A block diagram of this receiving unit indicating the functions of the various components is shown in Fig. 7.

The transmitter sends to a reperforator through the reperforator control switching unit which is in the normal position at this time. Read-back pins on the reperforator spaced 5 characters after the punch pins read the final tape and feed the characters to the computer and the character-reading matrix. The

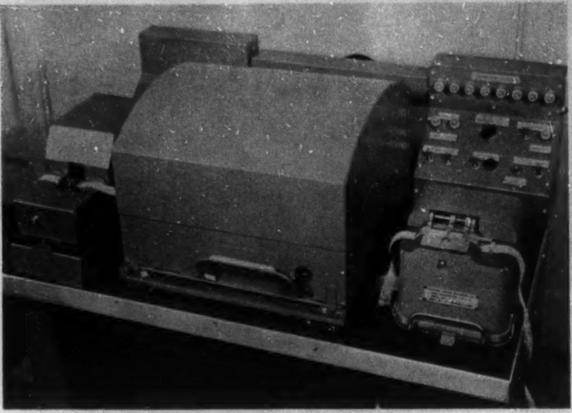

Fig. 6. Receiving station equipment

computer is turned off while the routing information at the beginning of the tape is passing over the read-back pins. When the characters *Figs*, *A*, *Letters* are read by the matrix associated with the reperforator the computer is turned on and totaling of the characters in the first data block starts.

The checking process is done in two different ways depending on whether the selector switch is in "Delete" or "Non-Delete" position. If it is desired that check characters shall not be punched in the final tape the Selector Switch is thrown to "Delete" and checking proceeds in the following manner.

The first data block continues to be sent from the transmitter to the reperforator until the matrix associated with the transmitter reads the *CR* at the end of the block. It should be remembered that the read-back pins on the reperforator are reading the 5th character before the *CR* because of the spacing of the punch pins and the read-back pins. The reperforator is turned off at this point and levels 1, 2, 4, and 5 of the two check characters are transmitted only to the computer. The computer control unit directs the four elements of the first character to stages 1–4 of the computer and the four elements of the second check character to stages 5–8 of the computer. The reperforator is then turned on again and the transmitter starts to send the characters of the second data block starting with *LF* and the read-back pins on the reperforator read the remaining characters of the first data block. When the read-back pins read the *CR* at the end of the first block this is detected by the character reading matrix associated with the reperforator. After the *CR* character is totaled a check is made to see if all stages of the counter are set to 1 and the counter is reset. If this check is satisfied the block is marked in black by the tape marker and checking of the second block proceeds without interruption. If any counter stage is set to 0 the system is stopped, an alarm is sounded and the errored block is marked in red. The "Reset" switch must be operated before checking will proceed. However, if the error switch is thrown to "Non-Stop" detection of an error will only cause red marking of the block. Checking of succeeding blocks will be continued and no alarm will be sounded.

This checking process proceeds until the reading matrix associated with the reperforator detects *Figs*, *A*, *F*, *Letters* after the check characters at the end of the last data block. The computer is turned off and any further characters in the received tape are punched but not checked.

To safeguard against improper operation of the checking circuitry a long-block indicator is provided to detect the absence of a check cycle within the maximum block length of 72 characters. This condition stops the equipment and sounds an alarm indicating that an end-of-block signal and a check cycle have been missed. Action can then be taken to recheck and if necessary rerun the skipped block.

on normal facilities and an inexpensive system was desired automatic error correction is not provided. When an error is detected the block must be identified and a rerun requested from the sending station.

Conclusions

At the present time only empirical figures can be given on the effectiveness of this system in detecting transmission errors. A calculated figure based on an assumption of a random distribution of single-bit errors throughout the levels and blocks would be meaningless as errors introduced in switching equipment have a different distribution from those introduced on the lines, and neither appear to be randomly distributed single-bit errors. A mathematical analysis of effectiveness will have to await the results of tests now under way to determine the rate, nature, and distribution of errors introduced by lines and equipment. However, while the precise distribution of errors is not yet known, experience and tests to date have given an indication of the general pattern of equipment and line errors.

This system has been designed to be particularly effective in detecting both of these types of errors while at the same time requiring a low degree of redundancy. Operational tests on typical switching systems and frequency-modulated telegraph circuits indicate that when the telegraph system error rate is one errored character per 50,000 characters transmitted, the undetected error rate will be about one undetected error per 100,000,000 characters transmitted.

Application of a New Carrier Telegraph System

T. B. COLLINS, JR.
ASSOCIATE MEMBER AIEE

J. E. PITTS
NONMEMBER AIEE

THE transmission of telegraph or data signals by carrier frequencies operating in the voice-frequency band involves considerations not normally associated with voice signals transmitted in this band. Transmission requirements for the data or telegraph carrier facility may range from those of a single-channel 2-wire system to the maximum of a 26-channel 4-wire system.

The bandwidth of the carrier facility is a determining factor in the number of channels that may be carried by the circuit. The signal-to-noise ratio has a direct bearing on the amount of distortion introduced into the telegraph signals.

When a telegraph channel is remote from the data or teleprinter equipment, the d-c pulses in the connecting circuit are affected by the distributed capacitance or inductance in the connecting circuit. These properties tend to alter the waveshape, or rate of rise and decay, of the d-c signals flowing in the circuit. Excessive distortion (change in waveshape) will cause transmission failure.

The type *23A* system uses frequency-shift keying with transmission of one frequency indicating a mark signal, and transmission of another frequency indicating a space signal. A block diagram of a typical channel with complementary equipment panels is shown in Fig. 1. A complete operating description of the system is included in a paper by Stephens.[1]

Fig. 2 shows a channel shelf with one unit disengaged from its mounting.

A subscriber set, Fig. 3, is used to install a single-channel unit at a subscriber's premises. The subscriber set consists of a cabinet to house a channel unit and the local d-c power supply. Contained in the cabinet as part of the set are 2- or 4-wire line-terminating equipment for the channel unit, loop-terminating equipment, and a terminal strip for connections to the line and teleprinter machine.

Auxiliary panels may be used to connect telegraph channels in multiple when the channels of a system are terminated at different locations. The panels are generally used in 2-wire applications but also may be used in some instances for 4-wire operation

A bridging panel may be used where one or more channels are connected at an intermediate point in a system.

A branching panel is used to join a maximum of three connecting lines to a main line at one intermediate point.

The discussion of telegraph carrier applications in this paper is divided into three sections.

1. Transmission considerations.
2. System application considerations.
3. Direct-current loop arrangements.

The equipment referred to in this paper is a new system developed by the Lenkurt Electric Company, the type *23A* Telegraph and Data Carrier System.

Transmission Considerations

Channel Frequencies

The frequency assignments of the *23A* system are shown in Tables I and II. These are not the actual frequencies transmitted; the transmitted frequencies are obtained by adding and subtracting the amount of specified shift from the mid-band frequency.

Low-Frequency Band Channels

The first 18 channels are generally considered as the low-frequency group. The frequency band of this group falls between 340 and 3,400 cps (cycles per second). The only requirement of frequency response over this band is that the difference in level between the mark and space frequency of any given channel should not exceed 1 db (decibel) for minimum effect on received signals bias. A greater difference is not detrimental in itself, but usually indicates a drop-off in filter response (low-pass filters, band separation filters, channel filters) which may cause a change in the velocity of transmission between the mark and space frequencies. This may, in turn, result in bias of the d-c signal output of the discriminator.

A greater slope than 1 db can, of course, be tolerated and the resulting bias can be removed by adjustment of the bias potentiometer during system lineup. However, if the channel is patched to a spare facility with a different slope characteristic, a change in the bias adjustment would probably be required for optimum performance.

Paper 59-1107, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11-16, 1959. Manuscript submitted June 8, 1959; made available for printing July 14, 1959.

When the connecting facility is nonloaded cable, which has a gradually rising attenuation characteristic at the higher frequencies, the only limitation other than the 1-db restriction mentioned will be the attenuation offered to the frequency of the highest channel to be transmitted.

HIGH-FREQUENCY BAND CHANNELS

The eight channels above 3,500 cycles are referred to as the high-frequency group. The same frequency response considerations will generally apply in the high-frequency group as outlined for the low-frequency channels. Where low-frequency telephone carrier is operated on the same facility as the high-frequency group, the band-separation filter cut-off frequency will be the determining factor. When the frequency assignment of an high-frequency telegraph channel falls near the knee of the band-separation filter, the difference in response between the mark and space frequencies should not exceed 1 db for minimum effect on telegraph signal bias.

DISTORTION

Distortion in telegraph and data signals can come from several sources. The drop equipment (printer machines) and the connecting loop to the carrier terminal are, of course, heavy contributors to the total distortion in a telegraph or data circuit. In the carrier portion of the circuit the sources of distortion are the channel terminal circuitry and relays, and the connecting circuit between the two terminals. The *23A* channel equipment has been designed to hold total distortion to a minimum at speeds up to 100 words per minute.

Bias is a form of distortion in which the transmitted signals are uniformly shortened or lengthened. If marking signals received at the receiving terminal are longer than the signals transmitted at the sending end, they are said to have marking bias. If the received marking signals are shorter than those transmitted, the signals are said to have spacing bias.

Bias contributed by the carrier equipment is caused by frequency error, temperature variation, voltage changes, aging of components, and residual bias in the polar keying relay. All of these sources of bias can be easily compensated for in the initial line-up and subsequent routine tests of the *23A* system.

EFFECTS OF LEVEL CHANGES AND NOISE

Telegraph systems with frequency shift keying can tolerate more variation in circuit levels than can comparable systems with make-and-break or amplitude keying.

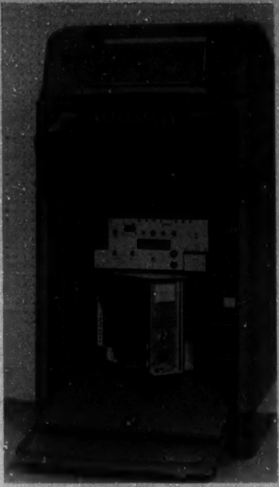

Fig. 3. Subscriber set mounted in model 28 teletypewriter console

In the *23A* system, with the channel discriminator preceded by a fast-acting limiter, input level changes of 35 db will produce less than 2% change in receiving bias.

Noise also has less effect on a frequency shift system than on an amplitude-modulated (AM) system. An AM system depends on the absence of tone (or carrier) as one of the indicating conditions. Noise present in the circuit during the tone-off period, if of sufficient amplitude, can cause errors in received data. In a frequency-modulated system, the tone (or carrier) is present for both indicating conditions; this tends to mask any noise present on the circuit.

SIGNAL LEVEL LIMITS

When telegraph carrier signals are transmitted over carrier-derived tele-

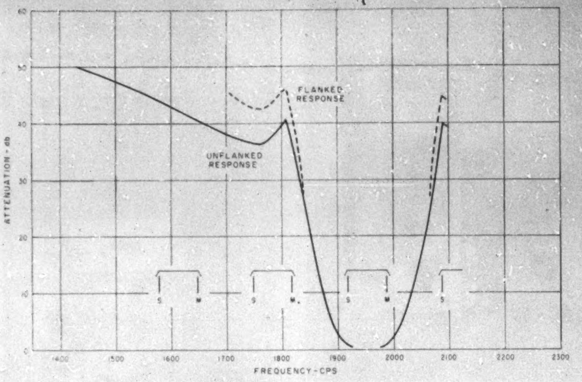

Fig. 4. Typical receive-filter-response low-frequency channels

phone channels, the transmit and receive levels are determined primarily by the requirements of the carrier telephone channel. The *23A* system has ample range to meet the requirements of any telephone carrier system. However, when *23A* systems are operated over physical circuits, the transmit and receive levels used will vary, depending on factors such as the type of circuit, the levels on adjacent circuits, and whether telephone carrier is also applied to the circuit.

The maximum total power output of either the single-channel or multichannel line amplifier in the *23A* system is +6 dbm (db referred to 1 milliwatt). Where crosstalk considerations and power-handling capability of the transmitting medium permit, the maximum possible line level should be used. This will improve the signal-to-noise ratio and increase the length of a physical circuit over which the *23A* system may be operated without repeaters.

As shown in Fig. 4, the minimum rejection of an unflanked filter to tones of an adjacent channel is slightly more than 35 db. The minimum rejection for a flanked filter is about 42 db. When several receiving channels are connected at one terminal, the difference in receiving levels between adjacent channels should not be greater than 15 db. This level difference will cause distortion of 2 to 3% at speeds of 100 words per minute. Smaller level differences should be used if at all possible, preferably not exceeding 5 db. Level differences of approximately 15 db may cause false operation of the supervisory feature on an adjacent channel when this option is used. For frequencies separated by two or more channel assignments, this level difference is somewhat less critical.

Because the per-channel receiver input level can be as low as −40 dbm, and the combined transmitting level can be as high as +6 dbm, the total line loss between transmitter and receiver can be as great as 46 db, line noise conditions permitting. The maximum permissible line loss will decrease as the number of channels in a system increases.

System Application Considerations

Operation on Carrier or Radio

Perhaps the most common application of telegraph carrier is on voice-frequency (v-f) carrier or radio facilities. This is usually on a 4-wire basis, since this permits the most efficient use of the available bandwidth. Also, these facilities are by their nature a 4-wire medium with

the transmitting and receiving paths fully separated. As described in the preceding section, the number of telegraph channels will depend on the bandwidth of the transmitting facility. The individual telegraph carrier channel transmitting level will be determined by the number of channels required in the telegraph system and the allowable voice-frequency channel input level of the particular carrier system used.

Assuming a v-f channel test tone input level of −16 dbm, the *23A* per-channel transmitting level would be set at −37.0 dbm on the basis of a full system of 18 telegraph channels. Table III shows permissible variation in maximum per-channel level with different numbers of channels in a system.

Note that the permissible per-channel level decreases more rapidly on v-f carrier channels than when using physical circuits. This is because the power-handling capacity of the v-f carrier channel is the limiting factor. This peak loading is not so critical on physical circuits. On carrier channels, the permissible per-channel level decreases on a logarithmic curve related to peak voltage, not average power, as in the case of physical circuits.

A fixed per-channel level generally is adopted as standard when several telegraph carrier systems terminate at one point. A per-channel tone level 21 db below the test tone level of the v-f carrier channel could probably be safely used for any number of channels up to the capacity of the v-f channel. Where only a few telegraph systems are operating on channels of a v-f carrier, this should not overload the v-f carrier system.

When the ultimate number of telegraph channels in a system will be less than 12, it may be desirable to operate the telegraph channels at as high a per-channel level as possible for the best signal-to-noise ratio.

Level Co-ordination with Low-Frequency Telephone Carrier Channels

There are two types of situations which require co-ordination between levels of telegraph systems and levels of low-frequency telephone carrier systems. Operating levels for the telegraph channels must be considered with relation to low-frequency telephone carrier channels operated on: (1) the same pair and (2) adjacent pairs.

Consider the case where *23A* channels operate on a physical circuit at frequencies occupied on adjacent pairs by low-frequency telephone carrier channels. Because the telegraph channels could crosstalk into the adjacent pairs, the transmitting level of the telegraph channels must be held below the point at which objectionable crosstalk could occur.

The most direct method of determining the allowable transmitting level for the *23A* system is to measure the near-end and far-end crosstalk levels between the circuit proposed for the *23A* and adjacent circuits which could be disturbed. For the low-frequency channels, crosstalk should be measured at 1,000 cps. A crosstalk coupling loss of 55 db may generally be taken as acceptable.

For *23A* systems operating in open-wire lines, sending levels will be governed by the type of transpositions in the line, the frequencies of carrier circuits, and the positions of these circuits with respect to the pin positions of the *23A* circuits. The effect of these conditions can be determined by measuring crosstalk coupling values on disturbed circuits. For the high-frequency channels, crosstalk measurements should be made at a frequency of approximately 4,500 cycles.

Where carrier circuits are operated in the same open-wire lead, the *23A* levels should be co-ordinated, insofar as possible, with other carrier levels to minimize the

crosstalk into any physical or carrier v-f circuit operating in the lead.

Two-Wire Transmission

Fig. 5 shows a typical frequency assignment for 2-wire operation. In order to transmit and receive on the same 2-wire circuit, it is necessary to combine the transmit and receive branches of the telegraph carrier circuit where they connect to the 2-wire line circuit. This is accomplished by means of a transformer with a balanced winding. The center tap of the balanced winding is connected through a balancing network.

Assuming the use of channel *1* of the high-frequency allocation with a sending frequency of 4,150 cps at the central office, the 2-wire line-equipment panel would be adjusted for maximum trans-hybrid loss at this frequency. Where more than one channel is used, the balance is made for the channel having the most closely spaced transmitting and receiving frequencies.

Bridging and Branching Circuits

Fig. 6 is an illustration of a typical 2-wire application using a bridging panel, a branching panel, and a subscriber set to serve widely separated subscribers from several central offices. One end of the telegraph carrier circuit terminates in the telegraph test room.

Fig. 6 also illustrates use of the terms "stem line" and "branch line." The stem line generally starts at the central office and applies to the section of the system carrying more than one channel away from the central office. The branches feed from the stem and distribute the circuits to the various subscribers' locations. A branch may carry more than one channel, and there may be instances where it is difficult to define just where the stem ends and a branch begins, since all channels but one may have left the stem as it continues to the farthest subscriber.

When the bridging panel is used, a loss of 1 db is introduced into the stem line, and a loss of about 16 db is introduced between the stem and the branch line. When the branching panel is used, the loss between the stem line and the branch lines can be varied between about 4 db and 18 db, depending on the number of branch lines involved and on the strapping used.

Wire Operation Under Carrier

The use of the various line circuit arrangements available with the *23A* system permits great flexibility in conjunction with carrier and v-f circuits. Fig. 7 illustrates operation of four *23A* channels on a 2-wire basis underneath the Lenkurt *45CA* or Western Electric *OA* system using separation filters. A band separation filter with the crossover at 1,900 cps divides the 2-wire line for the v-f telephone and *23A* telegraph carrier frequencies. Because of the low filter crossover point required by these telephone carrier systems, only frequencies between 425 and 1,785 cycles may be used for telegraph.

When the *23A* system is used in this application, the direction of transmission is co-ordinated with the *OA* or *45CA* system so that the low group transmitting (LGT) channels of the *OA* or *45CA* send in the same direction as the higher frequency channels (1,275 to 1,785 cycles) of the *23A* system. This places adjacent frequencies at more nearly the same levels and helps to minimize crosstalk.

Two-Wire Telegraph Superimposed on Subscriber Telephone

Fig. 8 illustrates a method of applying the higher frequency channels of the *23A* system to subscriber manual or dial lines for carrying up to four channels of telegraph to an outlying point on a 2-wire basis, in addition to the usual number of subscribers' telephones on the same circuit. Cable attenuation will be the limiting factor at the higher frequencies. Open-wire circuits would permit operation over longer distances since less attenuation is offered to the higher frequencies. This type of operation is also

called "speech-plus." Proper operation in applications of this type will also depend on other factors, one of which is potential interference between the telegraph and other services on the same line or cable.

This method of superimposed carrier operation provides an economical use of circuits, particularly where physical facilities may not be too plentiful.

In this "speech-plus" application, either a filter having a 1.9-kc separation frequency or a 3.0-kc separation frequency may be used. In either case, the lowest telegraph channel frequency will be governed by the filter crossover frequency, with due consideration of the 1 db mark/space level difference for telegraph covered in the preceding section.

Teleprinter Exchange Service With 2-Wire Carrier Operation

Fig. 9 illustrates teleprinter exchange service in 2-wire operation using the subscriber set. When the *23A* system is used in 2-wire service, it is advisable to assign the channel frequencies so that the high-frequency terminals send toward the central office. As telephone circuits get farther away from the central office, they are more exposed to noise-producing sources, such as power lines and lightning. The circuits near the central office are shielded by other circuits in the same cable, and by the cable sheath itself. Also, much of the route may be underground.

The higher channel frequencies are attenuated more than the lower channel frequencies. For a given circuit and channel frequency assignment, one direction of transmission will have more attenuation than the other. Therefore, it is advisable to assign the frequency having the greatest attenuation in the direction which is least subject to noise at the receiving terminal.

Bridging panels and/or branching panels are located at intermediate points as required to serve branch lines to intermediate subscribers.

Where line characteristics will permit, all the frequencies from 425 to 5,050 cps may be used. Typical assignments are shown in Fig. 5. These may, of course, be varied to suit local requirements; the channel filter networks would be selected to agree with the required frequencies.

Frequency and Direction Considerations

When laying out a telegraph carrier system which is to operate on the same facilities with open-wire carrier systems, the telegraph carrier frequencies and directions of transmission should be coordinated with the telephone carrier frequencies. Adjoining bands should always transmit in the same direction to minimize crosstalk.

Determination of the transmission level for the telegraph system will involve crosstalk and frequency considerations with any program circuits and/or low-frequency carrier systems operating on the same or adjacent circuits. These include such systems as the Lenkurt types *32E*, *33A*, *45CA*, and the Western Electric types *C*, *H*, and *OA*.

End-to-End Operation With 43A Terminal

Since the channel frequencies and shifts of the *23A* system and those of the Western Electric *43A* system are identical, the *23A* channels may be operated with the *43A* channels on an end-to-end basis. Any frequency combination required by the *43A* system may be met with the *23A* system. Channel operating levels and supervisory on-off functions are also compatible.

Terminating and D-C Loop Arrangements

Direct-Current Loops

Operation of telegraph carrier channels is closely related to operation of d-c telegraph circuits. Selection of the proper d-c loop termination is just as important to end-to-end circuit operation as is the proper application of telegraph carrier channels to various types of physical or carrier-derived circuits. The type of loop facility available, variable loop line conditions caused by weather, and the type of teleprinter service required are all determining factors in choosing the best loop option for a particular condition.

The loop may be two conductors, or may consist of one wire with ground as a return circuit. Full flexibility is offered; neutral, polar, half duplex, full duplex, inverse neutral, and any combination of battery voltages and polarities may be employed as required. By the simple process of changing a strapping plug, the loop operation can be changed from one option to the other.

With the use of the *2340* subscriber set, it is possible to extend the telegraph carrier frequencies on a speech-plus basis (by use of proper line filters) over the local telephone circuit to the teleprinter location. With the subscriber set at the teleprinter table, the loop becomes a very short one into the equipment on the table. Speech-plus operation can be obtained by use of line filters with a cutoff frequency from 1.9 kc to 3.5 kc together with proper selection of data or telegraph carrier frequencies. If considerable cable is involved the difference in the loss at the telegraph carrier frequency and at voice frequencies must be considered.

HUB OPERATION

Hub operation is a method of connecting a group of channels together for simultaneous or conference type of operation. One method is by means of a Western Electric Type *2* Service Board Hub Circuit. The system functions on essentially a voltage basis to operate the send keyers of the channels or loop repeaters. The complexities of a hub switchboard and the associated equipment required generally limit hub operation to the larger offices where the number of circuits and complexity of circuit layout make this type of operation economical.

When Lenkurt *23A* channels work into a hub board, auxiliary coupling units are not required to couple the send and receive hub circuitry into the channels. The send and receive legs are connected directly to the corresponding terminals on the hub equipment panel when operating on either a half- or full-duplex basis.

Operation into an inverse-neutral hub may also be employed.

DATA TRANSMISSION

Generally, when a telegraph system is used for data transmission and telemetering, the carrier terminal equipment should be installed near the data source since the carrier frequencies are much less affected by the transmitting medium than are d-c signals. When used in these applications, operation would probably be on a full-duplex basis.

The use of a receive keyer relay permits greater flexibility than could be achieved if the output transistors keyed the d-c loop directly; the loop polarity would necessarily remain fixed for a given transistor configuration.

In specialized data applications, where it may not be necessary to use the relay of the loop equipment unit, signals may be taken from the d-c keyer transistors in the channel unit. This will require furnishing 48 volts of battery through the signal receiving device. The normal operating condition of the transistor keyer circuit provides polar signals of approximately 20 milliamperes at a supply voltage of 48 volts d-c into a polar relay whose d-c coil resistance is 140 ohms per winding. An external receive bias adjusting potentiometer is used in the loop unit as a part of the receiving circuit. In other applications this control may or may not be required.

Conclusions

Consideration has been given to providing a compact, transistorized system using a minimum of power, with unusually low relay maintenance but with great flexibility of application for data, telemetering, or telegraph transmissions. With the growing demand for data and telegraph circuits, Lenkurt's type *23A* Datatel System offers a logical solution to the problem of meeting these needs.

◆

Discussion

A. B. Covey (American Telephone and Telegraph Company, New York, N. Y.): With reference to the introduction, "change in waveshape" is not necessarily distortion. Transmission of rectangular pulses always involves some rounding of the pulse, since there is some band limiting involved. Distortion is defined (American Standard *C*42.65) as time displacement of signal transitions with respect to their proper relative positions in perfectly timed signals. Since the signals are received by an electric circuit, rounded pulses are considered to be undistorted if the point on the transition at which the receiver responds occurs at the proper time.

Under the heading "Effects of Level Changes and Noise," it is stated that "input level changes of 35 db will produce less than 2% change in receiving bias." To be strictly correct, the stipulation should be added that this effect applies only if the level to which the signal drops is not so low as to be below the point at which limiting occurs.

The discussion under "Signal Level Limits" tends to be misleading. It is true that the levels employed on telephone carrier channels are governed by the total power-carrying capacity of the channel. However, where tones are transmitted on physical wire facilities it is noise influence considerations which limit the levels used. Noise influence is a function of the influence of the disturbing circuit, the susceptiveness of the disturbed circuit, and the loss in the coupling path. Each of these categories has variables within it, but since only the first is being discussed, it is a function of: (1) the level of the disturbing tone; (2) the frequency composition of the disturbing tone; and (3) the balance to ground of the disturbing circuit over the frequency range. Where multiple tones are used on the disturbing circuit, the interference depends on the total power of the combined tones after they have been weighted to account for the varying interference value of different frequencies of speech currents or program currents, as the case may be.

With regard to the actual levels tabulated in Table III, for one thing, the first two columns do not specify at what transmission level point the figures apply. For another, they do not specify whether the tones are being applied to an exchange cable or a toll cable. If we assume it to be the zero level point, which is the common method of specifying such levels, and that both columns refer to a toll grade facility, then the levels are considerably higher than those which the Bell System uses. For example, for the 17-channel case we use a level of −13 dbm per channel (at the 0 level point) if there are no program circuits in the exposed group and −23 dbm if program circuits are included. These levels are derived from the noise influence considerations described previously.

For less than 17 channels, any increase above these levels depends on which of the 17 frequencies are being used. For example, for a single channel we would allow a level of +13 dbm for the 425-cps channel, but only −16 dbm for the 3,145-cps channel from the standpoint of interference into nearby voice circuits.

With regard to the levels given in Table III for telephone carrier channels, it should be pointed out that the average power of a steady tone is about 8 db higher than the average power of a voice signal. For equivalent loading of the carrier system, then, the total power of the combined telegraph tones should be kept about 8 db below the normal telephone level. This means that for 16 channels, the single-channel level would have to be −36 dbm at the −16-dbm level point. For one channel, the corresponding level would be −24 dbm at the same point.

There is only one other comment, and that is on Fig. 8. It is assumed that this application to subscriber telephone lines can only be used for the case of a "dry" line, that is, a line using local battery subscriber's telephone set. It will not apply to the normal common battery subscriber loop carrying direct current.

T. B. Collins, Jr., and J. E. Pitts: The comments of Mr. Covey are appreciated. As indicated in his discussion and in the paper, noise and crosstalk considerations are of major concern in the operation of any carrier system. The particular levels chosen must take into account the characteristics of the facility over which the signals are to be transmitted. The need for standardization of operating practices in large companies sometimes makes it advisable to specify the lower operating levels to assure satisfactory performance with a minimum of engineering effort on each project. Provided that crosstalk performances for the particular facility are within proper limits, the higher levels will permit better signal-to-noise margin.

Operation of the *23A* equipment on common battery subscriber lines is satisfactory when the proper Lenkurt line filters are used. In such applications it is essential that the line filters used be so designed that the direct current in the subscriber loop does not saturate the inductors in the filter. The Lenkurt line filters used in this application provide entirely satisfactory performance.

Network Response to Transient Frequency Modulation Inputs

T. T. N. BUCHER
ASSOCIATE MEMBER AIEE

WHEN AN F-M (frequency modulated) signal is transmitted through a linear passive network, the output signal is hybrid, having both amplitude and frequency variations. The output expression can be written in terms of the input through use of circuit equations. However, the relationship is sufficiently complex that an evaluation of a direct solution of these equations is not possible except in simple cases. When the input modulation is periodic, or has a discontinuous step or impulse form, direct solution of the equation is useful; however, in other cases, approximations prove helpful in obtaining a solution.

Approximations have been given for cases where the transfer function of the network differs only slightly from the ideal and may be approximated simply. When the modulation is a relatively slowly varying signal, the "quasi-stationary" approximation and its many variations are useful.[1] However, when the network differs appreciably from the ideal and when the modulation varies rapidly, these techniques are of limited value. The present paper is concerned primarily with approximations which are useful for rather general network functions, when the input modulation varies rapidly during a relatively short period. Such modulations are encountered, for example, when television signals or pulse modulation signals are used to frequency modulate a carrier.

Instantaneous Amplitude and Phase

For purposes of analysis, it is convenient to represent the actual input and output signals of a network as the real parts of phasor functions. When an F-M signal is transmitted through a network, the output signal generally has variations in both amplitude and phase. A question arises as to the meaning of the terms (instantaneous) "amplitude" and "phase," when the signal under consideration is not of simple sinusoidal form.

A real function of time can be represented as the real part of any of an infinity of phasor functions formed by adding arbitrary imaginary functions to the original real function. Unless some restriction is placed on the imaginary function, the terms, amplitude and phase are relatively meaningless. For the purposes of this paper, amplitude and phase are defined as the magnitude and angle of that phasor function associated with the real function which has been called the "analytic" signal.[2-4] This signal is formed by adding to the real signal $f(t)$, a quadrature signal $g(t)$, derived from it by the Hilbert transform relationship[5]

$$g(t)=-\frac{1}{\pi}\int_{-\infty}^{\infty}\frac{f(\tau)}{\tau-t}d\tau \qquad (1)$$

The resulting phasor function

$$\psi(t)=f(t)+jg(t)=a(t)\epsilon^{j\theta(t)} \qquad (2)$$

is analytic throughout the upper half of the complex time plane. On the real time axis, its real part is the original signal $f(t)$. The spectrum (fourier transform) of $\psi(t)$ is zero on the negative real frequency axis and on the positive real frequency axis, has twice the value of the spectrum of the original real time function $f(t)$. Conversely, signals whose spectra are zero on the negative real frequency axis, are analytic signals.

When an analytic signal is applied to the input of a linear passive network, the output signal is analytic. The amplitude and phase of the analytic signal reduce to the usual definitions, when $f(t)$ is a sinusoidal function. When the real signal is a narrow band signal (spectrum spread small compared to center frequency), the amplitude and phase functions satisfy one's intuitive feelings concerning amplitude and phase. Further characteristics of such signals can be found in references 2-4. The (instantaneous) angular frequency is defined as the time derivative of the phase.

The Basic Network Equations

The problem under consideration can be visualized from the block diagram in Fig. 1. An input F-M signal is applied to a linear passive network (designated by a transfer function $T(\omega)$), and it is desired to determine the output signal amplitude and frequency as functions of time.

When the input signal is $\epsilon^{j\omega_0 t}\epsilon^{j\Delta\omega_p H(t)}$ a normalized output signal may be obtained by use of the superposition theorem as

$$\beta(t)\epsilon^{j\theta(t)}=\int_0^{\infty}\int_{-\infty}^{\infty}\epsilon^{j\Delta\omega_p H(\tau)}\epsilon^{j(\omega-\omega_0)(t-\tau)}\times \frac{T(\omega)}{T(\omega_0)}d\tau d\omega \qquad (3)$$

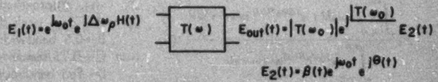
$$=\int_{-\infty}^{\infty}\epsilon^{j\Delta\omega_p H(\tau)}u(t-\tau)d\tau \qquad (4)$$

where

$\beta(t)$ = output amplitude divided by $|T(\omega_0)|$
$\theta(t)$ = output phase deviation from the reference phase, $\omega_0 t+\underline{/T(\omega_0)}$
$H(t)=\int_{-\infty}^{t}h(t)dt$
$\Delta\omega_p h(t)$ = angular frequency deviation from the reference angular frequency, ω_0
$\Delta\omega_p$ = peak angular frequency deviation
$u(t)=\int_0^{\infty}\epsilon^{j(\omega-\omega_0)t}\frac{T(\omega)}{T(\omega_0)}d\omega=u_r(t)+ju_i(t)$

The integration for $u(t)$ has the lower limit zero because of the assumption that input signal is analytic. When the inner integration is performed in equation 3, the resultant function is zero for negative frequencies. Hence only the integration along the positive frequency axis is required. Thus, $u(t)$ may be considered a normalized analytic impulse response of the network. (The equations can be used if the signal is not analytic, by extending the lower limit of the first integration in equation 3 to minus infinity, and allowing $u(t)$ to be the usual impulse response. However, the ambiguity in meaning of "amplitude" and "phase" then exists.)

The angular frequencies and time variable can be normalized by dividing the



E1(t)=e^{jω0t}e^{jΔωpH(t)}
T(ω)
Eout(t)=|T(ω0)|e^{j/T(ω0)} E2(t)
E2(t)=β(t)e^{jω0t}e^{jθ(t)}

former and multiplying the latter by an arbitrary factor with dimensions of angular frequency. In the examples presented later the normalizing factor is half of the 3-db (decibels) bandwidth (expressed in angular frequency) of the circuit under study.

By multiplying equation 4 by its complex conjugate, an expression for the square of the amplitude can be obtained

$$\beta^2(t)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\epsilon^{j\Delta\omega_p[H(\tau)-H(p)]}\times u(t-\tau)u^*(t-p)d\tau dp \quad (5)$$

u^* = complex conjugate of u

Since, generally, when a complex function z, has a derivative with respect to t, $d(\text{Arg } z)/dt = Im\ dz/zdt$, normalized angular frequency of the output can be expressed as

$$\frac{d\theta(t)}{dt}=Re\frac{\int_{-\infty}^{\infty}\Delta\omega_p h(\tau)\epsilon^{j\Delta\omega_p H(\tau)}u(t-\tau)d\tau}{\int_{-\infty}^{\infty}\epsilon^{j\Delta\omega_p H(\tau)}u(t-\tau)d\tau} \quad (6)$$

Evaluation of the Output Functions

The solution of the problem resides in the evaluation of the equations 5 and 6. In the past, a number of approaches have been used in performing this evaluation. The integrals can be evaluated directly in some simple cases: however, in many cases, some form of approximation has been employed.

If $H(t)$ is periodic, the first factor under the integrals in equation 3 can be expanded in an infinite trigonometric series. The response to each term of the series can be determined from the transfer function $T(\omega)$, and the resultant terms may be summed to provide as high a degree of accuracy as desired. In general, the output series will not be converted easily to closed form; however, in some cases, such a technique has proved effective.[8]

If, in equation 3, the form of $T(\omega)$ can be approximated simply, the equation may be evaluated without undue difficulty. In some cases, the magnitude of the transfer function has been assumed to vary from unity by only a small amount and the phase from linearity by a small amount.[7] The output then becomes equal to a delayed input plus perturbations resulting from the small variations in the transfer function.

A well-known approximation due to Carson and Fry[1] is obtained by expanding the exponential term in equation 4 as a power series in τ (and performing additional manipulation). This is the so-called quasi-stationary solution, which is useful when the modulation varies relatively slowly. While it can be shown that the resultant series is not generally convergent,[8] it may be used with a finite number of terms. Usually only the first two terms are employed.

Expansion for Rapidly Varying Modulation

When the modulating function varies rapidly, as in a pulse-like or step-like function, but the total phase has small variation, a useful expansion is obtained by expanding the equations 4–6 as power series in $\Delta\omega_p$. (The approximations are useful for any case where the total phase variation is small.) If $u(t)$, $h(t)$, and $H(t)$ are bounded, and differentiation under the integral sign is permitted, the resultant series converge. In this case, the various output functions can be expressed as follows (since developing these expressions, the author has become familiar with reference 9 which gives the same results for equation 9)

$$\beta(t)\epsilon^{j\theta(t)} = \sum_{m=0}^{\infty} \frac{(j\Delta\omega_p)^m}{m!} K_m(t) \tag{7}$$

$$\beta^2(t) = \sum_{m=0}^{\infty} \frac{(j\Delta\omega_p)^m}{m!} B_m(t) \tag{8}$$

$$\frac{d\theta(t)}{dt} = \Delta\omega_p Re\left[\sum_{m=0}^{\infty} (j\Delta\omega_p)^m A_m(t)\right] \tag{9}$$

where

$$\left.\begin{aligned} K_m(t) &= \int_{-\infty}^{\infty} H^m(\tau)u(t-\tau)d\tau \\ K_0(t) &= \int_{-\infty}^{\infty} u(t-\tau)d\tau = 1 \end{aligned}\right\} \tag{10}$$

$$B_m(t) = \sum_{r=0}^{m} (-1)^r \binom{m}{r} K_{m-r}(t)K_r^*(t) \tag{11}$$

$$A_m(t) = \begin{bmatrix} 1 & 0 & 0 & \ldots K_1'(t) \\ K_1(t) & 1 & 0 & \ldots \frac{K_2'(t)}{2!} \\ \frac{K_2(t)}{2!} & K_1(t) & 1 & \ldots \frac{K_3'(t)}{3!} \\ \frac{K_3(t)}{3!} & \frac{K_2(t)}{2!} & K_1(t) & \ldots \frac{K_4'(t)}{4!} \\ \vdots & & & \\ \frac{K_m(t)}{m!} & \frac{K_{m-1}(t)}{(m-1)!} & \frac{K_{m-2}(t)}{(m-2)!} & \ldots \frac{K_{m+1}'(t)}{(m-1)!} \end{bmatrix} \tag{12}$$

The first several coefficients, $B_m(t)$ and $A_m(t)$ are shown in Table I.

Remainder

The expansions can be terminated after a finite number of terms. Using Taylor's formula with the remainder, expressions can be determined from which the bounds of the resulting error can be evaluated. The expressions are so complex, however, that the bounds calculated are not very satisfactory. Consequently, some cases have been chosen where the original equations could be solved in closed form, and the results have been compared with the expansions using terms only up to the second order in $\Delta\omega_p$ in the approximations.

Rectangular Pulse or Step Modulation

If the modulation is a rectangular pulse in frequency, as indicated in Fig. 2, and if the network considered has a rectangular impulse response (transfer function is indicated in Fig. 3), it is possible to integrate the complete equations 5 and 6. A number of calculations have been made, for various widths of pulse, various modulation amplitudes and various degrees of detuning from the center frequency of the

filter. In each case, the output frequency and amplitude have been calculated, employing equations 5 and 6, and also employing up to second order terms of equations 8 and 9. (Cases employing this same input have been evaluated in reference 10 which came to the author's attention after completing this work. Ditl has developed a number of additional cases.) Where detuning is encountered, approximations are obtained with more terms than occur in equations 8 and 9.

Some typical results are shown in Figs. 4–13. For deviation approaching zero, the output frequency is identical with the amplitude output for a similarly amplitude-modulated signal applied to the same circuit.

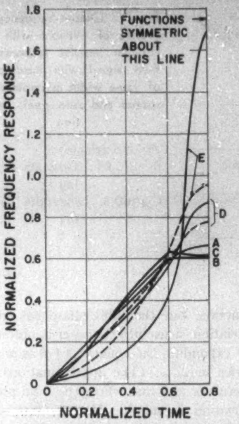

Fig. 12. Similar to Fig. 10, except that modulation has 0.6 width of impulse respnose

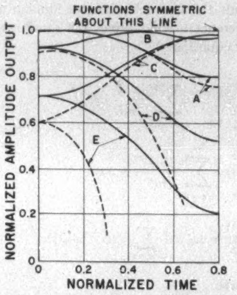

Fig. 13. Output amplitude response for same conditions as Fig. 12

The results suggest that for inputs of this general nature, the approximation for output frequency, using no higher than second-order terms, is good within a few percent so long as the peak deviation plus detuning stays within the 3-db bandwidth of the circuit. If 10% error is tolerable, the sum of these terms may approach $1^{1}/_{2}$ times this bandwidth.

For the amplitude approximation, using no higher than the second-order term, greater error is encountered. Within the 3-db bandwidth, errors of the order of 10% are encountered; for only a few percent error, the sum of detuning and peak deviation should remain within about 3/4 of the 3-db bandwidth.

Since these results have been established for only one class of pulses and circuit, the foregoing indications can only be considered to be guides, rather than firm estimates. These indications are about 6 times the allowable sum of detuning plus deviation which has been calculated in a few cases using the upper bounds for the remainder calculated from Taylor's formula.

In addition to the foregoing, similar calculations have been made for the same

19

modulating function when the network response is that of a single-tuned circuit. Some representative results are shown in Figs. 14 and 15. The second-order approximations are better in this case than in the previous one.

The approximations for the output frequency have been calculated for two other network response characteristics—a network comprising two cascaded tuned circuits and a network with Gaussian impulse response. Figs. 16 and 17 show the results of these calculations.

Triangular Pulse Modulation

To determine the effects of input modulation without discontinuities, the response of the network with rectangular response to triangular input pulses has also been calculated using equations 8 and 9. In this case, while up to second-order terms have been used in making the frequency approximation, up to fourth-order terms have been used in making the amplitude approximation. The results are shown in Figs. 18–20. One is struck by the relatively small effect, on the output frequency waveform caused by varying peak deviation up to the 3-db bandwidth in this case.

Conclusions

An approximation technique has been presented for calculating response of a linear passive network to pulse-like and step-like frequency modulating functions. Results obtained by this technique indicate that so long as the frequency deviation remains within the 3-db bandwidth of the network, reasonably good approximations of output amplitude and frequency may be obtained using no higher than second order terms in the approximation series. In cases close to those often encountered in practice, there is surprisingly little difference in output frequency waveform, when the peak deviation varies from very small values up to full 3-db bandwidth. While the approximation formulas are applicable rather generally, care should be taken in extending these rough rules of approximation to cases differing appreciably from those presented.

Two-Oscillator Scan Stability

HORACE M. JOSEPH
MEMBER AIEE

THE USUAL regularly repeated raster scan, such as used for television picture presentation, is the result of two perpendicular deflection waves which produce a complex Lissajous figure in the form of a set of closely interwoven lines. The number of lines that appear in this raster during each repetition is an important factor in determining the amount of video information that can be presented.

Ordinarily both of the (different frequency) waveforms are derived from a common sine-wave signal by generating two appropriate submultiples. For instance, the National Television Standards Committee (NTSC) raster can be formed by subdividing a 31,500-cycle-per-second wave by 2 and by 525 to supply the horizontal and vertical frequencies. The frequency ratio thus formed is 525 to 2. For the purpose of broadcasting synchronizing signals to millions of receivers, it is necessary that the frequency ratio be very stable. Apparently the need for this great stability is the reason little attention has been given to generating each frequency with separate oscillators.

Experiments using two separate oscillators have shown that a slight shift in the frequency of either oscillator from the optimum value produces a simpler raster with fewer scan lines and a loss of interlace. The consequence is a considerable reduction in scanning efficiency and hence in the rate of picture information presentation. The available video-circuit bandwidth is usually limited and hence the information rate cannot be increased to compensate for this loss. The reduction of scanning efficiency produced by oscillator drift is especially rapid for the "isotropic" scan where the horizontal and vertical frquencies are made nearly equal to meet the requirements of experiments in electronic image processing.

The early work at the National Bureau of Standards[1] was done with an isotropic scan that had no interlace. To avoid possible instability, synchronization was obtained by using submultiples of a common frequency. The frame rate was low, about one-half frame per second. Later the Avion Division–Alexandria built an image-processing equipment for use by the Air Force RADC. This equipment required conventional frame frequencies and, hence, higher scanning frequencies. To remove flicker effects, and also minimize video bandwidth, necessitated a quadruple interlace. To achieve a raster scan that met those requirements from a common signal entailed much circuitry for subdivision of a high-frequency and accurate frequency multiplication. Consequently, appreciable economy and reduction of circuit complexity could be obtained by generating each scan frequency with an independent oscillator.

It was recognized that each oscillator should be stabilized by a piezoelectric quartz crystal. This was done, but rather unexpectedly the raster stability obtained this way was insufficient for some apparently properly chosen pairs of scanning frequencies. Contrariwise, other nearby proper pairs of frequencies, stabilized by similar crystals, provided "good" rasters. In view of the circuit-simplicity obtained by using two independent oscillators and the demonstrated possibility of obtaining favorable results, it appeared valuable to determine the range of frequency variation that made it possible to obtain good scanning rasters.

Principal Raster Effects

The stability problem considered here is that of determining the largest relative range of one of the two deflecting frequencies over which the number of raster lines remains equal to or larger than the required number. It might be looked upon as the frequency range that maintains the complexity of a Lissajous figure above a given level. Once a frequency ratio has been determined, as given later, the sole cause of raster changes is a drift of scanning ratio, produced by a change in the frequency of one or both oscillators. Although many writers[2] have discussed the factors that affect the frequency of individual oscillators, little indication has been given of the raster effects produced by relative frequency drift. In addition, there are other factors that affect the number of raster lines observed by a viewer.

DRIFT OF SCANNING RATIOS

Fig. 1 shows a simple raster formed by two deflecting waves whose frequencies are nearly alike. Very little drift in frequency is required to alter the number of times the scanning spot traverses the raster before it returns to its starting point. Because of the integral numbers involved, the effect of frequency changes is determined by the properties of integers, those obtained by expressing the ratio of the number of vertical lines to the number of horizontal lines as a fraction reduced to lowest terms. An example of the rapidity with which the members of a "reduced" fraction can change as a result of a relatively small change in its numerator is 29/60. It becomes 1/2 (=30/60) by adding 1 to 29 and thus, when reduced, changes its denominator drastically. Since the ratio of uncontrolled oscillator frequencies can vary continuously, fractional changes in the numerator can occur, e.g., the numerator of 20/81 can drift to a somewhat larger value to produce $1/4(=20\frac{1}{4}/81)$. It will be shown that the permissible

HORACE M. JOSEPH, formerly with Avion Division, ACF Industries, Alexandria, Va., is now with The Johns Hopkins University, Silver Spring, Md.

Vol.
Pt. 1
195

range of drift can be found from the solution to the problem of determining the numerator range over which the lowest terms denominator of the fraction remains large enough. (The finite observation time prevents the occurrence of an infinite denominator.) Illustrations of the effect of drift in denominator value are given in Fig. 2.

PHASE

The position relation or relative phase difference between a point of the vertical y-wave and a corresponding point on the horizontal x-wave affects the number of interlaces. This change is one that causes some television sets to present black spaces between scan lines. It is shown in Appendix I that, in general, a drift in phase angle causes a drift from half the maximum number of raster lines up to the maximum number and down to half, etc. Fig. 3 presents an example of the effect of variation in phase angle upon the raster of Fig. 1.

TIME OF OBSERVATION

The preceding considerations are based on frequency ratios, which are essentially mathematical abstractions. The scanning frequencies are never exact numbers, but are approximations. The scan lines in succeeding frames do not exactly superimpose, but they appear to do so when they are "close enough." Also, the apparent number of raster lines depends upon the time of observation, for instance, the perception period of a viewer or the length of a photographic exposure. This time is usually short and, consequently, it is necessary to consider the ways of obtaining optimum, fine-structured raster coverage in order to scan most efficiently and gain as much image information as possible during the available time. Fig. 4 illustrates the loss of scanning efficiency that occurs on a television screen when the effective raster coverage is reduced (on one half).

TOTAL PERCEPTIBLE SCREEN RESOLUTION

The number of scan lines is also limited in practice by the number of scan lines that can be resolved either on the screen or by the viewing means.

DEFLECTION WAVEFORM

The waveform of each deflecting wave has been assumed to be one used for scanning. However, the calculations that follow represent counts of the number of lines and do not assume any distribution. It follows that the results apply to any "simple" waveform such as a sawtooth, sinusoid, or triangle, where each deflection wave proceeds monotonically from one extreme to the other and also returns monotonically, but possibly in a different way. In addition, the horizontal and vertical waveforms are assumed alike, except in period and amplitude.

For ease of illustration and visualization the deflection waveforms will be drawn as if they were symmetrical triangles. To avoid ambiguity, the phase will be expressed as a fraction of a wavelength or period rather than as an angle.

Relative Oscillator Stability

The calculation of the required relative oscillator stability is made by determining the ideal, or infinite, observation time, "permissible" drift of one scanning frequency relative to the other, and then finding how near a "practical" frequency can approach this value without departing from the conditions of maintaining the minimum usable number of scan lines. The scanning frequencies themselves are initially chosen on the premise that each should be as low as possible to reduce scanning velocity in order to minimize the effects of phosphor persistence and to reduce the bandwidth needed to reproduce picture detail with the least effect of random noise.[8] Consequently, the permissible change in scan line number must be very small. The value chosen for the change in the larger number of x-waves is unity and no decrease is permitted in the number of interlaces. The number of scan lines in a frame (for constant scanning frequencies) is determined by the number of x-wave and y-waves that exist between a particular pair of position-reference values and the reoccurrence of that pair. For convenience of discussion, the y-deflection period is chosen to be the longer period. It can then be related to the x-deflection period as follows:

$$T_y = T_x(1+a) \qquad (1)$$

where a is a positive quantity. Since it is the relation of the two frequencies that determines the number of scan lines, it will be assumed that all frequency drift

(A)
(B)
(C)

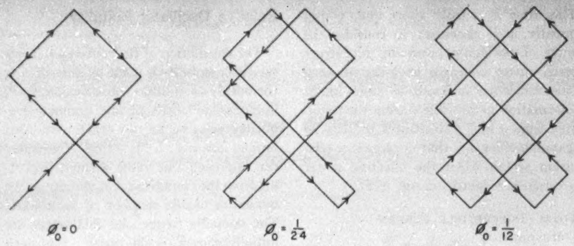

Fig. 3. Examples of effect of phase change in Fig. 2(A)

is produced by a change in the value of a. After a time, t, elapsed after the first time $x=0$, the number of x-wave periods is (an integer plus a fraction)

$$\phi_x = \frac{t}{T_x} \tag{2}$$

Also, the number of y-wave periods is (an integer plus a fraction)

$$\phi_y = \frac{\phi_x}{1+a} + \phi_0 \tag{3}$$

where ϕ_0 is the portion of the y-wave existing when $t=0$. The difference of the two phases is

$$\Delta\phi = \phi_y - \phi_x = \phi_0 - \frac{a}{1+a}\,\phi_x \tag{4}$$

When the time t is equal to the frame time, everything begins again. Consequently, at the end of a frame, an integral number of x-waves has occurred and also a different number of y-waves have passed. Then

$$\phi_x = N_x \tag{5}$$

an integer, and $\Delta\phi$ differs from ϕ_0 by another integer p, that is

$$\Delta\phi = \phi_0 - p \tag{6}$$

Hence

$$N_x = \frac{a}{1+a} = p \tag{7}$$

The quantity p is the smallest integral number that satisfies equation 7; it can be the number of interlaces, e.g., see Fig. 2.

Except for special values of phase ϕ (see Appendix I), which produce repetitions, each apex point, where a wave reverses, begins a scan line. Since no x-apexes and y-apexes coincide in a frame (by definition) and there are two apexes in a wave, the number of scan lines is

$$N_s(\max) = 2(N_x + N_y) = 2N_x\left(\frac{2+a}{1+a}\right) \tag{8}$$

As shown in Appendix I, coincidences of apexes can reduce a frame once, and and then only if ϕ_0 has an appropriate value. When an appropriate value of ϕ_0 occurs, there will be a reduction of the number of scan lines to a minimum of

$$N_s(\min) = \frac{2+a}{1+a}\,N_x - 1 \tag{9}$$

The average number of scan lines depends upon the way ϕ_0 varies and upon the value of the minimum separation that can be perceived between adjacent lines; see Appendix II. For typical conditions of slow, uniform frequency drift and closely spaced lines, the average number of lines is the arithmetic average of equations 8 and 9,

$$N_s(\text{avg}) = \frac{3}{2}\,N_x\,\frac{2+a}{1+a} - \frac{1}{2} \tag{10}$$

Under the conditions of nearly equal scanning rates, $N_x >> 1$, and $a << 1$,

$$N_s(\max) = 4N_x \tag{8A}$$

$$N_s(\min) = 2N_x \tag{9A}$$

and

$$N_s(\text{avg}) = 3N_x \tag{10A}$$

Equations 8, 9, and 10 can be used to determine N_x from the number of lines required for proper scan coverage.

As stated above, this value should be as low as feasible. Any appreciable further reduction in its value is considered intolerable. Hence the permissible value of

$$\Delta N_x = \pm 1 \tag{11}$$

or

$$\Delta p = 0 \tag{12}$$

whichever occurs sooner. The latter condition is more stringent if $p>1$. An example of the raster deterioration that results from exceeding the limit is diagrammed in Fig. 2. This follows from the Diophantine nature of equation 7, which is satisfied only with the smallest integral numbers for N_x and p. Relatively small variations, Δa's, can produce large changes in p and consequently in N_x.

The reduction can be expressed algebraically, and the values of Δa required to produce the change determined. Two different values of Δa can be found; a "conservative" value calculated relatively easily when the number of lines, N_s, is not very large, and a wider range of Δa for use when the required frequency stability should be minimized. The calculation begins by writing equation 7 in a different form:

$$\frac{N_x}{p} = M_x + \frac{n}{p} \tag{13}$$

where

M_x = the integral number of waves in a field
n = an integer less than p

Then determine the positive and negative changes in n, Δn_+, and Δn_- (not necessarily integers), which make p drop to $p-1$. The conservative answers, as shown in Appendix III, are

$$\Delta n\pm = \frac{\pm 1}{p-1} \tag{14}$$

The corresponding values of Δa are

$$\Delta a\pm = \frac{\pm a^2}{p^2 - p \pm a} \tag{15}$$

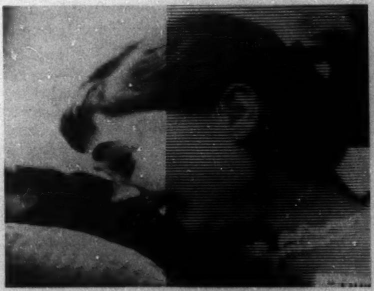

Fig. 4. Television viewing screen with right half showing effect of omission of half of the scan lines

The total range of Δa is

$$\Delta a = \frac{2(p^2-p)a^2}{(p^2-p)^2-a^2} \tag{16}$$

For the important case of no interlace, $p=1$, equation 11 is used. Then

$$\Delta a \pm = \frac{\mp a^2}{1+a} \tag{15A}$$

For the small a's the over-all range of Δa becomes

$$\Delta a \doteq 2a^2 \tag{15B}$$

A larger range, shown in Appendix III, is possible. For instance the range can be increased when $n=2$. Also still larger values are possible, when n is larger, if the numerator and denominator of the fractions,

$$\frac{n-1}{p-1}, \frac{n-2}{p-2}, \ldots$$

do not contain a common factor; each specific value should be tested. The largest possible ranges of Δn that make p drop to $(p-1)$ are

$$\Delta n_{+} = \frac{n}{p-1} \tag{17}$$

and

$$\Delta n_{-} = \frac{n-1}{p-1} \tag{18}$$

The corresponding values of Δa that will produce these Δn's are

$$\Delta a_{+} = -\frac{a^2 n}{p^2-p+an} \tag{19}$$

and

$$\Delta a_{-} = \frac{a^2(p-n)}{p^2-p-a(p-n)} \tag{20}$$

The over-all range is

$$\Delta a = \frac{a^2 p^2(p-1)}{(p^2-p+an)(p^2-p-ap+an)} \tag{21}$$

For small a's this reduces to

$$\Delta a \doteq \frac{a}{p-1} \tag{21A}$$

This value of Δa is larger than that indicated by equation 16, but caution is required. These equations show that the permissible oscillator drift decreases when the interlace is increased for a given ratio, a.

PRACTICAL CONSIDERATIONS

The stability considerations are most critical when a is small and, consequently, when equations 15(B) or 21(A) apply. Further, it is usual for $N_x >> p$. Therefore the value of n makes little difference in scanning velocity. However, the particular choice made may create an important difference in the rate of raster deterioration. The example of Fig. 2 was chosen to show a rapid change. The quantity n should be chosen so that n and $p-1$ are relative primes; if possible, the other conditions for equations 17 and 18 should be met. It was failure to meet this condition that produced the unsatisfactory pairs of crystal-controlled oscillator frequencies where the raster was not stable enough.

PRACTICAL FREQUENCY

The above calculated frequency deviation ratios are based on the properties of integers. They are abstractions which which can only be approached. Because of a finite observation time, such approaches are seen; for example, many people look at patterns in the form of television rasters or of Lissajous patterns on oscilloscopes. This closeness of approach depends on the minimum perceptible separation between scan lines perceived during the "time of observation." These quantities are functions of observer and equipment characteristics. Their values determine how close an approach to the calculated ends of the frequency ranges can occur without perceiving raster deterioration. The closeness of approach can be used as corrections derived from the measured perceptible line separation distances and observation times, by using the idea of a practical scanning frequency.

This frequency can be determined from the minimum average perceptible line spacing change that occurs in the observation time, taking account of the average effect of ϕ_0 discussed in Appendix II. The minimum visible spacing is defined as a fraction of the length of one side. It may be expressed as a fraction of the separation between lines:

$$S_v = vs = \frac{v}{2N_x} = v\frac{\theta}{2p} \tag{22}$$

where

S_v = visible fraction of raster side required for visibility
s = average fraction of raster side between adjacent lines
v = visible fraction of raster space between adjacent lines
θ = ratio p to N, the fraction of raster side occupied by the space between successive lines in a field

The practical number of x-cycles that occur during the observation time is designated N_{Tx}. With any change in spacings, a result of variation in a should be less than S_v. This change in a can be found by solving for Δa in an equation derived from equation 5:

$$\Delta\phi - \Delta\phi_T = \phi_0 - \frac{a}{1+a}N_{Tx} - \left(\phi_0 - \frac{a+\Delta a}{1+a+\Delta a}N_{Tx}\right) = \pm v\frac{\theta}{2p} \tag{23}$$

The resulting correction in Δa is used to reduce the variations permitted by equations 19 and 20. Inserting the correction reduces Δa_{+} to

$$\Delta a_{+}' = \frac{-a^2(1+a)\left[n\frac{N_{Tx}}{N_x} - \frac{p-1}{p'}\frac{v}{2}\right]}{(p^2-p+an)\times\left[(1+a)\frac{N_{Tx}}{N_x} - \frac{a^2}{p^2-p+an}\frac{v}{2}\frac{p-1}{p'}\right]} \tag{24}$$

where

p' = interlace that the first permissible positive increase in n may produce

The resulting corrected Δa_{-} is

$$\Delta a_{-}' = \frac{a^2(1+a)\left[(p-n)\frac{N_{Tx}}{N_x} - \frac{p-1}{p''}\times\frac{v}{2}\right]}{[p^2-p-a(p-n)]\times\left[(1+a)\frac{N_{Tx}}{N_x} + \frac{a^2}{p^2-p-a(p-n)}\times\frac{v}{2}\times\frac{p-1}{p''}\right]} \tag{25}$$

where

p'' = the reduced interlace that the permissible decrease in n may produce

Note that under relatively favorable conditions when N_x and n are chosen as so to obtain the proper relative primes (see Appendix III) either $p'=p-1$, or $p''=p-1$; if they are most favorable, $p'=p''=p-1$. However, when a good choice is not made, the permissible variation is reduced and under some conditions may not exist. The unfavorable crystal-controlled frequency pairs showed this effect.

Numerical Examples

Two numerical examples are given in the following to indicate the application of the equations to determine the 2-oscillator stability required to produce a good raster coverage with the number of lines called for by the conventional NTSC standard. The first example applies the calculations to an isotropic scan where the vertical and horizontal scan frequencies are nearly alike; where a is small. The second example applies to the conventional scan used in television broadcasting.

1. In addition to $a<<1$, and $N_x=525$ lines, $p=5$ is chosen. It is assumed that

the phosphor material and viewing screen size are chosen so that

$$\frac{N_{Tx}}{N_x}=10$$

and

$$v=0.5$$

From equation 10(A)

$$N_x=175 \text{ cycles}$$

From equation 7

$$\frac{175}{5}=35$$

but 175 is divisible without remainder by 5 and in that event $p=1$. Since this is not acceptable, N_x is increased to 176 It is found that $p'=2$ and $p''=1$. This produces a narrow range of Δa; hence N_x is increased to 177. For this choice

$$p'=p''=p-1=4$$

From equation 7,

$$a=\frac{5}{172}$$

From equations 24 and 25 the combined range is

$$\Delta a'=\Delta a_-'-\Delta a_+'=2.5\times 10^{-4}$$

However, after a warm-up period, the frequency of an oscillator wanders randomly around a central value. The probability of reaching the limit given above should be reduced to a low value, say 0.1%. Hence the corresponding 50% probability value[4] of the necessary oscillator stability is

$$\pm\frac{\Delta a}{2}=\pm 0.005\%=\pm 1/20{,}000$$

2. It may be of some interest to note that under the same conditions of observation time and perceptible line separation the relative oscillator stability required for the conventional NTSC scan of 525 horizontal and vertical scans per frame can be calculated. The corresponding quantities are

$N_x=525$ cycles

$a=523/2$

$N_s=1{,}054$ (The effective value is reduced by blanking.)

$p=523$ (The total number of horizontal and vertical cycles that are interlaced.)

From equation 13

$$\frac{N_x}{p}=2+\frac{4}{523}$$

and

$$n=4$$

Searching through the various possibilities of

$$\frac{1}{p-1},\ \frac{1}{p-2},\ \ldots$$

Appendix III shows that equations 24 and 25 apply with $p'=p''=p-1=522$. Accordingly

$$\Delta a_+'=-0.9919$$

and

$$\Delta a_-'=258.5$$

This indicates that N_x may be reduced by very nearly a whole cycle or more than doubled without causing a decrease in the number of raster lines as a result of changer in the ratio of scan frequencies, except for interlace changes due to phase-angle change.

Conclusions

The examples and formulas for the calculation of the relative stability required of the oscillators in the 2-oscillator method of producing a scan, when due regard to providing for phase-angle variation is given, provide stability tests for choosing frequency pairs. The results show that the frequency stability required can be well within that obtainable from piezoelectric crystal-stabilized oscillators. For exacting conditions when the viewing time is short, some searching is required to find frequencies that will provide a maximum range of variation. Although this must be done by arithmetic trials, the procedure for checking the range of stability is readily done.

The results also show that schemes which require nearly equal (small a) frequencies requires more stability. Consequently the number of raster lines may be very sensitive to relatively small influences that change the effective scan frequency, such as hum or noise frequency modulation of either oscillator, or an equivalent scan frequency modulation caused, for example, by variation of electron beam stiffness resulting from changes in accelerating voltage.

The calculations, except for the interpretation of phase, do not depend upon the waveform of the scan signals. They apply to sinusoidal Lissajous figures as well as those produced by sawtooth or symmetrical triangular waves. Consequently the formulas may be useful in the measurement of frequency by oscilloscope comparison, using a Lissajous figure.

Appendix I. Effect of Phase Angle

The initial value of the y-wave at $t=0$ is the phase fraction ϕ_0. Its value affects the number of scanning lines that occur in a frame as stated in equations 8, 9, and 10. The proof of these equations is completed by examining the behavior of $\Delta\phi$. (To facilitate visualization the proof is given for a symmetrical triangular wave. Neither the symmetry nor triangularity is essential.) See Fig. 5. First assume that

$$\phi_0=0$$

Then at the beginning of an x-wave, where $x=0$, equation 4 shows that

$$\phi_y=\frac{m_x}{2}+\Delta\phi$$

where

m_x = (integral) number of half x-waves that occurred after the beginning of the frame

The y-wave will reach its apex when

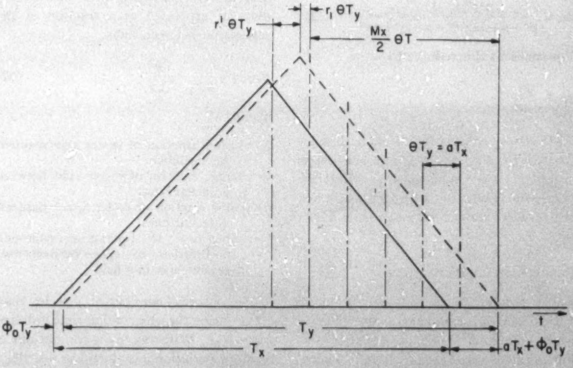

Fig. 5. Diagram of relation between x-waves and y-waves

$$\phi_y = \frac{m_x}{2} - \frac{1}{2}$$

and again reach zero when

$$\phi_y = \frac{m_x}{2} - 1$$

Also from equation 4, it is apparent there is a retrogression, of magnitude, θ, in the y-wave period for each cycle of the x-wave. The y-wave will lag by a half-period when

$$\Delta\phi = \frac{1}{2}$$

Also

$$\theta = \frac{a}{1+a}$$

The half-period lag occurs when

$$N_x = \frac{m_x}{2} + \frac{n}{2p} \tag{26}$$

An alternative statement of this is that after $m_x/2$ complete periods of the x-wave, the y-wave lags by $r_1\,\theta$ less than 1/2 cycle, where

$$r_1 = \frac{n}{2p} \tag{27}$$

At the end of the next succeeding x-wave, the y-wave lags by 1/2 cycle plus a fraction,

$$r_1'\theta$$

and

$$r_1' = 1 - \frac{n}{2p} \tag{28}$$

If the scan lines are not to overlap, then

$$1 - \frac{n}{2p} \neq \frac{n}{2p}$$

or

$$n \neq p \tag{29}$$

This condition is met for all values of p except when $p=1$. The process continues for an additional $(m_x/2-1)$ waves if

$$2n < p$$

or for $\frac{m_x}{2}$ waves if

$$2n \geq p$$

until $\Delta\phi$ is short of -1 by a fraction r_2 of θ, and

$$r_2 = 1 + \frac{n}{2p} - r_1' = \frac{n}{p} \tag{30}$$

In general, for the kth apex the fraction

$$r_k = 1 + \frac{n}{2p} - \left[1 - \frac{(k-1)n}{2p}\right] - m = \frac{kn}{2p} - m \tag{31}$$

and another fraction

$$r_k' = 1 - r_k = 1 + m - \frac{kn}{2p} \tag{32}$$

where m is the integer required to make r_k and r_k' proper fractions.

Since

$$1 \leq k < 2p \tag{33}$$

it follows that when

$$r_k = r_k'$$

$$\frac{kn}{p} = 1 + 2m \tag{34}$$

This, of course, can only occur when

$$k = p \tag{35}$$

since the fraction n/p is reduced to lowest terms, and then can occur only if n is an odd integer.

There may be additional coincidences. These may happen when k is odd near the crest, and the other when k is even. Substituting another index i for k and j for m, another set of r's is

$$r_i = \frac{in}{2p} - j \tag{36}$$

and

$$r_i' = 1 + j - \frac{in}{2p} \tag{37}$$

From the definition of p, when $i \neq k$

$$r_i \neq r_k \tag{38}$$

but consider the possibility that

$$r_i' = r_k$$

Then from equations 33, 36, 37, and 38

$$\left(\frac{k+i}{2}\right)\left(\frac{n}{p}\right) = 2m + j + 1 \tag{39}$$

Since

$$\frac{k+i}{2} < 2p \tag{40}$$

only one set of values of $(k+i)/2$, namely opposite ones, can make equation 39 correct. There is, therefore, one, and only one, set of overlapping lines. By similar reasoning when

$$\phi_0 \neq 0$$

$$\left(\frac{i+k}{2}\right)\left(\frac{n}{p}\right) = m + j - 2r_0 + 1 \tag{41}$$

where

$$r_0 = \frac{\phi_0}{\theta} \tag{42}$$

This shows that again only one overlap can occur; however, it occurs only if r_0 is an integral multiple of $n/2p$.

Appendix II. "Perceptible" Effect of Phase Angle

Equation 41 expresses another numerical-algebraic result which must be converted into practical terms of perceptible line spacing Now compare equation 22 which is valid when equation 41 is not satisfied with the equation when equation 41 is satisfied. The separation between adjacent lines is then

$$s_1 = \frac{\theta}{p} = 2s \tag{43}$$

where

s = separation given in equation 22

If r_0 progresses uniformly in value from one integral multiple of $n/2$p to the next, then s_1 decreases uniformly to s and increases again uniformly to $2s$. Because of this uniformity in rate the fractional part of the total time of that progression, when equation 43 effectively applies, is also v. The average number of lines, N_s, is the average of equations 8 and 9 weighted by v. Hence

$$N_s(\text{avg}) = N_x \frac{2+a}{1+a}(2-v) - v \tag{44}$$

When $a \ll 1$, and $N_x \gg 1$,

$$N_s(\text{avg}) \doteq 2(2-v)N_x \tag{44A}$$

Equation 44 becomes equation 10 when $v=1/2$, a usual value.

Appendix III. Obtaining a Sufficiently Large Denominator

There are four conditions which limit the range of Δn within which a fraction whose denominator remains equal to or larger than p over that range can be obtained. These conditions are discussed in the following in terms of a Δn expressed as a rational fraction, reduced to lowest terms, added to n.

1. The resulting new fraction is

$$\frac{n + \frac{\alpha}{b}}{p} = \frac{bn+\alpha}{pb} \tag{45}$$

where α and b are integers. Now the numerator $(bx+\alpha)$ is not factorable without remainder by b. However, it is possible that some choices of b and α will make the numerator factorable by p without remainder. In that event the denominator will be b. In order that the deterioration of the interlace and consequent number of scanning lines be limited, it is necessary to make

$$b \geq (p-1) \tag{46}$$

2. The fraction α/b can have any magnitude since a can vary continuously. This means that α should be limited to ≤ 1, since any fraction less than $1/b$ will have a denominator larger than b. This can be shown as follows:

By hypothesis that fraction

$$\frac{A}{B} < \frac{1}{b} \tag{47}$$

where A and B are positive integers.

From that

$$B > Ab$$

Hence

$$B > b \tag{48}$$

since A is an integer.

These two conditions are relatively easy to check. Consequently, they are the basis of the "conservative" values of Δa in equations 15 and 16.

3. On the other hand, to use a value of α larger than 1 may permit a reduction (if the numerator can be divided by p without remainder) of b below $(p-1)$. There is a risk, e.g., if $\alpha=2$ and b is an even number, the effective value of the denominator is $b/2$. However, the numerator is not always divisible by p when $b=(p-1)$. In that case, it is possible that the denominator is greater than p until, possibly, b is reduced to $(p-2)$, and if not then, Δn may be increased to $1/(p-3)$, and so on. Let

$$\Delta n=\frac{1}{p-d} \tag{49}$$

where

d = an integer less than p

Then

$$\frac{n+\Delta n}{p}=\frac{n-\dfrac{dn-1}{p}}{p-d}$$

The numerator will not be an integer unless

$$\frac{dn-1}{p}=\text{an integer} \tag{50}$$

However, if it is not an integer for a particular value of b, there is still the possibility that the fraction can be reduced to lower terms. Since the denominator of that fraction cannot be smaller than 2, to be safe, make

$$d<\frac{p}{2} \tag{51}$$

4. The limit of variation Δn is

$$\Delta n_{+}=\frac{n}{p-1} \tag{52}$$

since the reduction of the denominator to $(p-1)$ will then occur, and provided

$$\frac{1}{p-d}>\frac{n}{p-1}$$

for the first d that satisfies equation 50. Similarly, the limit of negative variation of Δn is

$$\Delta n_{-}=\frac{n-1}{p-1} \tag{53}$$

provided:

$$\frac{1}{p-d}>\frac{n-1}{p-1}$$

as above. It is also plain that equations 52 and 53 always apply to the case where

$n=1$, or 2

since the new denominator will be $p(p-1)/2$ $(>p)$ for $n=2$ (this condition also means that p is an odd number).

Electronic Network Synthesis of Linear Algebraic Matrix Equations

ROBERT E. HORN
ASSOCIATE MEMBER AIEE

PIERRE M. HONNELL
MEMBER AIEE

APPLICATIONS of matrix techniques to the electronic network synthesis of several types of equations have been discussed in previous publications.[1–5] A brief review of the basic theory is included in the Appendix. The objective of this paper is to apply these techniques to the synthesis of linear algebraic matrix equations. Existing methods are summarized and their domain of usefulness is indicated, particularly with respect to network stability.

Goldberg and Brown[6] and Korn,[7] emphasize that a paramount problem in solving algebraic systems on electronic network machines or computers is, surprisingly, that of stability; this is in contrast to the application of such electronic computers to the solution of differential equations systems, in which case stable synthesis networks are easily devised.

An ingenious solution to the stability problem was described by Adcock[8] on an electromechanical machine computer; the same principle was applied to an all-electronic computer by Gephart.[9] These apparently diverse methods are easily demonstrated, by a matrix formulation, to be closely akin.

The central problem is that of exhibiting the solution of the algebraic system

$$Ax=b \tag{1}$$

where $[A]$ is a square nonsingular matrix of real constant elements, x is a column matrix of n unknowns to be determined, and b is a column matrix of n prescribed real elements. This systems may also be represented as:

$$\sum_{j=1}^{n} a_{ij}x_j=b_i, \quad i=1, 2, \ldots, n \tag{2}$$

In the ideal electronic network machine computer, there would arise no stability problem, the determinant of $[A]$ being nonvanishing, since the system is algebraic. The synthesized network in an electronic computer is, however, physical; as such it then represents a differential equation, with the inherent stability problem with respect to oscillations. This arises from the inevitable deviations of the electronic amplifiers from the ideal, that is, a voltage amplification which is a positive (or negative) real constant; and also from parasitic effects, principally capacitive. Both of these factors introduce differential coefficients into the system; hence the differential equation.

Since it is not possible to synthesize a purely algebraic equation when high-amplification electronic amplifiers are involved, the key concept arises of converting the given mathematical algebraic problem to a mathematical differential equation system which has as its particular integral the desired solution to the original algebraic system and which has a stable synthesis on an electronic computer. In this conversion of equation systems, mathematical stability alone is not sufficient to insure computer stability.

Stability Problem

It is imperative for clarity to distinguish between two types of stability problems. One type arises from the statement of the mathematical problem per se, here purposely introduced by differential equations as such. The other type is the true

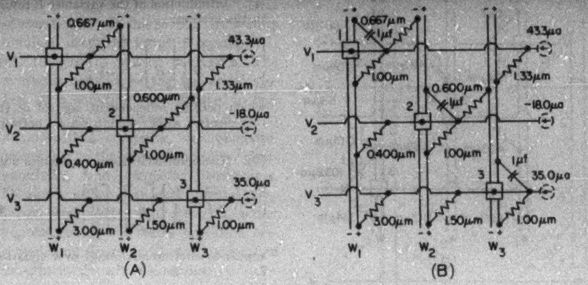

Fig. 1. Ideograph of numerical example

A—Using synthesis equation 1
B—Using synthesis equation 11

physical network stability that is actually encountered in the machine. The latter arises from a combination due to the intentionally introduced mathematical differential equation network representation and those arising from the parasitic parameters and amplifier characteristics.

The desired objective is to introduce the differential equation in such a manner that the stability is determined principally (entirely, if this could be achieved) by the stability consideration of the mathematical problem. In this paper the problem will be treated from the standpoint of systems known to be stable, rather than beginning with the generalized linear equations for mathematical stability and proving that nonideal amplifier characteristics do not introduce instability.

Adcock and Gephart introduce the following differential equation system, which is not only mathematically stable, but also network stable as shown by their experiments.

$$\sum_{j=1}^{n} A_{ij}x_j - b_i = e_i, \qquad i=1, 2, \ldots n$$

$$x_j = \sum_{i=1}^{n} E_i A_{ij}, \qquad j=1, 2, \ldots n$$

$$\frac{dE_i}{dt} = ke_i, \qquad i=1, 2, \ldots n \tag{3}$$

These consideration will be placed in a clearer light by the following: First of all, it is helpful to rewrite equation 3 in matrix notation as:

$$\begin{bmatrix} -I & A & 0 \\ 0 & I & {}_tA \\ -kI & 0 & D \end{bmatrix} \begin{bmatrix} e \\ X \\ E \end{bmatrix} = \begin{bmatrix} b \\ 0 \\ 0 \end{bmatrix} \tag{4}$$

where

$I = n$th order identity matrix
$D = I \cdot d/dt$
A, x, and B defined as in equations 1 and 2
e, E, and k defined as in equation 3
${}_tA =$ transpose of A

Equation 4 may be synthesized directly on an electronic machine and usually results in a network stable system if the matrix A itself is not positive definite. Premultiplication of matrix 4 by the transformation matrix

$$\begin{bmatrix} I & 0 & 0 \\ 0 & I & 0 \\ -I & 0 & \frac{1}{k}.I \end{bmatrix} \tag{5}$$

where I is the nth order identity matrix and k is positive real scalar, yields:

$$\begin{bmatrix} -I & A & 0 \\ 0 & I & {}_tA \\ 0 & -A & \frac{1}{k}D \end{bmatrix} \begin{bmatrix} e \\ x \\ E \end{bmatrix} = \begin{bmatrix} b \\ 0 \\ -b \end{bmatrix} \tag{6}$$

It is obvious that the desired solutions for x and E are obtainable from the reduced system

$$\begin{bmatrix} I & {}_tA \\ -A & \frac{1}{k}D \end{bmatrix} \begin{bmatrix} x \\ E \end{bmatrix} = \begin{bmatrix} 0 \\ -b \end{bmatrix} \tag{7}$$

in which network stability is further enhanced beyond that existing in the system 4. It should also be noted that if k is made indefinitely large, the form 7 goes over into that indicated by Goldberg and Brown.

The reason that the system 7 is likely to be more stable than 4 is not evident from these equations alone. The electronic network stability is determined by the complete network matrix which is the sum of the ideal synthesis matrix, the network error matrix, the equivalent source error matrix, and the parasitic error matrix.[8] In general, reducing the order of the system tends to reduce the effect of these error and parasitic matrices upon network stability.

The mathematical stability may be enhanced by a further reduction of the order of the system. Premultiplication of equation 7 by the transformation matrix of constant determinant

$$\begin{bmatrix} I & 0 \\ \frac{1}{k}D & -{}_tA \end{bmatrix} \tag{8}$$

results in

$$\begin{bmatrix} I & {}_tA \\ \left(\frac{1}{k}D + {}_tA \cdot A\right) & 0 \end{bmatrix} \begin{bmatrix} x \\ E \end{bmatrix} = \begin{bmatrix} 0 \\ {}_tA \cdot b \end{bmatrix} \tag{9}$$

Equation 9 as such is not the end in view, for it exhibits a zero matrix on the principal diagonal which, according to the previous discussion, emphasizes the undesired differential terms and may yield network instability. However, since this system is disjoint in a feedback sense, one can extract from equation 9 the following system:

$$\left(\frac{1}{k}D + {}_tA \cdot A\right)x = {}_tA \cdot b \tag{10}$$

Mathematically, equation 10 leads to a stable solution even if A itself is not positive definite. On the other hand, if the determinant of A is very small, then round-off errors become important; that is, the accuracy of the solution suffers from the finite resolution of the synthesis parameters. In fact, the squared determinant of A in equation 10 when

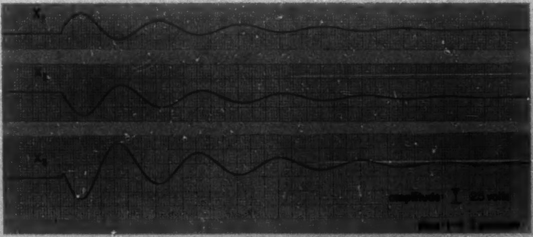

Fig. 2. Oscillogram corresponding to synthesis shown in Fig. 1(B)

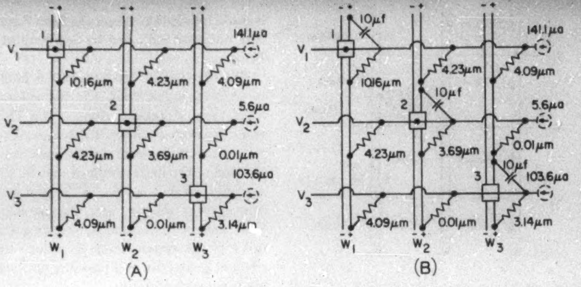

Fig. 3. Ideograph of numerical example

A—Using synthesis equation 12 B—Using synthesis equation 10

close to zero can as easily become negative as positive, due to the finite precision of setting of the synthesis network elements, and the computer thereby become unstable physically, vitiating the raison d'être of equation 10:

It should be emphasized that if A is known to be positive definite, the desired solution may be obtained directly from

$$\left(\frac{1}{k}D+A\right)x=b \tag{11}$$

without recourse to the forms 4, 7, or 10.

One obvious advantage of equation 11 over equation 10 is that in 10 the computation ${}_{t}A\cdot A$ and ${}_{t}A\cdot b$ must be performed by other means. In design applications this feature may be highly undesirable, because independent control of coefficients is lost. If the matrix A is positive definite even though almost singular, equation 11 is definitely superior to the others. Electronic computer application of these matrix equation forms may be summarized as follows:

1. Matrix A positive definite:

(*a*). $Ax=b$ (1)

may be utilized, but in many computers, inherent amplifier characteristics result in instability of the computer network approximation.

(*b*). $\left(\frac{1}{k}D+A\right)x=b$ (11)

results in the most usable form by masking amplifier characteristics, utilizing fewer amplifiers than equations 4 or 7 and maintaining independent control of coefficients.

(*c*). The other forms appear to offer no particular advantage in the application.

2. Matrix A not positive definite:

(*a*). ${}_{t}A\cdot Ax={}_{t}A\cdot b$ (12)

suffers the same limitations as equation 1 with the added disadvantage that the matrices ${}_{t}A\cdot A$ and ${}_{t}A\cdot b$ must be computed.

(*b*). $\left(\frac{1}{k}D+{}_{t}A\cdot A\right)x={}_{t}A\cdot b$ (10)

will yield stable computer networks, but as in equation 12, ${}_{t}A\cdot A$ and ${}_{t}A\cdot b$ must be computed.

(*c*). Introduction of the variables E results in the system:

$$\begin{bmatrix} I & {}_{t}A \\ -A & \frac{1}{k}D \end{bmatrix}\begin{bmatrix} x \\ E \end{bmatrix}=\begin{bmatrix} 0 \\ -b \end{bmatrix} \tag{7}$$

which permits independent control of the coefficients while maintaining network stability.

(*d*). The additional display variables e in

$$\begin{bmatrix} -I & A & 0 \\ 0 & I & {}_{t}A \\ -kI & 0 & D \end{bmatrix}\begin{bmatrix} e \\ x \\ E \end{bmatrix}=\begin{bmatrix} b \\ 0 \\ 0 \end{bmatrix} \tag{4}$$

appear to offer no advantage over equation 7.

Experimental Results

A particularly good example of a critical system from the standpoint of electronic network stability is one furnished by Gephart:[9]

$$\begin{bmatrix} 1.00 & -0.667 & 1.33 \\ 0.400 & 1.00 & -0.600 \\ 3.00 & 1.50 & 100 \end{bmatrix}\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix}=\begin{bmatrix} 43.3 \\ -18.0 \\ 35.0 \end{bmatrix} \tag{13}$$

The matrix has the following roots:

$$\begin{aligned} \lambda&=2.96 \\ \lambda&=0.01871\pm j0.238 \end{aligned} \tag{14}$$

These roots indicate that it should be possible to synthesize the network in all the forms previously indicated. Gephart gives the results obtained for the system in equation 4 and indicates also the use

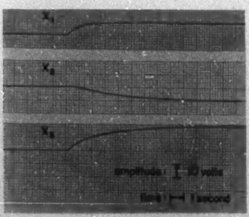

Fig. 4 (left). Oscillogram corresponding to synthesis shown in Fig. 3(B)

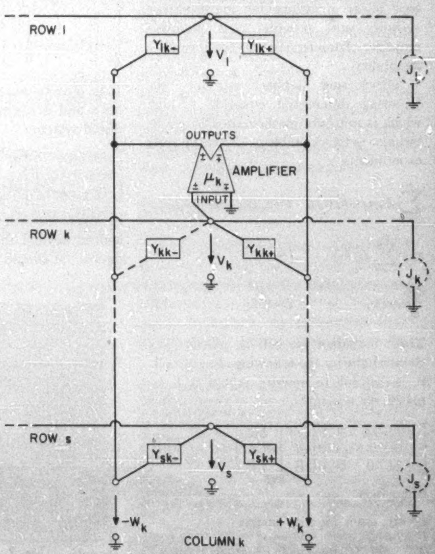

Fig. 5 (right). Electronic synthesis of kth column of mathematical matrix problem

of equation 7. In this section, the results obtained using the forms of equations 1, 11, 12, and 10 will be discussed. The synthesis network of the numerical system 13 in equation 1 is indicated in Fig. 1(A). When this network was placed on a commercial computer, instability resulted due to the inherent amplifier characteristics and parasitic parameters. However, utilizing an experimental computer, with simple *R-C* cutoff amplifier characteristics, the stable operation predicted from the roots 14 could be verified experimentally with the results:

$$x_1=10.1$$
$$x_2=-10.1$$
$$x_3=19.9 \qquad (15)$$

compared with the exact values

$$x_1=10$$
$$x_2=-10$$
$$x_3=20 \qquad (16)$$

The numerical equations 13 in the form

$$\left(\frac{1}{k}D+A\right)x=b \qquad (11)$$

result in the synthesis network depicted in Fig. 1(B). The case shown is for $k=1$. Obviously, the only distinction in the computing networks of Figs. 1(A) and (B) is in the addition of capacitors on each of the principal diagonal positions of Fig. 1(B). However, this form resulted in a stable system on the experimental and commercial computers, yielding the numerical values:

$$x_1=10.1$$
$$x_2=-10.1 \qquad (17)$$
$$x_3=20.0$$

The transient solution obtained is illustrated in the oscillogram of Fig. 2. These results indicate the advantage of equation 11 on commercial analog computers. By intentionally introducing the differential equation system, the parasitic terms tend to be masked and the actual network approaches more closely the ideal network. Of course, the solution response oscillates, as predicted by the roots 14 before settling down to the steady-state values.

Premultiplication of equation 13 by the transpose of the matrix of coefficients results in the equations:

$$\begin{bmatrix} 10.16 & 4.23 & 4.09 \\ 4.23 & 3.69 & 0.01 \\ 4.09 & 0.01 & 3.14 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 141.1 \\ 5.6 \\ 103.6 \end{bmatrix} \qquad (18)$$

and the corresponding roots of the characteristic equation for $k=0.1$:

$$\lambda=1.359$$
$$\lambda=0.340$$
$$\lambda=0.0000615 \qquad (19)$$

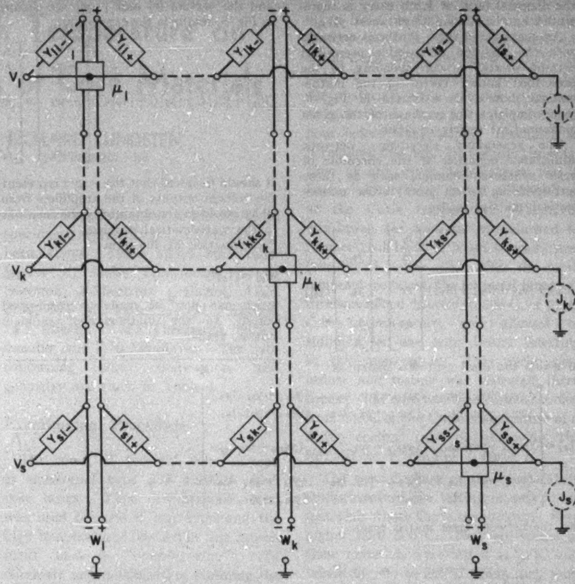

Fig. 6. Ideograph of ensemble of synthesis columns or complete synthesis network

The ideographs of Figs. 3(A) and (B) indicate the synthesis networks for the numerical equation 18 corresponding to equations 12 and 10 respectively. Again, the inclusion of the *d*:s on the principal diagonal in Fig. 3(B), was essential for stable operation of the experimental computer. Fig. 4 is the oscillographic record of the solution taken with $k=0.1$, and shows substantial agreement with the solutions previously obtained. As predicted by equation 19, the transient is now nonoscillatory.

The principal disadvantage of equation 18 as compared to equation 13 lies in the extreme dependence of the results of 18 upon the precision of the coefficient settings. In equation 18 changes of about 1% in the numerical values of the *b*:s, for example may cause errors of 100% or more in the measured magnitudes of the *x*:s, clearly indicating the desirability of avoiding this method if possible.

Conclusions

By use of the matrix formulation of the equation systems and the method of synthesis using the 1-to-1 correspondence between matrix equation and electronic network, a convenient tabulation of procedures applicable to solution of linear algebraic equations has been obtained. In addition, the use of the form

$$\left(\frac{1}{k}D+A\right)x=b \qquad (11)$$

has been shown to have considerable advantage in preventing instability resulting from inherent amplifier characteristics.

Appendix

The fundamental theory of the electronic synthesis of matrix equations is based upon an ensemble of the basic synthesis network shown in Fig. 5. It employs a combination of suitable amplifying devices such as electron tubes, transistors, and the like, and dinode network elements (such as capacitances, conductances, and inductances) or their combinations for the synthesis of one column of a mathematical matrix.

The synthesis of the *k*th column of an $(s\times s)$ order mathematical matrix is accomplished by the voltage amplifier μ_k, Fig. 5, of voltage amplification μ with its input connected to the *k*th row of the synthesis network, and its output of bipolarity connected to the *k*th column, together with suitable self and mutual admittances. The nondiagonal entries of the mathematical matrix are represented by the dinode admittances $y_{1k\pm}$, $y_{2k\pm}$, and so on, and the diagonal term or k,kth entry is represented by the dinode admittances y_{kk_m}.

An ensemble of these synthesis networks with the addition of suitable prescribed current sources j_k corresponding to the prescribed known vector in the mathematical matrix, as indicated in Fig. 6, then completes the synthesis of the given mathematical matrix equation.

The generalized electronic network admittance equation of the ensemble of basic synthesis columns, such as those corresponding to an $(s\times s)$ order mathematical matrix, reads:

$$([1_y]+[2_y]+[3_y]+[4_y])\cdot\begin{bmatrix}v_1\\v_2\\\cdot\\v_k\\\cdot\\v_r\\v_s\end{bmatrix}=\begin{bmatrix}j_1'\\j_2'\\\cdot\\j_k'\\\cdot\\j_r'\\j_s'\end{bmatrix}\qquad(20)$$

in which the ideal synthesis matrix is:

$$[1_y]=\begin{bmatrix}(y_{11+}-y_{11-})\mu_1\ldots(y_{1k+}-y_{1k-})\mu_k\ldots(y_{1s+}-y_{1s-})\mu_s\\(y_{21+}-y_{21-})\mu_1\ldots(y_{2k+}-y_{2k-})\mu_k\ldots(y_{2s+}-y_{2s-})\mu_s\\\vdots\qquad\ldots\qquad\cdot\qquad\ldots\qquad\cdot\\(y_{k1+}-y_{kl-})\mu_1\ldots(y_{kk+}-y_{kk-})\mu_k\ldots(y_{ks+}-y_{ks-})\mu_s\\\vdots\qquad\ldots\qquad\cdot\qquad\ldots\qquad\cdot\\(y_{r1+}-y_{r1-})\mu_1\ldots(y_{rk+}-y_{rk-})\mu_k\ldots(y_{rs+}-y_{rs-})\mu_s\\(y_{s1+}-y_{s1-})\mu_1\ldots(y_{sk+}-y_{sk-})\mu_k\ldots(y_{ss+}-y_{ss-})\mu_s\end{bmatrix}\qquad(21)$$

and the network error matrix reads:

$$[2_y]=\begin{bmatrix}\sum_{i=1}^{s}(y_{1i+}+y_{1i-})\ldots & 0 & \ldots & 0\\0 & \ldots & 0\quad\ldots & 0\\\vdots & \ldots & \vdots\quad\ldots & \vdots\\0 & \ldots\sum_{i=1}^{s}(y_{ki+}+y_{ki-}) & & 0\\\vdots & \ldots & \vdots\quad\ldots & \vdots\\0 & \ldots & 0\quad\ldots & 0\\0 & \ldots & 0 & \sum_{i=1}^{s}(y_{si+}+y_{si-})\end{bmatrix}\qquad(22)$$

The equivalent source error matrix $[{}^3_y]$ and the parasitic error matrix $[{}^4_y]$ may or may not be significant, depending upon the magnitudes of the particular problem, but can be made as small as desired. Finally, the right-hand column vector of j':s in equation 20 represents the current-source equivalents actually constructed from intrinsic voltage sources and series impedances.

Applying to equation 20 the transformation:

$$[v]=C\cdot(-w)\qquad(23)$$

where

$$C=\begin{bmatrix}\frac{1}{\mu_1} & 0\ldots.0\ldots.0 & 0\\0 & \frac{1}{\mu_2}\ldots0\ldots.0 & 0\\\vdots & \cdot\quad\cdot\quad\cdot\quad\cdot\quad\cdot & \cdot\\0 & 0\ldots.\frac{1}{\mu_k}\ldots0 & 0\\\vdots & \cdot\quad\cdot\quad\cdot\quad\cdot\quad\cdot & \cdot\\0 & 0\ldots.0\ldots.\frac{1}{\mu_r} & 0\\0 & 0\ldots.0\ldots.0 & \frac{1}{\mu_s}\end{bmatrix}\qquad(24)$$

and the vectors $[v]$ and $[-w]$ are defined in Fig. 5, results in the expression:

$$([0_y]+[2_y]C+[3_y]C+[4_y]C)\cdot\begin{bmatrix}-w_1\\-w_2\\\cdot\\-w_k\\\cdot\\-w_r\\-w_s\end{bmatrix}=\begin{bmatrix}j_1'\\j_2'\\\cdot\\j_k'\\\cdot\\j_r'\\j_s'\end{bmatrix}\qquad(25)$$

It should be noted that the $-w$:s represent the voltage outputs of the amplifiers from which readings are obtained of the solutions to the mathematical problem.

In equation 25, the term

$$[0_y]=[1_y]C\qquad(26)$$

which can now be made to correspond exactly to the mathematical problem matrix, reads:

$$[0_y]=\begin{bmatrix}(y_{11+}-y_{11-})\ldots(y_{1k+}-y_{1k-})\ldots(y_{1s+}-y_{1s-})\\(y_{21+}-y_{21-})\ldots(y_{2k+}-y_{2k-})\ldots(y_{2s+}-y_{2s-})\\\vdots\qquad\ldots\qquad\cdot\qquad\ldots\qquad\cdot\\(y_{k1+}-y_{k1-})\ldots(y_{kk+}-y_{kk-})\ldots(y_{ks+}-y_{ks-})\\\vdots\qquad\ldots\qquad\cdot\qquad\ldots\qquad\cdot\\(y_{r1+}-y_{r1-})\ldots(y_{rk+}-y_{rk-})\ldots(y_{rs+}-y_{rs-})\\(y_{s1+}-y_{s1-})\ldots(y_{sk+}-y_{sk-})\ldots(y_{ss+}-y_{ss-})\end{bmatrix}\qquad(27)$$

and no longer exhibits the amplifier voltage gains, μ:s.

Furthermore, the entries in the matrices $[{}^2_y]\cdot C$, $[{}^3_y]\cdot C$, and $[{}^4_y]\cdot C$ may be made as small as desired by making the respective μ:s sufficiently large.

The stability of the electronic synthesis network depends upon the frequency response of the amplifier and is discussed in reference 3. Briefly, the network has an equation of state which is always of differential-equation type, due to the amplifier characteristics and stray admittances, even for the synthesis of a purely algebraic mathematical problem. The stability of the synthesis network thus depends not only upon the mathematical problem to be solved, but is in fact heavily influenced by the amplifier characteristics and stray admittances as mentioned. Intentionally placing the capacitances on the principal diagonal terms, as indicated in the paper, tends to mask these effects and thus to yield a stable synthesis network, provided the problem to be solved is itself mathematically stable, of course.

Finally, therefore, to the degree of approximation desired, the electronic synthesis is described by the matrix admittance equation:

$$[0_y].[-w]=[j']\qquad(28)$$

and is now in the desired form, and homeomorphic, entry per entry, to a purely mathematical matrix equation to be solved.

Effects of Ultrahigh Temperature on Magnetic Properties of Core Materials

MICHAEL PASNAK
NONMEMBER AIEE

RICHARD LUNDSTEN

Synopsis: An experimental study has been made of the effects of temperature on the magnetic properties of the following ferromagnetic alloys: Orthonol, *4-79* Mo Permalloy, AEM *4750*, *L* and *Z* Silectron, Transformer *A*, Audio Transformer *A*, *11.7* Alfenol, *15.5* Alfenol, *3* Mo Thermenol, *7-70* Perminvar, and Supermendur. Measurements were made of the d-c and 60 cps (cycles per second) magnetic properties in the temperature range of 24–800 C (degrees centigrade). The materials were also evaluated after several temperature cycles between 24–500 C. The results indicate that, in general, high temperature decreased the maximum induction and the residual induction from their 24 C values. For all materials tested, with the exception of Supermendur and *11.7* Alfenol, the coercive force decreased with increase in temperature. The maximum permeability increased with increasing temperature until the Curie temperature was approached, then it started to decrease. The initial permeability also increased with increasing temperature, but unlike the maximum permeability, it generally started to decrease at a greater rate and at a lower temperature. Grain-oriented materials were more affected by temperature cycling than were unoriented materials. The effects of temperature cycling on the magnetic properties generally appeared as an increase in the coercive force, a decrease in the maximum permeability, a decrease in the residual flux density, and a decrease in the squareness ratio.

A STUDY of the effects of large temperature variations on the properties of magnetic core materials was made to facilitate the development of military components for operation under extreme environmental conditions.[1,2] The materials chosen are used in transformers, magnetic amplifiers, relays, and servo components.

This paper describes the effect of ambient temperature variations on the d-c and 60-cps magnetic properties of 30 specimens, representing 12 different magnetic alloys. These alloys are Transformer *A*, Audio Transformer *A*, *L*-Silectron, *Z*-Silectron, Orthonol, AEM *4750*, *4-79* Mo Permalloy, *11.7* Alfenol, *15.5* Alfenol, *3* Mo Thermenol, Supermendur, and *7-70* Perminvar. The data concerning core composition and geometry are given in Table I.

Experimental Procedure

The cores, all toroidal, were encased in uncovered type *304* stainless steel core boxes. Type *304* stainless steel was used because it can withstand the high temperatures reached in this experiment and is "nonmagnetic."[3] To eliminate any possibility of straining the specimen as a result of tightness in the core box, the core boxes were made oversize to allow for changes in core and box dimensions with temperature.

The toroidal laminations were coated with magnesium oxide and further insulated from each other by 0.004-inch Fiberglas laminations, while the convolutions of the spiral-wound tape cores were insulated only with magnesium oxide. The cores, in their stainless-steel core boxes, were wound with Silotex insulated wire supplied by Anaconda Wire and Cable Company.

The temperature study consisted of two phases. In the first phase, all the materials were tested at temperatures up to 500 C in 100 C steps or until the Curie point of the material was exceeded, if the Curie point was below 500 C. In order to insure temperature stability, the materials were allowed to remain at each temperature for a period of one hour before being tested. Inasmuch as it required one hour for testing, the total time at any given temperature was 2 hours. After being tested at 500 C or at the Curie temperature, whichever was lower, the material was allowed to furnace cool back to room temperature; (see Fig. 1, curve *A*). After the room temperature retest, the material temperature was raised directly to 500 C, or to its Curie temperature, and allowed to stabilize for one hour before retesting at this temperature. This cyclic procedure and testing was repeated three times. The core was then furnace cooled from 500 C or the Curie temperature at a faster cooling rate by removing the furnace cover; see Fig. 1, curve *B*.

The second phase of the temperature study involved the testing of only those materials whose Curie temperatures were higher than 500 C. New specimens of these materials were tested at 24 C and taken directly to 500 C where they were allowed to temperature stabilize for one hour before being tested. Then the temperature was raised from 500 C, in steps of 100 C, until the Curie temperature was exceeded for each material, and the materials were tested at each step. The materials were then allowed to furnace cool along curve *A* in Fig. 1, after which they were tested at 24 C.

Standard d-c test methods were used to obtain the static magnetic properties. The 60-cps dynamic loops were obtained by using a new instrument called the Ferrotracer.[4,5] Unless specified, the 60-cps dynamic loops shown in this report were obtained with the test core driven by a sine-wave "current source."

Table I. Core Materials Used in Temperature Study

Specimen	Composition, %	Core Construction	Inner Diameter, Inches	Outer Diameter, Inches	Thickness, Inches
Transformer *A*	4.7 Si+95.3 Fe	Toroidal laminations	$1^{5}/_{8}$	2	0.015
Audio transformer *A*	3.6 Si+96.4 Fe	Toroidal laminations	$1^{5}/_{8}$	2	0.014
L Silectron	3 Si+97 Fe	Spiral tape	$1^{5}/_{8}$	2	0.004
Z Silectron	3 Si+97 Fe	Spiral tape	$1^{5}/_{8}$	2	0.004
Orthonol	50 Ni+50 Fe	Spiral tape	$1^{5}/_{8}$	2	0.002
Orthonol	50 Ni+50 Fe	Square laminations	1.1875*	1.750†	0.002
AEM *4750*	47–50 Ni+47–50 Fe	Toroidal laminations	$1^{5}/_{8}$	2	0.014
4-79 Mo Permalloy	4 Mo+79 Ni+17 Fe	Toroidal laminations	$1^{5}/_{8}$	2	0.014
11.7 Alfenol	11.7 Al+88.3 Fe	Toroidal laminations	$1^{5}/_{8}$	2	0.014
15.5 Alfenol	15.5 Al+84.5 Fe	Toroidal laminations	$1^{5}/_{8}$	2	0.014
3 Mo Thermenol	3 Mo+16 Al+81 Fe	Toroidal laminations	$1^{5}/_{8}$	2	0.014
Supermendur	2 V+49 Co+49 Fe	Spiral tape	$1^{5}/_{8}$	2	0.002
7-70 Perminvar	7 Co+70 Ni+23 Fe	Toroidal laminations	$1^{5}/_{8}$	2	0.014

Results and Discussion

The influence of temperature, temperature cycling, and cooling rate is illustrated in Figs. 2–16.

SILICON-IRON

Of the four silicon-iron materials tested, the grain-oriented alloys *L* and *Z* Silectron, were more affected than the unoriented silicon-iron alloys, Audio Transformer *A* and Transformer *A*. The effects of temperature (up to 500 C) upon the d-c induction curves of the foregoing materials are shown in Fig. 2, where *L*-Silectron is grain oriented and Audio Transfomer *A* is unoriented. From this figure, one may well conclude that even though the grain-oriented material displayed greater over-all changes than the unoriented material, its properties are still superior to those of the unoriented material during the course of one temperature cycle. However, this superiority decreases with each temperature cycle as indicated by the behavior of the d-c induction curves of *Z*-Silectron and Transformer *A* shown in Fig. 3. In this figure, it is seen that temperature cycling from 24 C to 500 C and back to 24 C has little or no effect on the unoriented silicon-iron core. Whereas the same temperature cycling performed on the grain-oriented silicon-iron core resulted in a continuous degradation of its induction curves until they are comparable to those of the unoriented silicon-iron core.

The magnetic properites of the grain-oriented silicon-irons deteriorated with each temperature cycle in the 24–500 C range, indicating that the temperature was high enough to cause some degree of disorientation with each cycle. That disorientation had begun to take place is further evidenced when comparing the dynamic loops above 500 C of the grain-oriented material, Fig. 4, with those of the unoriented material, Fig. 5. By direct comparison of these two figures, it is seen that the dynamic loops of these two materials are very similar in this temperature range, and that disorientation of the grain-oriented material is almost complete. The grain-oriented material still displayed superior magnetic properties upon returning to 24 C from 800 C since it may not have been at the high temperature for sufficient time for permanent changes to occur.

Another factor very probably contributing to the deterioration of the magnetic properties of the silicon-iron alloys was the severe oxidation which occurred along the edges of the tape core and along the edges of the toroidal laminations. This oxidation of material, appearing as a heavy caked coating of rust, would decrease the effective area of the core material and produce a decrease in the maximum flux. This decrease in the effective area was not taken into account when calculating the maximum and residual flux densities.

NICKEL-IRON

The effect of temperature upon the 60-cps dynamic loops of the grain-oriented nickel-iron, Orthonol, shown in Fig. 6, indicated only a very small loss of rectangularity with increasing temperature.

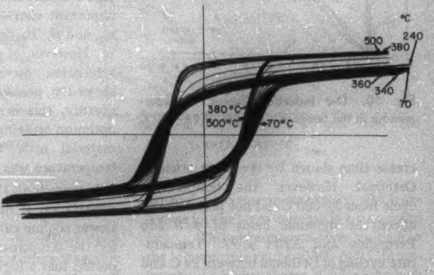

Fig. 8. Continuous 60-cps dynamic loops of 11.7 Alfenol while cooling from 500–24 C

At 380 C Bm and Br stopped increasing and started decreasing

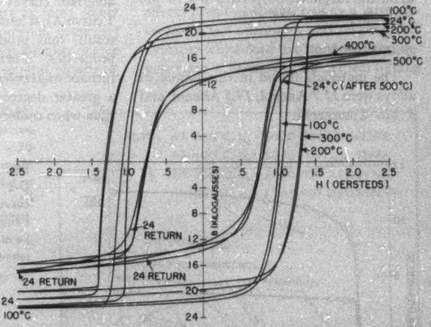

Fig. 9. 60-cps dynamic loops of Supermendur in the temperature range of 24–500 C

Upon returning to 24 C from 500 C a new dynamic loop was obtained which differs from the initial 24 C loop in that it has both a smaller coercive force and maximum flux density for the same field intensity. The decrease in a-c coercive force is probably an indication that some degree of disorder in the crystal structure had occurred. The d-c induction curves indicated an increase in d-c coercive force implying that some disorientation had taken place. Disorientation increases the d-c coercive force and decreases the maximum flux density.

The 60-cps dynamic loops of the unoriented nickel-iron materials (AEM *4750* and *4-79* Mo Permalloy) indicated a greater deterioration with temperature in-

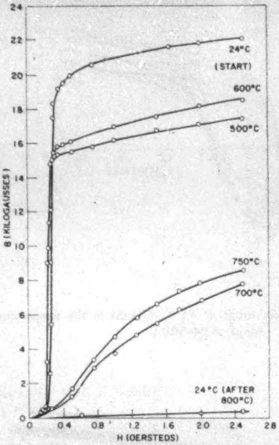

Fig. 10. D-c induction curves of Supermendur in the temperature range of 24–750 C

crease than shown by the grain oriented Orthonol. However, the temperature cycle from 24–500 C did not permanently affect the dynamic loops of *4-79* Mo Permalloy and AEM *4750*. Temperature cycling of Orthonol between 24 C and 500 C had a very pronounced effect upon its maximum permeability and coercive force. Whereas, the same temperature cycling had little or no effect upon the magnetic properties of *4-79* Mo Permalloy and AEM *4750*.

ALUMINUM-IRON

The materials tested in this family of alloys were *11.7* Alfenol, *15.5* Alfenol, and *3* Mo Thermenol.

As previously reported,[6] the optimum magnetic properties of aluminum-iron alloys are related to order-disorder within the crystal structures. For aluminum contents below 13%, Alfenol exhibits optimum magnetic properties in the ordered state, whereas optimum properties for Alfenols with aluminum contents above 13% require a disorder condition. The temperature study made on the above alloys substantiates this general behavior.

The *11.7* Alfenol core used in this experiment was given a furnace cool to obtain an ordered state for optimum magnetic properties. The phase diagram[7] of iron-aluminum alloys indicates the highest degree of ordering of *11.7* Alfenol occurs at approximately 550 C. As the temperature was increased from 24 C to 400 C such important characteristics as B_m, B_r, H_c, u_m, and B_r/B_m decreased as shown in Fig. 7. However, at 500 C, these same characteristics, except the coercive force, showed a pronounced increase. Consequently, this is a good indication that optimum ordering was not present in this material until the optimum ordering temperature was approached.

Inasmuch as the furnace used for the preparation of this specimen has a much slower cooling rate than the furnace used for the temperature test, it is to be expected that a higher degree of ordering in the specimen would be obtained in the former furnace. Therefore, it can be expected that upon returning to 24 C at a faster rate, as given by the cooling characteristic curves of the test furnace (Fig. 1 curve A), a lesser degree of ordering will result, thus producing inferior magnetic properties. Furthermore, when the test furnace was cooled along curve B in Fig. 1, a greater degree of disordering resulted than when cooled along curve A.

Fig. 8 is a continuous recording of the 60-cps dynamic loops of this core material while cooling from 500 to 24 C. Since the order-disorder condition varies while cooling is taking place, the dynamic loops do not indicate a continuous increase in flux density and coercive force. Instead, the flux density and coercive force values for the dynamic loops of *11.7* Alfenol are dictated by the conditions or order-disorder present at various temperatures.

The *3* Mo Thermenol and *15.5* Alfenol were prepared as disordered state specimens in order to obtain optimum magnetic properties. From Figs. 12–16, it can be seen that as *15.5* Alfenol approached higher temperatures, a greater degree of ordering took place and the magnetic properties deteriorated. When this material was returned to 24 C inferior magnetic properties resulted in the form of decrease in B_m, B_r, u_o, u_m and an increase in H_c. These inferior magnetic characteristics are caused by an increase in ordering that resulted from the test furnace cool, which was slow, relative to the water quench required to bring about a high degree of disorder. As this material became more ordered with each temperature cycle its magnetic properties continued to deteriorate.

The behavior of *3* Mo Thermenol at elevated temperatures was similar in all respects to *15.5* Alfenol. The only exceptions are that the Curie temperature of *3* Mo Thermenol was approximately 300 C and that upon returning to 24 C from 300 C, the maximum flux density increased instead of decreased, as it did for *15.5* Alfenol.

SUPERMENDUR

Supermendur differed from all other specimens tested in that from 24 to 300 C

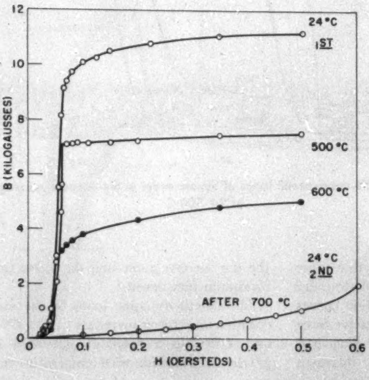

Fig. 11 (left). D-c induction curves of 7-70 Perminvar in the temperature range of 24–600 C

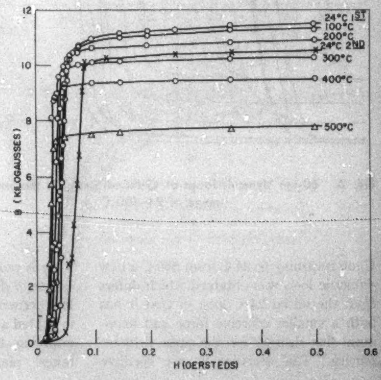
Fig. 12 (right). D-c induction curves of 7-70 Perminvar in the temperature range of 24–500 C



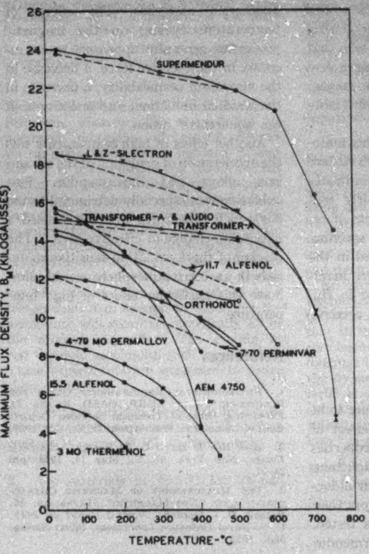


Fig. 13 (left). D-c maximum flux density at 30 oersteds versus temperature curves of all materials tested

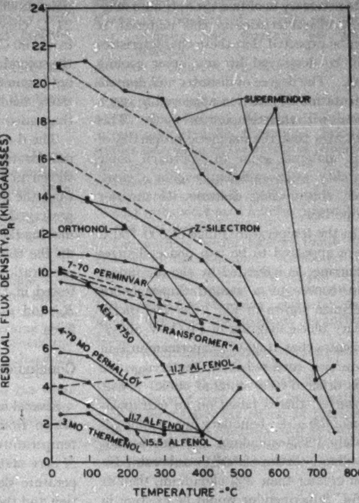

Fig. 14 (right). D-c residual flux density at 30 oersteds versus temperature curves of all materials tested

there was approximately a 10% decrease in the d-c coercive force and a 30% increase in the a-c coercive force. From 300 C to 500 C, the d-c coercive force increased approximately 10%, while the a-c coercive force decreased approximately 42%. Further, the d-c and a-c residual flux densitites showed sharp drops at temperatures above 300 C. This behavior is seen in the dynamic loops of Supermendur shown in Fig. 9.

In addition to being dependent upon domain orientation for optimum magnetic properties, the magnetic properties of Supermendur are also critically dependent upon the cooling rate to which it is subjected. In view of these facts, it is reasonable to conclude that in the temperature range of 24–300 C there is most likely an order-disorder phenomenon occurring which tends to bring about a higher degree of ordering within the crystal structure, causing a decrease in resistivity, which accounts for the large increase in a-c coercive force. This phenomenon reverses itself in the temperature range of 300–500 C bringing about a higher degree of disorder which increases the resistivity, thus decreasing the a-c coercive force. Apparently, the effect of temperature upon domain orientation is not felt until 400 C where its effects manifest themselves as a large decrease in the maximum and residual flux densities which lead to a very poor squareness ratio. Because of the critical cooling

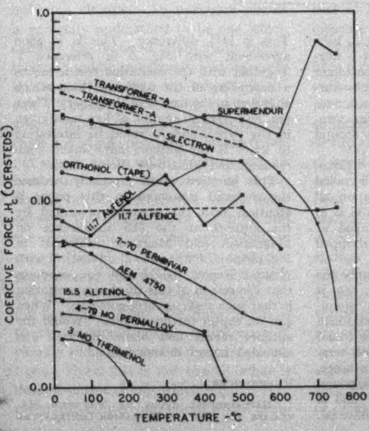

Fig. 15 (left). D-c coercive force at 30 oersteds versus temperature curves of all materials tested

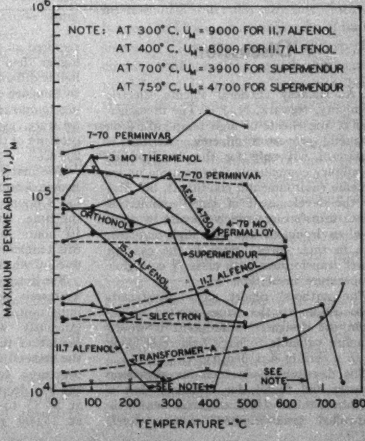

Fig. 16 (right). D-c maximum permeability versus temperature curves for all materials tested rate necessary to obtain the optimum magnetic characteristics in this material, it can be expected that these characteristics will be destroyed by any other cooling rate. The degree of disorder and domain orientation destruction appeared to reach a limit with each temperature cycle. This indicates that the magnetic properties of this material seem to approach some stability after sufficient cycling. However, this cycling destroys its superior properties

In the temperature range of 500–750 C there appeared to be two phase changes occurring, as indicated by the d-c induction curves of a second Supermendur specimen shown in Fig 10. The quasi-binary phase diagram of Fe-Co-V alloys[7] indicates that at 500 C, Supermendur is in an $\alpha'+\gamma$ (ordered-body centered cubic plus ordered-face centered cubic) phase. However, this is based on an extrapolation of the $\alpha'+\gamma$ boundary line to approximately 1.8% vanadium. If this boundary line is extrapolated to any composition greater than 2% vanadium, then at 500 C Supermendur would be existing in the α' phase, and at 600 C in the $\alpha'+\gamma$ phase, at 700 C in the α' phase, and at 750 C in the α phase. The behavior of the induction curves of Fig. 10 indicates that the $\alpha'+\gamma$ boundary in the quasi-binary phase diagram in reference should be extrapolated to a vanadium content of greater than 2% in order to account for their behavior.

7-70 PERMINVAR

Like Supermendur, 7-70 Perminvar depends upon cooling rate for the desired magnetic properties, especially when cooled from temperatures above its Curie point as shown in Fig. 11 where the second 24 C curve was obtained after cooling from 700 C. In this figure, it is seen that the second 24 C d-c induction curve had not begun to saturate for the same magnetizing fields, which previously were more than adequate for saturation.

The d-c induction curves of this material for temperatures up to 500 C are shown in Fig. 12. This figure indicates that the rectangularity was fairly well preserved. In Fig. 11, the effects of removing the magnetic anneal and speeding up the cooling rate over the used in the preparation of this specimen were manifested in the form of a decrease in B_m, B_r, and u_m and an increase in coercive force.

Conclusions

Several important conclusions are to be drawn from this study of the effect of temperature on the magnetic properties of core materials. In general, high temperature decreased the maximum induction and the residual induction from their 24 C values. For all materials tested, with the exception of Supermendur and *11.7* Alfenol, the coercive force decreased with increase in temperature. The maximum permeability increased with increasing temperature until the Curie temperature was approached, then it started to decrease. The initial permeability also increased with increasing temperature, but unlike the maximum permeability, it generally started to decrease at a greater rate and at a lower temperature.

Grain-oriented materials were more affected by temperature cycling than were unoriented materials. The effects of temperature cycling on the magnetic properties generally appeared as an increase in the coercive force, a decrease in the maximum permeability, a decrease in the residual induction, and a decrease in the squareness ration.

Another effect of high temperature was the acceleration of oxidation of the silicon-iron alloys and Supermendur. This oxidation was especially detrimetal to the 0.004-inch tape cores where it caused a noticeable change in effective area. The placing of these oxidation sensitive materials in an inert atmosphere would eliminate this particular effect of high temperature.

Discussion

A. A. Halacsy (Federal Pacific Electric Company, Newark, N. J.): The investigation of the effects of high temperature on magnetic properties of core materials is important not only for the development of military components for operation under extreme environmental conditions, but also for the development of quite commercial power transformers which operate in quite usual environment but with high temperature in their cores. Such is the case in power transformers with class *H* or higher temperature insulation.

The authors' report shows hysteresis loops all up to the same oersted value. From the designers' standpoint it would be more valuable to have hysteresis loops up to a certain flux density.

The discusser made such investigations recently and found, for instance, that a 0.012-inch-thick *M6X* material which is cold-rolled grain-oriented silicone steel, required an exciting current at 233 C, 10% higher than at 20 C. This is not a negligible difference, and it warns the customer to compare exciting currents at the operating temperature and not at the cold temperature, especially if the operating temperature of the steel core is high, say around 200 C.

The material was heat cycled five times. It was heated for 16 hours and air-cooled for 8 hours with 60-cps excitation on all the time. It reached the steady 233 C in 10 hours during the heating, stayed at this temperature for 6 hours, then dropped to 65 C during the next 8 hours.

For a transformer designer not only the hysteresis loop but the loss curve, too, is important. We made loss-tests simultaneously with the already mentioned excitation tests and, of course, we found the losses decreasing with increased temperature. In a typical case, for instance, the loss decreased from 0.562 watts/pound at 20 C to 0.500 watt/pound at 233 C at 15,000 gauss in an *M6X* material. This is 11% difference. This is in good agreement with Fig. 5 of reference 1. Together with the excitation test it means a narrowing of the hysteresis loop which shows up in the figures of the paper. There are, however, no results, of loss-tests given in the paper, and it would be interesting to know if the authors have taken such readings and what were their results.

This question arises especially because the material presented in this paper is identical with the material presented by the authors at the 4th Conference on Magnetism and Magnetic Materials in Philadelphia, Pa., and is also identical with Navord Report 6132,[2] and one supposes that the reason of this third representation is that such tests are still going on. When can we expect further results? Would the authors reveal how their material was annealed before it was tested?

Weston Morrill (General Electric Company, Pittsfield, Mass.): The degradation of magnetic properties of crystal-oriented silicon irons, when cycled between 24 and 500 C, is not caused by a disorientation within the grain-oriented material, but is caused by a chemical aging phenomenon. Interstitial elements, such as carbon, held in supersaturated solution, will precipitate at an accelerated rate with increasing aging temperatures, resulting in an attendant damage of magnetic characteristics. Carrying the material for short periods to a temperature high enough to redissolve the precipitate will recapture practically all of the original properties. The cycling at 800 C would accomplish such regeneration. These experiments are suggested to prove these points:

1. Chemical analysis for carbon by a low-pressure combustion method. If carbon content is over 0.001% chemical aging is possible.

2. Age materials at 150 C for 100-odd hours and establish the magnitude of magnetic degradation. It probably will be as great as any noted in the original work.

3. Recycle at the lower temperatures the material which has been regenerated by heating to 800 C, and note a duplicate degradation of properties.

Michael Pasnak and **Richard H. Lundsten:** The magnetizing fields used by the authors were such that the core materials were being driven well into saturation. Therefore, it was felt that the magnetizing field could be interpolated at any desired flux level from the submitted induction curves and dynamic loops.

No loss measurements were made with wattmeters or any of the acceptable bridge techniques. Here again, the authors felt that all the necessary data concerning total core losses were obtained in the form of the dynamic loops. Since the area enclosed by the dynamic loop of a magnetic core material is directly proportional to the total core losses, these losses can be obtained by substituting the area of the dynamic loop into the equation

$$W=\frac{KA}{4\pi}$$

where

K = to the product of gausses per unit ordinate and oersteds per unit abscissa

A = area of dynamic loop in cm^2

W = ergs/cm^3 cycle

This paper was not re-presented at the AIEE Fall General Meeting. It was merely submitted for discussion. Further studies pertaining to the effects of temperature on the magnetic properties of core materials have been discontinued.

Standard annealing temperatures and cooling rates were used for the preparation of the test specimens.

The authors would like to thank Dr. Halacsy for his discussion. We should also like to take this opportunity to suggest the use of the Ferrotracer as an invaluable instrument for obtaining magnetic data under dynamic conditions of magnetization.

Mr. Morrill's comments and suggestions are appreciated. The authors feel that contamination of the materials due to the air atmosphere used in their investigations may have masked the effects of precipitation of interstitial elements such as carbon. However, if time allows, in the future we will investigate Mr. Morrill's proposed suggestions.

A Comparison of Sequential and Iterative Circuits

E. J. McCLUSKEY, JR.
NONMEMBER AIEE

TRADITIONALLY, the major effort of switching theory has been devoted to finding techniques for synthesizing optimum circuits. An optimum circuit is generally understood to be one which exhibits the required relationship among its input and output signals, and also costs less to construct than any other such circuit. The requirements on the relation among input and output signals can include not only a specification of which output signals are to result from the various combinations or sequences of input signals, but also a restriction on the delay between the application of the input and the appearance of the corresponding output signal. The desired synthesis procedure is one which does not place any restrictions on the form of the resulting network. Thus, the final circuit is to be optimum for the entire class of circuits which satisfy the design specifications. Even this is not exactly what is desired since a circuit which requires very complicated interconnections would probably be undesirable because of difficulties involved in maintaining proper operation. To be completely accurate, the cost of the circuit should include some measure of the circuit complexity.

It is not too surprising that there has been a general lack of success in obtaining such synthesis procedures. Since the problem of designing optimum circuits is so difficult, attempts have been made to devise synthesis schemes which make use of greatly simplified measures of circuit cost. Thus a great deal of attention has been directed towards a procedure for designing 2-terminal contact networks in which the number of contacts and springs are minimized. The fact that extra springs on a relay may actually cost nothing is ignored as is also the effect of wiring complexity. In spite of the seeming simplicity of this problem it is still unsolved. Solutions do exist for certain other simplified problems; for example, that of obtaining a circuit constructed of AND-gates, OR-gates, and inverters which contains the minimum number of inverters,[1] and that of obtaining a 2-stage single-output diode-gate network containing the minimum number of gates.[2,3]

In practice, the design of switching circuits is usually done by making an initial assumption as to the general form of the final circuit. Specialized design techniques for circuits having the chosen form are then used to obtain the actual design. For example, special methods exist for designing circuits which have n-inputs and 2^n-outputs, only one of which is equal to 1 for each combination of input signals.[4] However, many of the special circuit configurations which are commonly used in practice have not been studied theoretically. When such circuits are to be designed it is necessary to resort to informal or trial and error techniques. This paper is discussion of one special form of circuit: a combinational circuit (a circuit which does not contain any storage or memory such as flip-flops, self-locking relays, etc; its present output is determined only by its present input).

Paper 59-1160, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted Feb. 6, 1959; made available for printing August 10, 1959.

constructed as a series of identical "cells" or subnetworks. Such a circuit is commonly called an iterative circuit. Typical examples of iterative circuits are the parallel binary adder and the relay parity check circuit; see Figs. 1 and 2. A discussion of the reasons for using iterative networks has been given elsewhere.[5] Iterative circuits were first studied theoretically in the book by Keister, Ritchie, and Washburn.[6] In this book, an informal method is given for designing iterative contact networks. These networks are divided into two types: 1. symmetric circuits in which the outputs depend only on the number of relays operated, and 2. positional circuits in which the outputs depend on the relative positions of operated and unoperated relays. (A typical symmetric circuit is one which has output only if 2 or 4 of the inputs are equal to 1, and a typical positional circuit is one which has an output only if exactly two adjacent inputs are equal to 1.) The positional circuits include many important circuits having binary numbers as inputs.

Formal design procedures for iterative contact networks were proposed by Caldwell[7] and Huffman.[8] Huffman's method makes direct use of an analogy between iterative circuits and sequential circuits, and carries out the iterative network design by means of a flow table similar to that used in sequential circuit theory.[7,9] The method used by Caldwell is similar to Kleene's technique for sequential circuits,[10,11] but does not contain a formal procedure for going from a statement of the desired behavior to the actual circuit.

There are actually two general classes of iterative circuit: The first class consists of those circuits which have their outputs derived only from the final cell. These circuts will be called circuit-output iterative networks. Fig. 1 is an example of such a circuit. These are the types of circuits which have been studied theoretically by Caldwell and Huffman.

A large porportion of the iterative circuits which are actually used belong to the second class in which the circuit outputs are obtained from each of the individual cells. The circuit of Fig. 2 is an example of such a circuit. These circuits will be called cell-output iterative networks.

Design Procedure

The analogy between sequential and iterative circuits will be illustrated by means of an example. First a sequential circuit will be designed which compares two binary numbers, $A=a_na_{n-1}\ldots a_1a_0$ and $B=b_nb_{n-1}\ldots b_1b_0$; and has an output only if $A<B$. The first pulses to appear at the circuit inputs will correspond to a_n, a_n', b_n, b_n', the second pulses to a_{n-1}, a'_{n-1}, b_{n-1}, b'_{n-1}, etc. (a_n' represents the complement of a_n. A pulse will appear on the a lead if the corresponding bit is equal to 1 and on the a' lead if the corresponding bit is equal to 0.) The appropriate flow table and circuit are shown in Fig. 3.[13] The circuit diagram is incomplete since some additional circuitry would be necessary to insure coincidence of the input pulses and the y_1 and y_2 pulses from the delay amplifiers, and also to reset the circuit to the proper initial state. This circuitry has been omitted since it does not affect the logical structure of the circuit and simplifies the analogy with iterative circuits. It is assumed that the delay of the delay amplifiers is the same as the time interval between successive input pulses. All time in this circuit will be measured in terms of this interval between pulses. Thus, t_0 is the time when the first input pulses arrive, t_1 is the time when the second input pulses arrive, etc. Before t_0 the circuit is in its initial state, with $Y_1=y_1=0$ and $Y_1=y_2=1$. At t_0 the input pulses representing a_n and b_n arrive. If $a_n=0$ and $b_n=0$ or $a_n=1$ and $b_n=1$; the inputs to the delay amplifiers Y_1 and Y_2, remain unchanged. If $a_n=0$ and $b_n=1$, Y_1 becomes equal to 1 and Y_2 becomes equal to 0. If $a_n=1$ and $b_n=0$, Y_1 and Y_2 both become equal to 0. The values of y_1 and y_2 at t_1 will be equal to values of Y_1 and Y_2 at t_0. More simply $y_1(t_i+1)=Y_1(t_i)$ and $y_2(t_i+1)=Y_2\ (t_i)$ where $y_1(t_i+1)$ represents the value of y_1 at time t_i+1, etc. The values of $Y_1(t_i)$, $Y_2(t_i)$ and $Z(t_i)$ are determined by $a(t_i)$, $b(t_i)$, $y_1(t_i)$ and $y_2(t_i)$.

If all of the input bits: $a_n, a_{n-1}, \ldots, a_0$ and $b_n, b_{n-1}, \ldots b_0$, are available simultaneously (as d-c signals rather than pulses), it is possible to build an iterative network which performs the same function as this equential circuit. This is done by removing the delay amplifiers from the circuit of Fig. 3(C) and constructing n copies of the resulting circuit, Fig. 4. These copies of the sequential circuit form the cells of the iterative net-

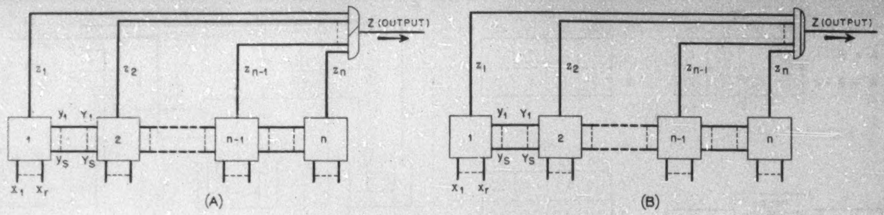

Fig. 7. **General form of OR-gate and AND-gate networks**

A—OR-gate network B—AND-gate network

work. Instead of being connected to the inputs of the delay amplifiers, Y_1 and Y_2 are now connected to the y_1 and y_2 inputs of the next cell of the iterative circuit. It is only necessary to derive an output from the final cell, since the circuit should have an output only if $Y_1=1$ and $Y_2=0$ for the final cell. This allows certain simplifications in the final cell since Y_1 and Y_2 need not be formed explicitly. It is very simple to verify that the iterative network will perform the same function as the sequential circuit. In both circuits: $y_i(t+1)=Y_i(t)$; and $Y_1(t)$ and $Y_2(t)$ are derived from $a(t)$, $b(t)$, $y_1(t)$, and $y_2(t)$ according to the same rules. This shows that an iterative network can be designed by the same techniques used to design sequential circuits.

Reduction of Delay in Forming an Output

In the circuit of Fig. 3, $Y_1=0$ and $Y_2=1$ as long as the inputs are either $a=0$ and $b=0$ or $a=1$ and $b=1$. As soon as some input for which $a=1$ and $b=0$ occurs, Y_2 becomes equal to 0, and Y_1 and Y_2 both remain equal to 0 regardless of the values of the subsequent inputs. Similarly, if the input $a=0$, $b=1$ occurs before $a=1$, $b=0$; Y_1 and Z become equal to 1 and Y_2 becomes equal to 0, and subsequent inputs have no effect on Y_1, Y_2, or Z. This makes possible an alternate realization of the sequential circuit in which a pulse occurs on a z-lead if the input $a=0$, $b=1$ occurs before the input $a=1$, $b=0$. This z pulse is used to set a flip-flop in the 1-condition and the circuit output is derived from the output of this flip-flop.[12] This circuit is shown in Fig. 5. The arrangements for synchronizing pulses and resetting the circuit to its initial condition have been omitted from the figure. A comparison of the economy of the circuits of Figs. 3 and 5 depends on the relative cost of delay amplifiers, flip-flop, and gate circuits.

A similar modification of the iterative circuit of Fig. 4 can be carried out. In the iterative circuit, an OR-gate is used instead of the flip-flop so that an output on the z-lead of any cell will produce a circuit output. This is shown in Fig. 6. In the modified iterative circuit of Fig. 6 the output will appear sooner than in the original circuit since the output can come directly from an intermediate cell rather than propagating through all of the remaining cells to the final cell. These can also be a saving in equipment in the modified circuit since $2n$ OR-gates each with two inputs are being replaced by a single OR-gate with n-inputs.

An iterative network in which the output is derived from an OR-gate which has one input from each cell of the network will be called an "OR-gate network." The general form of such a network is shown in Fig. 7(A). Not all iterative networks can be designed as OR-gate networks, but it is possible to determine directly from the flow-table whether such a realization is possible. The criterion for whether an OR-gate network is possible depends on the terminal states of the flow table. A state from which it is not possible to go to any other state is called a "terminal state." In the table of Fig. 3(A), states 2 and 3 are terminal states.

A circuit-output iterative network can be designed as an OR-gate network if and only if there is a terminal state for which the output is to equal 1. The design is obtained by deleting the terminal state from the flow table and generating a 1-output from a cell whenever the next state should be the terminal state which was removed. The table of Fig. 5(A) is obtained from the table of Fig. 3(A) by removing state 3 and generating a 1-output wherever the next-state entry of the

original table was 3 (for $a=0$, $b=1$, and present state 1). In Fig. 5(A) a dash is used for the next state entry when the present state is 1 and $a=0$, $b=1$; since whenever this condition occurs, a 1-output will be generated and the next-state will be unimportant. Once an output has been generated, any further circuit action is unimportant since it cannot remove the output. In actually designing the circuit a state must be chosen to replace the dash, but this is done so as to minimize the equipment in the cell. The dash entry in the state table thus becomes a "don't care" entry in the output table; see Fig. 5(B).

It is also possible to design a circuit-output network in which the circuit output is derived from an AND-gate which has one input per cell; see Fig. 7(B). Such a network is called an "AND-gate iterative network." A circuit-output network can be designed as an AND-gate network if and only if there is a terminal state for which the circuit is to have a 0-output. The procedure for designing such a circuit as an AND-gate network is directly analogous to designing an OR-gate network. The terminal state for which there is to be a 0-output is deleted and a 1-output is generated from all cells for which the output state is not the terminal state being removed. For the table of Fig. 3(A) this requires the removal of state 2 and an output to be generated for all conditions except when the input state is 1 and the inputs are $a=1$, $b=0$. The resulting flow table and circuit are shown in Fig. 8. It is not true that there will always be both a terminal state with a 1-output and a terminal state with a 0-output. A circuit which has one terminal state can only be designed as an OR-gate network if the terminal state corresponds to a 1-output and can only be designed as an an AND-gate network if the terminal state corresponds to a 0-output from the circuit.

For a network with a single output, if there are no terminal states, neither an OR-gate network nor an AND-gate network is possible and the circuit must be designed as in Fig. 4.

The preceding discussion applies specifically to networks with a single output. For a network with more than one output, it may be possible to realize the network as an OR-gate or AND-gate network even if the original network does not contain any terminal states. For multiple-output networks it is necessary to consider terminal sets of states rather than terminal states. "A terminal set" of states or "terminal set" is defined as a set of states such that once the network is in any state of the set, it will never go to a state which is not one of the states of the set. For example, in Table I(A) states 3 and 4 form a terminal set.

If any output Z_k is equal to 1 for all states of a terminal set, it is possible to generate Z_k by means of an OR-gate network. This is done by setting $z_k=1$ for all combinations of inputs and input-states which have as output-states, states which are members of the terminal set. For input states which are members of the terminal set, z_k can be either zero or one (z_k is a "don't care") since the required output has already been generated by a previous cell. Table I(B) shows the modification of Table I(A) which arises because $Z_k=1$ for the terminal set consisting of states 3 and 4. The circuit output Z_2 is derived from an OR-gate whose inputs are the z_2 outputs of the individual cells.

If an output Z_r is equal to 0 for all states of a terminal set, an AND-gate realization is possible with z_r equal to 1 for all combinations of inputs and input-states except those which have a state of the terminal set as their output-state. Again, z_r is a "don't care" when the input-state is one of the states of the terminal set.

In Table I(B), states 1 and 3 are equivalent if z_2 is set equal to 0 for $s_j=3$, and states 2 and 4 are equivalent if z_2 is set equal to 0 for $s_j=4$, $x_i=0$ and z_2 is set equal to 1 for $s_j=4$, $x_i=1$. Table I(B) can therefore be simplified to Table I(C).

In the example just discussed, no states were eliminated in forming the table for the OR-gate network. In general it is only possible to eliminate a terminal set for which all outputs have the same values for all members of the set (such a terminal set can contain only one state and is therefore a terminal state). An output-state entry becomes a "don't care" only when the corresponding input-state is eliminated from the table. This is illustrated by state 5 in Table II(A).

Table II. State Tables for Network for Which $Z_1=1$ If 4 or More Inputs Are Equal to 1, And $Z_2=1$ If 2 or Fewer Inputs Are Equal to 1

$s_j \backslash x_i$	0	1	Z_1	Z_2
1	1	2	0	1
2	2	3	0	1
3	3	4	0	1
4	4	5	0	0
5	5	5	1	0

S_j

(A)

$s_j \backslash x_i$	0	1
1	1,01	2,01
2	2,01	3,01
3	3,01	4,00
4	4,0d	—,1d

$S_j, z_1 z_2$

$Z_1 = z_{11}+z_{12}+\dots+z_{1n}$

$Z_2 = z_{21} z_{22} \dots z_{2n}$

(B)

It is possible to have a network in which one of the outputs is generated by an AND-gate and another output is generated by an OR-gate. For example, in Table II(B), Z_1 must be generated by an OR-gate and Z_2 must be generated by an AND-gate.

The preceding discussion of circuit-output networks has been concerned solely with electronic networks. For relay networks, the remarks concerning OR-gate and AND-gate networks are not applicable since there is not a corresponding delay associated with transmitting a signal through many cells. The relay circuit corresponding to an OR-gate network would be a network with an output bus wire which can have a signal placed on it from any cell. There is no relay circuit corresponding to the AND-gate network. Whether a relay network will have an output bus wire will be determined directly by the coding which is assigned to the states.

It has been shown that single-output circuit-output networks can be designed as OR-gate networks if there is a terminal state for which the output is to be one and as AND-gate networks if there is a terminal state for which the output is to be zero. For multiple-output networks the situation is the same except that terminal sets of states rather than terminal states must be considered. Examples have been given for the procedure to be followed in converting to OR-gate or AND-gate networks.

The K24A Syncroplex Telephone Carrier System

Part I: Historical Background and Description

A MOST significant turning point in the history of telephone transmission occurred shortly before 1920 with the introduction of carrier equipment as a means of multiplying the capacity of open-wire line facilities. The 20-year period between 1918 and 1938 witnessed the firm establishment of single-side-band techniques in telephone transmission through the *C* carrier and the development of the 12-channel *J* and *K* systems for open wire and cable, respectively. This was a period of rapid expansion of carrier applications to long-haul toll circuits and, by and large, a consolidation of carrier design for this realm of service. If the *L* system is included, which is essentially an expansion of the *K*, the equipment which supports the majority of long-haul toll transmissions is still of the *J*, *K*, or *L* type.

A new departure in carrier equipment development occurred around 1950 with the introduction of carrier to short-haul toll circuits, as well as to tributary, trunk, and long-exchange lines. New economies in design and manufacture produced the *N*, *O*, and *ON* equipments, a class of systems which made the application of carrier to circuits between 20 and 200 miles long economically feasible. With the advent of these carrier systems, the number of carrier channel miles in the nation advanced to a new order of magnitude.

As this application of carrier began to gain momentum, the attention of telephone communication engineers turned to an area of the telephone transmission plant which had heretofore defied the economic application of carrier techniques on any significant scale, viz., the trunk and exchange circuit where more than 50% of the circuits fall in the 5- to 20-mile range. If a carrier equipment could be produced to serve this class of circuit, still another order of magnitude of carrier application to telephone transmission could be achieved, with its attendant gain in service to the subscriber.

After a study of design possibilities and available techniques, a decision was made at the ITT (International Telephone and Telegraph Corporation) Laboratories in mid-1957 to proceed with the development of an exchange carrier system. This culminated in the field trials of the *K24* Syncroplex System towards the end of 1958. Because of the tremendous pressure of demand for circuits, an objective was set up to compress the usual 4- to 5-year cycle of development and testing of a basically new carrier system into $1^{1}/_{2}$ to 2 years.

Characteristics of Trunk and Exchange Transmission Facility

One of the most important aspects of the design and development problem in the telephone transmission field is that of a large existing facility which it is desirable to improve and which it is virtually impossible to redesign in any radical way. This, then, means the development of equipment to work on, and with, existing facilities which were frequently designed and installed at great cost, for a different type of use than that now intended. If one were starting over again, more suitable facilities could be designed, but this is small comfort.

In the case of the exchange and trunk facility, there is an essentially low-frequency medium. For voice transmission, these lines are equalized for response in the 0- to 4-kc frequency range by the addition of loading coils. Repeaters of the hybrid or negative-impedance type are employed to provide gain where necessary. In addition to voice, the physical line is, of course, capable of transmitting d-c signaling pulses and all possible states of the loop battery; i.e., battery on, off, normal, or reverse. If a carrier system were economically to replace this service, it would have to be capable of using the facility to an order of 1/2 mc (megacycle), accommodate a relatively complicated signaling transmission requirement, provide a very high degree of quality and reliability, be simple to install and maintain, and cost one half to one quarter the cost of previously applied systems, a truly imposing challenge.

The electrical characteristics of typical exchange lines are depicted in Fig. 1. The attenuation characteristics are shown

(B)

in Fig. 1(A) and the thermal in Fig. 1(B).* Three other characteristics of great importance are those of near-end crosstalk, far-end crosstalk, and impulse noise power. These are parameters which, due to the nature of the medium, can only be described statistically. On the basis of very limited tests, the range in which these parameters fall is shown in Table I.

From an assessment of this data, it follows that an exchange carrier system must have the following principal characteristics:

1. Economical application on line lengths between 5 and 20 miles, or attenuations in the order of 200 db (decibels) at 500 kc.
2. Repeaters providing for equalization in the low-frequency to 500-kc range of from a few db to a maximum of approximately 16 db.
3. Adequate system regulation for 15- to 18-db variation in 175- to 200-db lines.
4. Transmission quality of a maximum of 20 dba (db adjusted) for all types of noise.

The fourth requirement implies that for a 15-mile system the minimum signal levels would have to stay above −35 dbm (db referred to 1 mw[milliwatt]) (lower, to the extent that the modulation system chosen would have some improvement factor). In addition, the system would have to provide for 15 to 25 db of improvement on far-end crosstalk for about 25% of the pairs and 10 to 20 db of improvement on near-end crosstalk, again for about 25% of the pairs, depending on level differentials between the maximum transmitting power and the minimum receiving power.

In consideration of power and space economies, as well as design obsolescence, it was a foregone conclusion that design would be based on transistors rather than on vacuum tubes.

Choice of Modulation System

One of the obvious answers to many of the transmission problems would have been the choice of a modulation system capable of trading noise for bandwidth, such as pulse code. However, adequate data were not readily available with regard to the peak impulse interference characteristics of exchange cables, nor could such information be gathered fast enough to assure the development of a system in the time prescribed. On the other hand, consideration of the near-end crosstalk and available power-handling capacities of high-frequency transistors indicated that a modulation scheme which was reasonably conservative of spectrum consumption and reasonably efficient with regard to multichannel loading would be desirable. A modulation system which did not require a wide band per channel would permit an interleaved modulation spectrum for near-end crosstalk immunity without going beyond 500 kc of spectrum for the 24 channels. If, in addition, it did not emit a redundant and power-consuming carrier, it would be possible to make efficient use of readily available transistors which offered a peak power-handling capacity of the order of +13 dbm.

At about this time, a development at the ITT Laboratories produced an economical means of detecting double-sideband suppressed-carrier amplitude modulation (a-m). Although it was recognized for many years that double-sideband suppressed-carrier a-m could offer a close approach to the performance characteristics of single-sideband suppressed-carrier a-m in the matters of band conservation and load factors while avoiding the high channel filter costs of single sideband, its use had been hampered by the lack of a means of detection sufficiently economical to warrant its choice over single sideband in consequence of its use of twice the bandwidth and its fourfold greater loading factor. In view of the laboratory development of a detector, it appeared that a modulation system was available to satisfy all but one of the combined requirements of an exchange system, viz., far-end crosstalk on about 40 or 50% of arbitrarily selected pairs. It was decided that the system would be so designed that a compandor or some other type of noise-reducing circuitry could be introduced by the simple substitution of a plug-in panel. In this manner, a system was available which, for 50 to 60% of the arbitrarily chosen pairs, would not require the expense of noise-suppression equipment, while, at the same time, the infrequent incidence of pairs with higher crosstalk would permit simple treatment by the substitution of the vf (voice frequency) panel by an alternate one containing circuitry furnishing the necessary noise suppression. A Sonad* (Speech-Operated Noise-Attenuation Device), providing an additional 14–18-db noise suppression during idle-circuit periods, was developed at the ITT Laboratories and is undergoing extensive tests to determine its application possibilities. For larger improvements, 20–26 db, a syllabic compandor is available.

Table I. Cable Crosstalk Characteristics

	Per Cent of Pairs Whose Characteristics Are Worse Than Value Indicated			
Parameter, 500 Kc	100%	50%	25%	10%
Near-end crosstalk coupling loss, db	95	82	74	68
Far-end crosstalk coupling loss, db/mile	85	63	56	52
Impulse noise, dbm, rms	−100			

The modulation plan and frequency assignment are shown in Fig. 2, from which it is seen that the system is based on an 8-kc spectrum occupancy per channel, with a spacing of 16 kc between channels, allowing 24 channels between 60 and 480 kc. The 16-kc spacing permits interleaving the reverse direction of transmission and thus provides for immunity to near-end crosstalk.

The loading characteristic is shown in Fig. 3 in comparison with single-sideband suppressed carrier. With a 20-db load factor for 24 channels and a transistor-repeater overload capacity of +13 dbm, it was possible to transmit at a level of −8 dbm per channel and handle a better than 25-db span without dropping below the established minimum signal level of −35 dbm.

Regulation was incorporated in the repeaters to provide for a stability of ±1 db for an 8-db line-level variation; and in the channel terminals, for a stability of ±0.5 db for an 8-db variation, resulting in a level stability of ±0.5 db for a 175-db system. Regulation is not affected by the addition of SONAD circuitry. In the case of compandored channels, the stability is 1.0 to 1.5 db under the same line conditions.

Equipment linearity was maintained to hold all types of distortion down to 20 dba for an 8-repeater system.

The system block diagram is shown in Fig. 4.

Signaling

An exchange carrier system must provide a choice of signaling facilities not previously provided as an integral part of carrier systems. Two types of signaling are of principal interest. In their simplest terms these two types require the transmission of the following information:

1. *Loop signaling.* This signaling option requires the transmission of closed-loop open-loop conditions from an originating to a terminating office at a rate of 0- to −14 alternations per second. In the reverse direction, the transmission is that of the condition of the battery, normal or reverse, at a somewhat slower rate.

2. *Revertive signaling.* In this signaling option, the originating-to-terminating office transmission consists of loop-open loop-closed conditions at up to an equivalent of 36 alternations per second and, in the reverse direction, all states of the loop battery; viz., on, off, reverse, or normal.

The familiar E and M (electric and magnetic) signaling facilities normally offered by carrier systems must be augmented by a 4-wire to 2-wire, or a 4-wire to 3-wire converter, to provide loop signaling. The third wire in the 3-wire option furnishes supervisory information normally provided by the outgoing trunk circuit and, when used, eliminates the need for this appliqué panel. In the case of the revertive system, a facility capable of transmitting one-half bit more information from the terminating office to the originating office is necessitated, a requirement of one-half bit more than

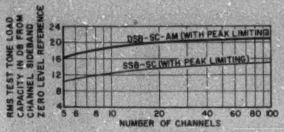

Fig. 3. Comparison of load factors, DSB-SC versus SSB-SC

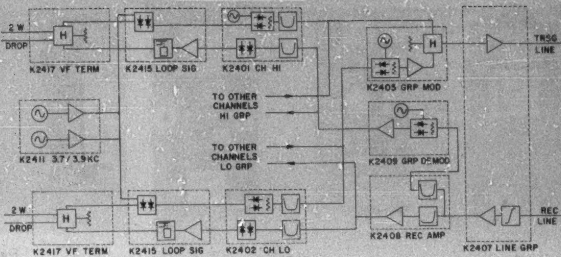

Fig. 4. K24A terminal

E and M or loop-signaling systems are capable of handling. Despite the fact, therefore, that a double-sideband suppressed-carrier a-m system offers an economical one-bit transmission system in the availability of the carrier for control-information transmission purposes, the need for providing for revertive signaling led to the choice of frequency-shift signaling, which is capable of two bits of information transmission by offering the alternatives of sending either one of the two frequencies, both, or none at all. Moreover, it yields a vehicle for channel regulation.

The resulting signaling facility is thus, in fact, an excellent telemeter channel, capable of handling up to 30 bits per second with pulse distortion less than 5%.

Mechanical Aspects of K24 System

In a search for the simplest and most flexible mechanical formula, a computer-type system was evolved, as shown in Fig. 5. The system features printed-circuit wiring, "banjo"-type rack wiring and plug-in, "bookshelf" construction. As indicated earlier, a channel is broken up to permit the easy assembly of a system for any application; signaling cards can be readily substituted to provide E and M, loop, or revertive signaling without disrupting or realigning the remainder of the system. Similarly, the vf term panel can be readily substituted to provide 2-wire, 4-wire, compandor, or SONAD facilities, etc.

SUMMARY OF SYSTEM PARAMETERS

Following is a summary of the *K24* system parameters:

Number of channels, 24
Frequency spectrum, 60 to 480 kc
Transmit levels per channel sideband, −8 dbm
Receive levels per channel sideband, −33 dbm
24-channel load factor, 20 db
Repeater maximum power capacity, +13 dbm

Span: attenuation, 25 db maximum
slope, 18 db maximum
System regulation, ±0.5 db
Channel equivalent, 0 or −3 db
Terminal noise, 20 dba at the zero level (maximum all types)
System noise, 25 dba maximum for 175 db
Signaling, E and M, loop, or revertive
Compandors, optional
SONAD, optional
Size, 31.5 inches of rack space per 24-channel terminal
Power consumption, approximately 100 watts at 48 volts per 24-channel terminal
Repeaters, power consumption 50 mils at 30 volts; optional, regulated or non-regulated
Alarms, power failure, common equipment failure, and system failure

Part II: Equipment Considerations

The *K24A* Syncroplex Telephone Carrier System is a 24-channel multiplex equipment based on double-sideband suppressed-carrier modulation, in which a base group of 12-channel modulators (transmitters) operates at carrier frequencies between 292 and 476 kc and a corresponding base group of 12-channel demodulators (receivers) operates between 68 and 252 kc. Each channel occupies 8 kc of spectrum; thus adjacent channel spacing can be as close as 8 kc. In the case of the *K24A* system, which is arranged for exchange cable applications, the spacing is 16 kc to permit interleaving of the two directions of transmission and to prevent crosstalk as explained in Part I.

To close the transmission path between the 12-channel modulator group and the 12-channel demodulator group, it is thus necessary to translate (group-modulate, or demodulate) once.

For an appreciation of the equipment design, the *K24A* system can be divided into four parts; namely:

1. *Channel terminal equipment.* This group, shown in Fig. 6, consists of the modem unit necessary to derive the channel signal from the multichannel spectrum, the signaling unit necessary to accommodate the transmission of various systems of switching information, and the terminating unit necessary to provide 4-wire to 2-wire conversion for the signaling circuit, as well as other functions such as vf companding, signal limiting, etc.

A great variety of arrangements of chan-

Table II. Functional Description of K24 Units

Group	Unit	Option	Function	Type No
I. Channel terminal equipment	Channel modem	Master	Channel transmitter and receiver including crystal controlled carrier supply for two transmitters	K2401
		Slave	Like K2401, except without carrier oscillator	K2402
	Signaling unit	E and M	Frequency-shift transmitter and receiver discriminator, including signaling tone pick-off filter, agc rectifier, and relay	K2419
		Loop, 2-wire	Like K2419 except arranged to operate from and into a-b leads of vf term set. Provided in originating and term office versions	K2415–16
		Loop, 3-wire	Like K2415–16 except control lead added at originating office to eliminate need for outgoing pulse repeaters in step-by-step offices	K2425–26
		Revertive	Like K2415–16 except equipped to provide channel for revertive pulse transmission	K2403–04
	Vf term unit	2- to 4-wire term set	2- to 4-wire vf hybrid, a-b lead connections, vf limiter	K2417
		2- to 4-wire term set and Sonad	Like K2417 except Sonad added	K2418
		2- to 4-wire term set and compandor	Like K2417 except compandor added	K2428
II. Terminal common equipment	Group modulator		Translates 12 high group transmit channels to low group spectrum, combines both groups, generates pilot tone	K2405
	Group receiving amplifier		Separates high group from low group, amplifies low group for channel detection	K2408
	Group demodulator		Translates 12 high group received channels to low group spectrum and amplifies the group for channel detection	K2409
	Line amplifier		Amplifies channel to line level for transmission, provides span adjustment, equalization and amplification for received signals. Includes facilities for connecting repeater power	K2407
III. Terminal auxiliary equipment	Signal supply		Low-impedance power source of 3.7-kc and 3.9-kc tones for 24 signaling units	K2411
	Fuse and alarm panel		Contains fuses, power-supply failure alarm, pilot failure alarm, common equipment and channel failure alarm	K2406
	Power supply regulator		Converts −48 volt close-open supply to −30-volt regulated supply	K2412
IV. Repeater equipment	Repeater	Regulator repeater	25-db span amplifier including span pads and equalizers	K2414
		Nonregulator repeater	Like K2414 but without regulating circuit	K2413
V. Terminal shelf			Accommodates the 79 panels composing a 24-channel terminal, terminal strip, and repeater supply current control	K2410
VI. Test, line-up and maintenance equipment	Alignment set		Facilities for testing repeaters and line sections for span length adjustment, equalization, and trouble shooting	K2480
	Unit-extension test sets		Facilities for extending units out of shelf and making test measurements	K2481–3

nel terminal is possible through the appropriate choice of signaling and vf terminating units, thus yielding excellent flexibility for many system applications.

2. *Group equipment.* The set of units shown in Fig. 7 is comprised of the 12-channel group-frequency translating equipment and a 24-channel line amplifier.

3. *Auxiliary equipment.* This group includes the terminal-voltage regulator, the fuse-and-alarm unit, and the 24-channel signaling-tone supply.

4. *Line equipment.* For operation over exchange cables, there are provided repeaters of both regulating and nonregulating types, equipped with span pads and equalizers.

For ease of reference, the entire complement of units and their functional descriptions are summarized in Table II.

Circuits

The *K24A* system uses transistors throughout the equipment. This represents one of the first large-scale applications of transistors to carrier telephony up to 1/2 mc of carrier spectrum. Many stringent performance requirements, which are probably more peculiar to multichannel telephony than to other areas of communication, have to be met. Accordingly, several basic circuits were developed and were used in a variety of functional units. The principle of these units will be described now and later referred to in the description of units in which they occur.

AMPLIFIER, 32 DB[2–4]

This is a 3-stage 60–480-kc wide-band amplifier with an average of 25 db of feedback in the specified range of application. An interesting aspect of this unit is that the transistors used in it exhibit a mean beta cutoff of 250 kc, whereas the amount of feedback necessary to achieve linearity required a controlled feedback characteristic to beyond 4 mc.

A simplified schematic of this amplifier is shown in Fig. 8. It consists of three common emitter stages in cascade. The design was accomplished by successive *R-C* compensation of each of the three stages in such a way as to maintain a 30-degree phase margin to beyond the point of unit gain in the feedback loop. The output impedance is bridge stabilized, and the input impedance is stabilized by means of passive resistance. The result is an over-all impedance stability of better than 5% across its operating band.

The feedback and unfeedback gain characteristics of the amplifier are shown in Fig. 9(A), its load characteristic in Fig. 9(B), and its linearity characteristic in Fig. 9(C).

The amplifier is the basic circuit in the regulating and nonregulating repeaters, the transmit section of the line amplifier, and the group demodulator.

AMPLIFIER, 15-DB

Except for gain, the characteristics of this amplifier, insofar as linearity, feedback, and load-handling capacity are concerned, are the same as those of the 32-db amplifier. The lower gain required permits the use of two stages, a common base and a common emitter, in cascade. The amplifier is impedance stabilized with bridge feedback at both the output and the input.

CRYSTAL-CONTROLLED CARRIER-SUPPLY OSCILLATOR

The requirement for stable medium-power constant-voltage source of carrier supply exists in many units of the system, e.g., channel modulators, group modulators and demodulators, pilot generators, etc.

The circuit chosen was that of a modified Colpitts[5] (commonly referred to as the Clapp or Gouriet) oscillator, d-c coupled to a boot-strap amplifier. A simplified circuit is shown in Fig. 10.

The use of a boot-strap buffer provides a device with a very high impedance load for the crystal oscillator, a very low output impedance which permits driving multiple loads with extremely low coupling, and good power gain and overload characteristics. The resultant carrier supply is capable of 20–24 mw of output power from a source impedance of a few ohms.

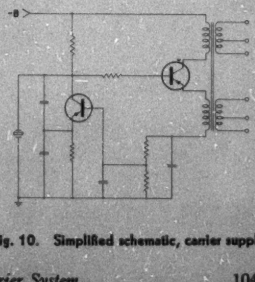

Fig. 10. Simplified schematic, carrier supply

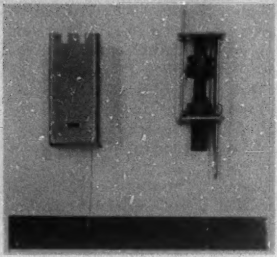

Fig. 11. K24A channel transmit filter

L-C Oscillator

Due to the cost or size of low-frequency crystals, or the inflexibility of crystal oscillators, a stable *L-C* circuit is desired in units such as the signaling-tone supply and the local oscillator source in the channel modem. For these applications, a tuned collector-emitter feedback circuit was designed. The oscillator operates at frequencies of 3.7 to 252 kc and, without the aid of a buffer, provides over 25 mw of power with a frequency stability of better than 0.1% over a temperature range of 0–60 C (degrees centigrade).

Filters

Considerations of economy in filtering are all-important in carrier equipment design, particularly at the channel-modem level where they are numerous. The structure used in the *K24A* system is that of an intermediate-frequency-type filter in which universal coil construction and adjustable leakage coupling are used to achieve the elements of a mesh. Fig. 11 shows the transmit filter, and Figs. 12(A) and (B) are typical insertion-loss curves of the transmit and receiver filters.

The simplicity of the receive filters results in low selectivity, but this can be tolerated because both the adjacent channels are demodulated out-of-band with synchronous detection; in single sideband, with normal channel spacing, one of the adjacent channels will be demodulated in-band. With emitted-carrier double-sideband and envelope detection, all channels are demodulated in-band.

Units of K24A System

The functions of the various units constituting a *K24* terminal, briefly described in Table II, are further described in the block diagram of Figs. 13(A) and (B).

Units of particular interest will be detailed in the following paragraphs.

Channel Modem

The carrier oscillator used in the transmit section was described in an earlier section. The remainder of the circuit consists of two passive elements, a balanced lattice modulator, and a transmit filter of the type shown in Fig. 11.

The receiver consists of essentially four elements: a variolosser controlled by the level of the received frequency-shift signal in the signaling unit, a carrier amplifier, a local oscillator, and a ring demodulator.

The ability of the receiver to detect double-sideband suppressed-carrier a-m signals is due to a synchronizing circuit which controls the local oscillator. With the synchronizing circuit disabled the unit resembles a conventional nonsynchronous single-sideband demodulator. In the case of the reception of double-sideband suppressed-carrier a-m signals, the synchronizing circuit detects the zero crossings of the double-sideband channel signal. These occur at twice the suppressed-carrier rate, with perturbation at a rate equal to twice the modulating frequency. The local oscillator is designed to synchronize at alternate impulses provided by the synchronizer and to ignore the perturbing impulses due to modulation. The result is a local oscillator source, synchronized rigidly in both frequency and phase, which therefore makes possible coherent detection of the double-sideband suppressed-carrier signal with fidelity.

The receive section of a channel modem is thus a fixed-frequency receiver which with an appropriate transmitter can, in principle, detect double-sideband emitted-carrier a-m, double-sideband suppressed-carrier a-m, or single sideband. To the extent that a carrier is present in the received double-sideband signal, it is detected as direct current and can be used for control purposes.

The excellent phase linearity of the modem can be judged from Fig. 14, which displays the response of the modem to square-wave excitation at various frequencies.

As noted earlier, the transmitter and receiver, on a common modem card, operate in two separate bands of frequencies. A number of considerations led to this arrangement. High-frequency operation of transmitters permits an economical crystal oscillator design. On the other hand, the receiver is better operated at low frequencies due to improved performance of transistors. In addition, of course, the wide separation of frequencies obviates any coupling problems between transmitter and receiver on a single card.

SIGNALING UNIT

There are a number of systems of transmission of switching information between exchanges. The simplest, and perhaps most common, is E and M, which is essentially the provision of a 4-wire low-speed data-transmission channel in conjunction with the voice circuit. Two other systems are usually referred to as "loop" and "revertive." In loop signaling, the the 4-wire E-and-M data circuit is converted to 2-wire operation over the loop used for voice transmission. An optional version provides supervisory information on a third control wire, eliminating the trunk circuit normally required. In revertive signaling applications, the functions of loop signaling are augmented by a third supervisory function. Space does not permit a detailed description of these systems.

In order to satisfy the functional requirements of these three systems of signaling transmission, three options of signaling unit are available as shown in Table II.

The need for transmission of more than one bit of information in the case of revertive signaling influenced the choice of frequency-shift modulation for the signaling channel, in that three states are possible: one or the other of the two frequencies, or, for short duration, both.

Transmission of a frequency-shift signal is accomplished by the provision of two tones to all 24 channels from a common supply. The tones are at 3.7 and 3.9 kc, just above the voice band. The "shift" is achieved in the signaling transmitter by means of a diode switch designed to fade-in and fade-out the alternate frequencies and thus hold fortuitous switching distortion to acceptable limits. The signaling receiver is a conventional Round-Travis discriminator which serves the dual purpose of driving a signaling relay and an agc (automatic gain control) rectifier.

Three steps of signaling distortion adjustment are provided to compensate for varying external plant conditions.

VF TERMINATING UNIT

This unit contains as its main element a transformer bridge, or hybrid, which serves to convert the 4-wire voice circuit provided by the modem to a 2-wire circuit capable of connecting with the exchange loop. It similarly permits the conversion of the 4-wire facility of the signaling unit into loop signaling.

The SONAD has been designed so that it may be added to the basic vf terminal card at any time. An optional version of the vf terminating unit contains a compandor, thus permitting the application of the system to exceptionally noisy transmission media.

Fig. 15 indicates the channel-response characteristics. It is largely influenced at the lower end of the vf spectrum by the characteristics of the terminating unit and, at the upper end, by the signaling-tone reject filters in the signaling unit.

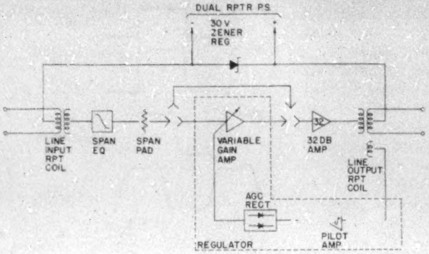

Fig. 16. Regulating and nonregulating repeater

REPEATERS

The main element of the repeater is its 32-db amplifier, described earlier. The regulating repeater shown in block form in Fig. 16 contains an additional circuit. This circuit consists of a frequency-selective amplifier which picks off a pilot located midway between the spectra occupied by two 12-channel groups, a rectifier, and a variable gain stage. Gain variation is achieved by thermistor action in the collector-to-base feedback loop of a single-stage amplifier. The stage is a "reflex" circuit in that it serves both as a wide-band multichannel signal amplifier and as an amplifier of direct current for the control of its thermistor feedback circuit.

The repeater also accommodates, as plug-in elements, a span pad and a span equalizer. Power is obtained from a constant-current 60-ma (milliampere) source which is series-fed around the phantom circuit formed by the east and west pairs of a system.

Part III: Applications and Maintenance

At the outset of the development of the *K24* system, it was determined that the success of a 5- to 15-mile short-haul carrier would be very dependent on the simplification of application, installation, lineup, and maintenance techniques to a degree not previously attained in the common carrier field. How the system meets these objectives is discussed here, the equipment approach to the system having been outlined in Part II.

The high density of circuits used in the exchange area of telephone plant, together with the obvious impracticability of having adequate staffs of skilled personnel available for its installation, adjustment, and maintenance, dictated the necessity of eliminating measurements and calculations normally associated with a carrier installation. The end product is a system which incorporates one continuously adjustable control per channel for the purpose of accurately setting up the circuit equivalent. In the remainder of the system, adjustments are provided on a group basis in discrete steps. These adjustments relate to span pads and equalizers at the input to both the repeaters and the receiving amplifier of the terminals.

System Description

The *K24A* system provides up to 24 circuits on two cable pairs between offices where the attenuation of these trunks does not exceed approximately 200 db at 480 kc. This is a distance varying between 10 and 20 miles, depending on the gage and capacity of the cable pairs involved. The frequency modulation plan of the system is shown in Fig. 2.

The line frequencies for the channels of a terminal are on 16-kc centers. Each channel occupies 8 kc of spectrum, i.e., 4-kc upper and lower sidebands. The line frequencies for the channels at the opposite terminal are also on 16-kc centers, but all frequencies are shifted 8 kc above those for the first terminal. Since each channel occupies 8 kc of spectrum, there is no overlapping of frequencies when considering the two directions of transmission. This "staggering" of frequencies for opposite directions of transmission eliminates near-end crosstalk problems and simplifies filter requirements.

The lowest channel-carrier frequency in the top 12-channel group is 292 kc, and the highest channel-carrier frequency is 476 kc.

The line frequencies of the high group were chosen to permit operation of 12-channel systems in the same cable sheath with Western Electric Company *N-1* carrier systems.

The system terminal is designed to mount in $31^1/_2$ inches of vertical space on 19-inch relay racks. Four system terminals will mount in one 11-foot, 6-inch bay.

The system is completely transistorized with unit plug-in module-type construction employed in both terminal and repeater equipment. Printed-circuit wiring techniques are used on all plug-in cards. Printed wiring connectors on the ends of each card mate with multicontact plugs mounted on the terminal shelves. The boards are guided into position by grooves in the shelves.

Handles on each plug-in unit assure easy withdrawal of the board from the shelf. There are seven shelves in a terminal, the top shelf housing the common equipment and the remaining six shelves, the 24-channel terminals. The circuitry for each channel is divided into three cards, viz., modem, signaling, and vf term. Three shelves mount 12 channels, with the three cards of any one channel appearing vertically in the terminal.

A separate card is used for each of the three available signaling options, i.e., loop, E and M, and revertive.

Compandors and SONADS are available on an optional basis and, when furnished, are included on the vf terminal cards. A SONAD may be added to a channel at any time by plugging the subassembly into the vf term card of the channel. Circuit interconnections are made by means of a multipin plug-and-socket arrangement. Compandors may also be added to a channel at any time, merely by changing the vf terminal card; no wiring or strapping procedures are required to implement the change.

A static 48- to 130-volt d-c to d-c converter completes the equipment available at terminal locations. Appliqué auxiliary line equipment such as filters, terminations, matching transformers, etc., normally associated with carrier applications, are not required when using this equipment. For instance, when the loop signaling option is used, step-by-step equipment, or the outgoing trunk circuit (depending on whether the 3-wire or the 2-wire loop signaling unit is to be used), connects directly into the drops

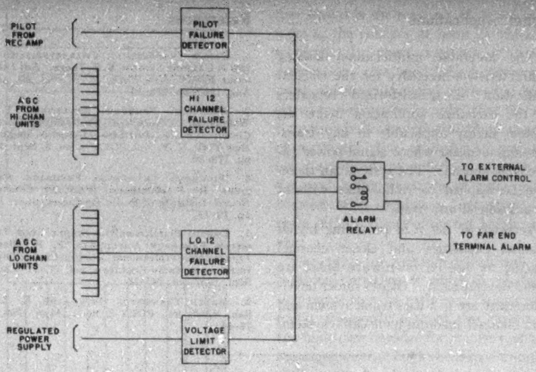

Fig. 17. K24A terminal alarm

of one terminal, and the opposite terminal drops are connected directly into the incoming selector equipment.

Regulating and nonregulating repeaters are used with this system. Both types of repeaters furnish a normal 25 db of gain at the highest line frequency of 480 kc. The regulating repeaters compensate for line variations of ±8 db. Every third repeater in a system should be of the regulating type. Repeaters are installed at the same point for both directions of transmission, regardless of the type required. Repeaters are power-fed over the same pairs on which they are installed, and up to five, in tandem, may be fed from each end. A system may use up to ten repeaters, therefore, without requiring an intermediate power source.

System Engineering

A minimum of engineering is required to install this system. At terminals, it is only necessary to specify the number of channels and the type of signaling option desired. The number and type of repeaters are determined by referring to Table III. It will be noted repeaters are normally located at 6,000-foot (*H*-loading) intervals, or multiples thereof, depending upon the gage and capacity of the cable pairs involved.

If vf-loaded pairs have to be unloaded for an initial installation of this carrier system, it is possible to effect a considerable economy in the cable-splicing operations involved. This is accomplished by unloading more than the number of pairs required for initial installation. These extra pairs are then reloaded by mounting the loading coils on plug-in cards designed to fit in the repeater housings. Additional systems are then added merely by replacing the loadging-coil cards with repeaters.

Installation and Alignment

REPEATERS

A repeater-alignment test set is the only instrument required when aligning or checking the performance of a repeater. Operating power for this set is derived from the cable pair under test. When installing repeaters, the instrument is calibrated so as to easily indicate the appropriate span pad and equalizer to be used. No other adjustments or measurement are required for installing either regulating or nonregulating types of repeaters.

TERMINALS

Alignment of the terminals consists essentially of selecting the appropriate equalizer and span pad and adjusting the circuit equivalents. The alignment test set is used at the terminal to select the pads required in a fashion similar to that used at the repeaters.

Extension units provide access to units permitting measurements on both a bridging and a terminating basis.

SIGNALING

An infrequently required, but nevertheless available, step adjustment is the one for pulse distortion. By a solder-strap change provided, bias may be varied ±10% from the nominal setting.

ALARM SYSTEM

The design of the alarm system aimed at three objectives: 1. protection of the equipment from damage due to abnormal power-supply occurrences, 2. prevention of seizure of the exchange facility in the event of equipment failure, and 3. indications which would pinpoint as unambiguously as possible the source of the trouble.

The alarm system is shown in block form in Fig. 17.

A predetermined change in the voltage of either the exchange battery or the output of the power-supply regulator actuates a relay and shuts down the terminal.

The relay may also be actuated by the failure of the system pilot or the failure of agc loops in all of either the lower group of 12 channels, the upper group of 12 channels, or all 24 channels.

Measurements at the test jacks associated with the alarm system allow the trouble shooter to isolate the failure in one of the following areas:

1. Power supply.
2. Line transmission facility, including the line amplifier in the terminal, the repeaters, or the line itself. A further degree of identification of the offending unit requires the use of the alignment test set.
3. Group modulators, demodulators, and signal supply.

Protection of the exchange from tie-up due to system failure is achieved by the inherent operating characteristics of the system. The signaling conditions corresponding to channel failure are those of either battery-normal or no-battery at the originating office and loop-open at the terminating office. This assures that in the case of failure the exchange equipment and subscribers are released.

TROUBLE SHOOTING AND MAINTENANCE

Virtually complete trouble shooting can be accomplished by means of measurements made through the unit extension panels, or by the use of the alignment test set. Test points, per se, have been eliminated from the units of this equipment in the interests of economy. However, the extension panels furnish even more complete access to each unit than that normally provided by test points.

The alignment test set described earlier is equipped, of course, to provide all of the pertinent information necessary to indicate the performance of any repeater.

POWER SUPPLY

The *K24A* system operates from 30 volts direct current. The supply is derived from the 48-volt exchange battery at the terminal locations through a power regulator. The average total consumption of a 24-channel terminal is approximately 100 watts at 48 volts.

The repeater requirement is 30 volts at 55 mils. Repeaters are supplied in series, and the individual supply is Zener regulated. Accordingly, a 5-repeater system requires a source supply of 150 volts plus the voltage drop of the cable pair. Thus, for a 1-repeater system, the 48-volt exchange battery is an adequate supply. For two repeaters or more, the 48-volt and 130-volt exchange supplies must be put in series. When the 130-volt battery is not available in an exchange, the 48- to 130-volt d-c converter may be used.

Other Applications

The favorable multichannel loading characteristics necessary for the efficient utilization of transistorized repeaters in the exchange application make the system highly applicable to any transmission medium where signal-power capacity is limited. The system can therefore be applied to radio links without adaptation of any kind.

Versions of the *K24* providing higher channel capacities and closer channel spacing for use on microwave links, are under development. Others under development are a 4-wire trunk system and a 12-channel medium-haul cable system.

Discussion

Arthur F. Rose (New York, N. Y.): As the authors point out, the use of carrier for providing intercity toll circuits is an old story and over the years development engineers have had as an objective a continuous reduction in cost. This has resulted generally in cheaper and better toll service. However, up to the present time the cost reductions have not been sufficient for carrier applications in the local plant to appear economically attractive. Also there has been some reluctance to introduce new techniques to the local plant people who are relatively unskilled in the electronic arts, unless the savings appeared likely to be substantial.

The new Kellogg Switchboard and Supply Company *K24* carrier system described in this paper is so low in cost that it should extend the economic range of carrier to distances well below 10 miles. In addition, the equipment itself, the installation, and maintenance procedures, are all so simple that the plant forces should accept it as merely another tool for providing telephone circuits in the short-haul range. Several installations have been in service for many weeks and the maintenance attention required has been very small.

This new system should be of great help to the telephone companies' planning engineers who are faced with the increasing tempo of telephone usage which was not anticipated a few years back. In some cases costly conduit reinforcement can be avoided and in others the uncertainties of the future can be handled without major investment until the trends have been clarified. Changes in rate structures, involving increases in extended area service, and the consequent large increase in trunk requirements can be cared for more quickly, and frequently more cheaply, by this new type of carrier than by other forms of construction.

The telephone industry should welcome this new facility and the engineers who developed it should be congratulated on their major contribution to the communication art.

Asynchronous Multiplexing

J. E. TAYLOR
NONMEMBER AIEE

THIS PAPER will consider theoretical limitations and capabilities of general types of asynchronous multiplexing systems for networks of the type shown in Fig. 1. The kth station of the ith channel of the network is S_{ik}. All stations belonging to a channel are in communication with each other. The purpose of the multiplexing system is to provide this communication when stations of all channels use a common transmission medium in which signals and noise mix additively. Fig. 1 adequately describes a mobile communication system, for instance, in which the individual communication paths vary widely in direction and length.

An asynchronous multiplexing system multiplexes the individual transmissions in a way which does not require synchronization between channels. Frequency division multiplex is a well-known asynchronous system and is considered here only as a comparison standard; other systems which operate asynchronously are to be discussed.

The exclusion of frequency division coupled with requirements of no synchronization and finite time duration waveforms implies the channels will transmit nonorthogonal signals.

A pair of nonorthogonal signals are such that the energy contained in one is not completely separable from that contained in the other. This is equivalent to the mathematic statement that the inner product of the two signal functions is nonzero. If orthogonality were to be maintained for all possible time shifts between two signals, then their spectral density distributions can have no common frequency components. Similarly here, channels which are defined by the multiplexing process in a manner such that

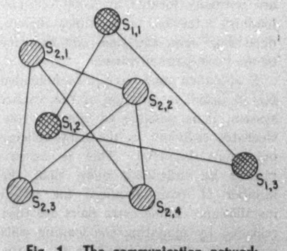

Fig. 1. The communication network

Paper 59-1146, recommended by the AIEE Communication Theory Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted January 22, 1959; made available for printing July 31, 1959.

J. E. Taylor is with the General Electric Company, Schenectady, N. Y.

The author wishes to acknowledge indebtedness to L. G. Abraham and C. A. Stutt for interesting discussions, and to R. L. Shuey, whose unfailing interest in asynchronous multiplexing stimulated most of the research reported here. The figures were prepared by J. A. Segit.

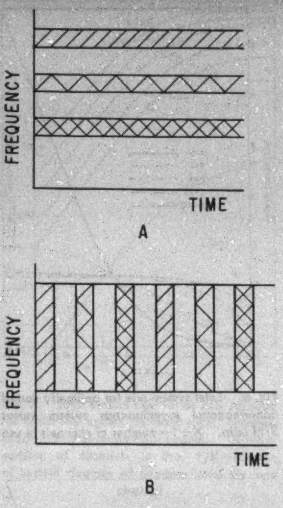

Fig. 2. Orthogonal multiplexing systems

A—Frequency division
B—Synchronous time division

signal energy in one does not get into another will also be called orthogonal. Examples of orthogonal and nonorthogonal channels are shown schematically in Figs. 2 and 3. In Fig. 2, orthogonal channels are defined by systems of frequency division and by synchronous time division, while Fig. 3 shows nonorthogonal channels which are specified by, in Fig. 3(A), a unique time period between a signal and its repetition and, in Fig. 3(B), a unique pulse repetition-frequency.

Since every reception process exhibits a threshold feature, in that a decision must be made as to what has been transmitted, it should be understood that the requirement of a communication system is to ensure almost orthogonal signals only at the place in the system where the decision must be made. Thus, in the model of a communication system shown in Fig. 4, the distinction between modulation coding and multiplex coding is made. This distinction is quite arbitrary and in some cases is difficult to make. Modulation coding determines the form in which intelligence is added to a signal, e.g., amplitude modulation. Multiplex coding is the process by which channels are separated from each other. In most communication systems the modulation coder is specified, but the input waveform is determined exclusively by the user, and it is the recovery of that waveform at the receiver at point *D* which is required. In most systems of communication, this modulating waveform must be transmitted and received at high signal-to-noise ratio in order that the information be recovered with a high degree of accuracy. For example, in systems using amplitude modulation, recovery of the modulating waveform at high signal-to-noise ratio requires a high signal-to-noise ratio in the transmitted bandwidth also.

The types of systems which will be considered are those in which the modulation signal-to-noise ratio may be assumed to be sufficiently high at the output of the multiplex decoder for recovery of the messages, even though the signal-to-noise ratio in the transmitted time frequency region is low; and this must remain true even when several asynchronous channels are operating in the network.

Asynchronous multiplexing systems, then, are of interest insofar as they are capable of solving this communication problem efficiently, while at the same time providing certain other advantages. Two facts indicate that interesting possibilities do exist. One is the fact that coding schemes exist for error correcting and other forms of interference rejection, which may be viewed as restoring orthogonality at the output of a nonorthogonal system. The second is that many communication networks of the type diagrammed in Fig. 1 are such that very few of the stations of the network transmit during any given interval of time. Thus we may be able to design systems which will provide random access to the communication medium for any assigned station at any time, and maintain efficient communication with tolerable interference only if less than a certain number of the stations will be in use at any one instant. The interference becomes intolerable when the number of stations in use exceeds this critical number.

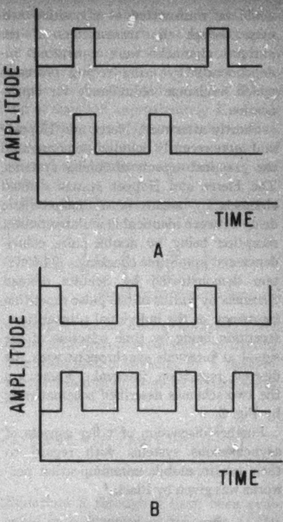

Fig. 3. Nonorthogonal multiplexing systems. Demultiplexing by

A—Spacing of repeated sample points (Pierce & Hopper[3])
B—Pulse carrier repetition rate

The purpose of this report is to summarize present knowledge of asynchronous multiplexing systems, the methods of analyzing them, to evaluate that knowledge, and to point out the most important problem areas remaining.

Survey of Early Literature

In 1950, White[1] gave a theoretical discussion of the transmission of information by a group of nonsynchronous pulse-type communication channels. His discussion was essentially a feasibility study of asynchronous multiplexing systems. He showed that some such systems do exist conceptually at least; that information

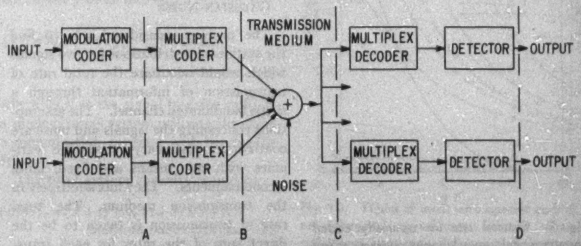

Fig. 4. General asynchronous multiplexing system

could be transmitted at a positive rate even though the transmitters of the various channels were operating independently by using coding processes which exchange redundancy for equivocation.

Shortly afterward, Pierce and Hopper[2] and more recently Schultz[3] demonstrated the practical aspects of similar systems. The Pierce and Hopper system defined channels by means of a characteristic delay between identical modulated pulses, reception being by double-pulse coincidence and amplitude checking. The system demonstrated by Schultz defined channels by means of the pulse repetition frequency of the individual transmitters, reception being by time selection of the signal at intervals synchronous with the desired repetition interval. These are the two schemes described schematically by Fig. 3.

Further discussion of other aspects of asynchronous systems with regard to their use in mobile communication networks was given by Black.[4]

Description and Evaluation of Theoretical Approaches

INFORMATION THEORY APPROACHES TO A STUDY OF ASYNCHRONOUS MULTIPLEXING SYSTEMS

There are two general areas in which the methods of information theory[5] apply to a study of asynchronous multiplexing systems. One of these concerns the synthesis of the best asynchronous system. It requires specification of the channel in terms of the statistics of the noise and certain other properties of the signals, such as their power limitations. Calculus of variations and other suitable methods of analysis are used to find the statistical distributions of the signal variables which provide optimum performance and a measure of this optimum performance in terms of rate of transmission. The details of a specific coding procedure, however, would not be given by such a study.

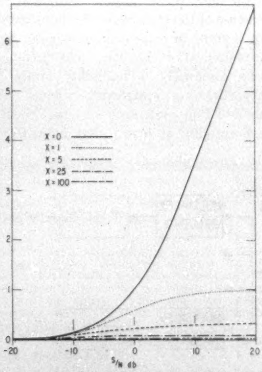

Fig. 5. Channel rate for optimally coded nonorthogonal asynchronous system versus S/N ratio. X+1 = number of channels in use

The other area concerns the use of information theory methods in the analysis of specific systems. Here, knowledge of the statistical properties of the actual signals and the noise or interference is required. The capacity of the system is then calculated in terms of source entropy and equivocation. Such a study will give the theoretical limitations of any similar system using codes which have the same statistical properties.

CODING THEORY APPROACH

A coding theory analysis can be made only if certain assumptions are made. A specific coding scheme must be chosen for which the coding theory is known, and the necessary properties of the communication system, in terms of the signals, noise, and interference must be such that the coding theory is applicable.

The coding theory study can then provide either an analysis of a specific system, or when carried out in terms of variable parameters, a synthesis procedure for the best system. It will also provide answers to the access questions; that is, how many stations can be assigned to the network, and how many can use the system simultaneously. The complexity of practical systems can be estimated in terms of what equipment will be necessary to perform the coding. The coding theory analysis will apply to practical systems only insofar as the assumptions do.

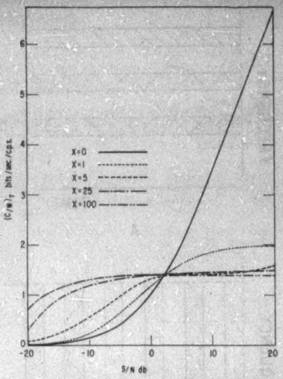

Fig. 6. Total system rate for optimally coded nonorthogonal asynchronous system versus S/N ratio. X+1 = number of channels in use

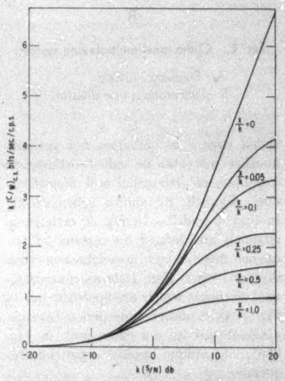

Fig. 7. Channel rate for optimally coded, nonorthogonal, channel-synchronized asynchronous system versus (KS/N) ratio. X+1 = number of channels in use. 1/K = fraction of channel

Applications of Information Theory

THE OPTIMUM STATISTICS FOR TWO CONTINUOUS SIGNALS IN ADDITIVE GAUSSIAN NOISE

The problem considered was to find the statistical distributions for two signals which would maximize the total rate of transmission of information through a single bandlimited channel. The assumptions concerning the signals and noise are continuous, stationary, stochastic variables with zero means and fixed, finite second moments. They mix additively in the transmission medium. The total rate of transmission is taken to be the direct sum of the rates for each transmitter, where one transmitted variable, say x, encounters a "noise" equal to the sum of the actual noise, n, and the other transmitted variable, y.

Maximization of the total rate is accomplished by applying calculus of variations methods. The condition necessary for a stationary rate is given by the solution of the Euler equations which are found to be nonlinear integral equations for which no general solution is known.

By direct substitution one can show that Gaussian distributions for the signals solve the Euler equations, giving a stationary rate equal to

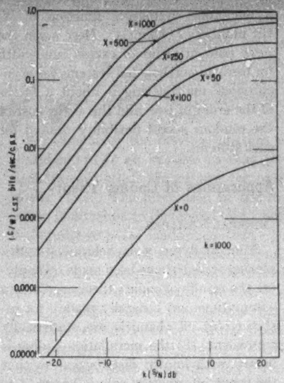

Fig. 8. Total system rate versus K(S/N) ratio for optimally coded nonorthogonal, channel-synchonized asynchronous system. X+1 = number of channels in use. 1/K = fraction of system degrees of freedom used by one channel

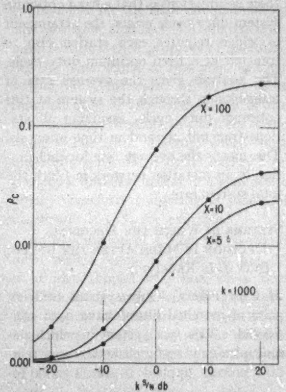

Fig. 9. Figure of merit ratio, channel synchronized versus optimal coded, nonorthogonal asynchronous system. X+1 = number of channels in use. 1/K = fraction of system degrees of freedom used by one channel

$$R/W=\log_2\left(1+\frac{S_x}{S_y+N}\right)\left(1+\frac{S_y}{S_x+N}\right)$$
bits/sec/cps (cycles per second) (1)

where S_x, S_y, and N are the second moments of the distributions of the variables x, y, and n, and W is the bandwidth of the channel. It has not been possible so far to determine the nature of this stationary rate, whether it is a relative maximum or minimum, or the sufficient conditions for it to be a maximum.

Bounds on the Performance of Asynchronous Systems

R. L. Shuey of the General Electric Company has made a study of the maximum rate at which information can be transmitted through a bandlimited transmission medium under the assumption that the coding is such as to make the interference in one channel a result of the signals of all other channels look like white bandlimited Gaussian noise. It might be expected that this requirement would be met easily when a large number of channels are in use when the central limit theorem can be made to apply. However, it is of more interest to consider the consequence of the assumption in the absence of that limit. The consequences are that each signal must be a Gaussian distributed variable[6] and the Shannon-Tuller law[5] must hold. This study avoids the question of the validity of the Shannon-Tuller law in the absence of synchronization. Its results are, however, probably valid bounds for infinite length messages.

Two further assumptions were made which make a more or less natural division between hypothetical coding systems for the purposes of analysis. One is that the various channels of the system are all sensitive to the same general regions of frequency time space, and the other is that each channel is sensitive to only a fraction of the total region of frequency time space accessible to and utilized by the system. The first assumption describes what will be called general asynchronous systems, while the second describes systems which will be termed channel-synchronized asynchronous systems.

General asynchronous systems, then, define channels in such a manner that each channel accepts as interference all the signal energy from all others. For a system of $X+1$ identical, independent channels each using signals of power S, the capacity of an individual channel is

$$C/W=\log_2\left(1+\frac{S}{XS+N}\right)\text{ bits/unit bandwidth/sec}\quad(2)$$

where S/N is the signal-to-noise ratio of a single channel system utilizing the same communication medium and bandwidth W.

The total system capacity would be

$$(C/W)_T=(X+1)\log_2(1+S/XS+N)\text{ bits/unit bandwidth/sec}\quad(3)$$

The channel-synchronized asynchronous system, on the other hand, defines channels in a manner such that each occupies, for example, only $1/k$th of the total system degrees of freedom. A channel whose signals are bandlimited to about W cps and of duration approximately T seconds has $2TW$ degrees of freedom or dimensions. The systems of Fig. 3 are examples of channel-synchronized asynchronous systems.

Thus the channel capacity for such a system is

$$(C/W)_{\text{C.S.}}=\frac{1}{k}\log_2\left(1+\frac{kS}{XS+N}\right)\text{ bits/unit bandwidth/sec}\quad(4)$$

since each channel also accepts only $1/k$th of the total system noise and interference. The total system capacity for a channel-synchronized asynchronous system would be

$$(C/W)_{\text{C.S.T.}}=\frac{X+1}{k}\log_2\left(1+\frac{kS}{XS+N}\right)\text{ bits/unit bandwidth/sec}\quad(5)$$

Equations 2 through 5 have been evaluated as a function of the ratio (S/N) and are shown in Figs. 5 through 8. The comparison of these two systems is of interest, and the ratio of total capacities can be written

$$\rho_c=\frac{\left(\frac{C}{W}\right)_{\text{C.S.T.}}}{\left(\frac{C}{W}\right)_T}=\frac{k}{1}\,\frac{\log\left(1+\frac{kS}{XS+N}\right)}{\log\left(1+\frac{S}{XS+N}\right)}\quad(6)$$

$\rho_c<1$ for all X, $k>1$, and is shown in Fig. 9.

Thus ρ_c is a measure of the price paid

GENERAL ASYNCHRONOUS SYSTEM VS. FREQUENCY DIVISION MULTIPLEXING SYSTEM

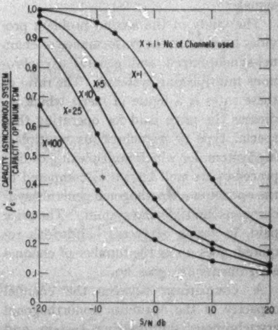

Fig. 10. Figure of merit ratio optimal coded, nonorthogonal asynchronous system versus orthogonal frequency division multiplex system. X+1 = number of channels in use

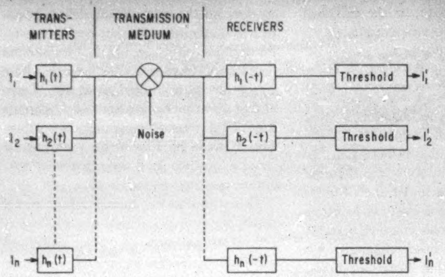

Fig. 11. Matched filter asynchronous multiplexing system

for the use of the channel-synchronized asynchronous system, and can be considered as a figure of merit for them. Systems of this type would, in general, be interesting when the parameters have values in the regions $S/N>10$, $X>10$, $(X/k)(S/N)<1$, say and then ρ_c is of the order of one tenth. The advantage of such a system is that it provides asynchronous channels in which the modulation is recovered at a high signal-to-noise ratio by using known coding methods. The disadvantages of the system lie in the implied requirement of excess bandwidth for transmission at reasonable rates.

Summary Remarks

In the study of the first problem, the methods of analysis lead to unsolved integral equations. The rate can be evaluated, however, in the closed form for the special case of Gaussian distributions, but the question arises: With respect to what statistical distributions is this a maximum? Does an optimum set of statistics exist for any general class of signals?

The study of the second problem provides bounds on the performance of channel-synchronized and general asynchronous multiplexing systems. The ratio of these rates is a figure of merit which indicates the price paid for operating that special type of asynchronous multiplexing system, for which multiplexing coding processes are well known as compared to the optimum nonorthogonal general asynchronous multiplexing system. The price paid, in terms of excess bandwidth required, goes up as the number of channel assignments (k) goes up.

A comparison between the channel capacity of the optimum nonorthogonal asynchronous multiplexing system and that for an optimally coded orthogonal system, utilizing frequency division multiplex, would indicate the price paid for nonorthogonal transmission as well. Thus we compare equation 3 to the channel capacity per unit bandwidth of a system also having $(X+1)$ channels used in frequency division. For optimal coding, the Shannon-Tuller law would hold for the ith channel, whose capacity is

$$C_i=W_i\log_2\left(1+\frac{S_i}{N_oW_i}\right)\text{ bits/sec}$$

where for the comparison, $N_o=N/W$ =noise power per unit bandwidth in the system transmission bandwidth, $W_i=W/X+1$ =bandwidth of the ith channel, $S_i=S$ signal power in each channel. Then the total system capacity when $X+1$ channels of the frequency division multiplexing (FDM) system are used is

$$C_T=W\log_2\left(1+\frac{(X+1)S}{N}\right)\text{ bits/sec}$$

and

$$\frac{C_i}{W_i}=\frac{C_T}{W}=\log_2\left(1+\frac{S(X+1)}{N}\right).\text{ bits/sec/cps}$$

The ratio of capacity of the optimum nonorthogonal asynchronous system to that of the optimum (optimally coded) FDM system is

$$\rho_c'=\frac{(X+1)\log\left(1+\dfrac{S}{XS+N}\right)}{\log\left(1+\dfrac{(X+1)S}{N}\right)} \tag{7}$$

Equation 7 is shown plotted in Fig. 10. A typical range of interest is where S/N is large, say $(S/N)=10$, and with X in the range 10 to 1,000.

Then

$$\rho_c'\rightarrow\frac{1}{4.5}\text{ to }\frac{1}{10}.$$

$$\text{For very large } X,\ \rho_c'\rightarrow\frac{X\log_e\left(1+\dfrac{1}{X}\right)}{\log_e\left(1+\dfrac{XS}{N}\right)}\rightarrow\frac{1}{\log_e\left(1+\dfrac{XS}{N}\right)}$$

a monotone decreasing function of X, the number of channels. Here again the price paid in terms of excess bandwidth for using nonorthogonal systems for asynchronous multiplexing is about a factor of the order of five, and this is the cost of the random access flexibility desired for such systems.

Applications of Coding Theory

General Remarks

Some analyses of asynchronous multiplexing systems have been made by applying the results of coding theory. Certain assumptions are generally made; for instance, (a) all channels are statistically equivalent, (b) the modulation coding is binary with known distribution so that the input information rate is known. It has further been assumed that the multiplex coding involves the restriction to fixed length (time sequences) and/or fixed energy signals. The multiplex coded signals may involve alphabets of two symbols, three symbols, or they may be assumed continuous. A consequence of these assumptions is that a fixed optimum system duty cycle exists, the attainment of which requires each station also to transmit at a fixed optimum duty cycle. The analysis gives the average rate of transmission through the system at this optimum duty cycle, assuming all stations transmit at random time intervals. This means the average rate for each station in an n station network is $1/n$th the total system rate.

Systems in Which the Decoding Decision Is Made After the Entire Signal Is Received

Matched Filters. Only systems utilizing pairs of matched filters[7] have been considered. This is a system in which demultiplexing is accomplished by a correlation process applied to the signals re-

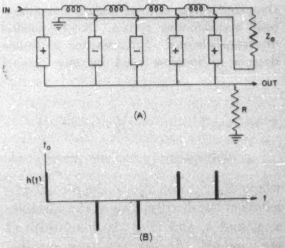

Fig. 12. (A)—Idealized matched filter. (B)—Pulse response

ceived. Fig. 11 shows schematically such a system. The filter used at the transmitter codes binary information into a signal $h(t)$ which is a function of its impulse response and the form of the driving function which is the binary alphabet symbol 1.

For simplicity the driving function is considered to be an impulse so that the signal output $h(t)$ is the impulse response of the filter. The filter used at the receiver is matched to this signal by having its impulse response made equal to $h(-t)$, the time reversal of the desired signal. This use of the matched filter as the stored reference for the correlation process has the advantage that no time synchronization between the receiver and the transmitter is required for the process of correlation to take place, since the filter correlates the received signal continually with the stored reference.

A matched filter performs the optimum operation on a mixture of known signal and additive Gaussian noise in the sense of extracting a maximum amount of information concerning the signal while destroying the irrelevant information due to the noise, for the class of equal energy equi-probable signals.[7,8] A related optimum feature is their property of maximizing the peak signal to rms noise in their output.[9,10] This ratio of (S/N) is a function only of the total energy of the matched signal and not of the form of the signal. The form of signal which most uniformly spreads the signal energy over the signal duration is that of a symmetric binary waveform consisting of pulses of amplitude $\pm\sqrt{S}$, for example.

An idealization of a filter which would form such a signal is shown in Fig. 12 as an ideal tapped delay line, whose taps feed isolating amplifiers of gain ±1. The outputs of these amplifiers are added together to form $h(t)$ as shown which is mathematically described by the sequence of binary digits, 1, −1, −1, 1, 1.

What relationship such a multiplexing arrangement has to an optimum for any noise or interference distribution which is different from Gaussian is not known, but in view of the asymptotic approach of the distribution of a sum of a large number of variables to a normal distribution, such systems have been considered. Such a system becomes more and more advantageous from the standpoint of the number of possible channels available as the length of the filter (sequence) increases. As a practical matter, however long delay lines imply distortion of the delay signal. The question arises as to how the use of nonlinear regenerative devices along the delay line would affect its operation. An analysis of the action of such a matched filter preceded by a 2-level quantizer has been made by Shuey and shows that such a quantization of the input to the filter, which is a sum of white Gaussian noise and a symmetric binary signal $(\pm\sqrt{S})$ does not affect the operation of the filter so far as the output signal-to-noise ratio is concerned to within a multiplicative constant. Specifically, the output signal-to-noise ratio is found to be of the form

$$K\left(\frac{2E}{N_o}\right)^{1/2}$$

with K of the order of 1/2 when $S/2WN_o$ is small enough that $[1\text{-}Erf(S/2WN_o)]$ can be approximated well by the first term in its expansion. Here S is the signal power, E the total energy in the signal, WN_o is the total noise power in the band used (of width W cps).

Uncorrelated Sequences. A study was made[11] of how many sequences of binary digits could be picked such that both their autocorrelation and their cross-correlation sequences were bounded in absolute magnitude with the length of the sequence N and the bounding value T as parameters. This is the question: How many channels can be assigned to a multiplexing system of the type shown in Fig. 11? The matched filters here are assumed to be linear, without quantizers so that with no input, no ouput is obtained. Thus the input alphabet to each receiving filter consists of the symbols 0, +1, −1. A binary input to the ith transmitting filter is a positive or negative impulse, causing $\pm h_i(t)$ to be transmitted, where $h_i(t)$ is a sequence of binaries ±1. A 0 is assumed to be the input at all other times.

All correlation sequences required for the analysis of this system, taking into account known symmetry properties of the correlation sequence, were calculated for $N=5$ and 6. An exhaustive selection process was then used to find maximal sets of binary sequences whose correlation sequences obeyed the criterion of being less than or equal to T in magnitude, except for the central term of every autocorrelation sequence. This requirement allows recovering synchronization information from the signal and is excessively severe for the simple communication problem. The results of the investigation are given in Fig. 13 where $M(N,T)$ is the maximum number of members in a set such that the correlation of all members behave as required. The monotone properties of $M(N,T)$ are evident. It was shown that $M(N,T=N-2)\approx 1+2^{N-1/2}$, and that in principle one can extend the analysis from a consideration of N digit sequences to $N+1$ digit sequences without a direct calculation of the correlation sequences. The analysis was then extended to 7-digit sequences, but was extended no farther for practical reasons.

Randomly Selected Binary Sequences. In order to solve this access question in a range of sequence length which is of more

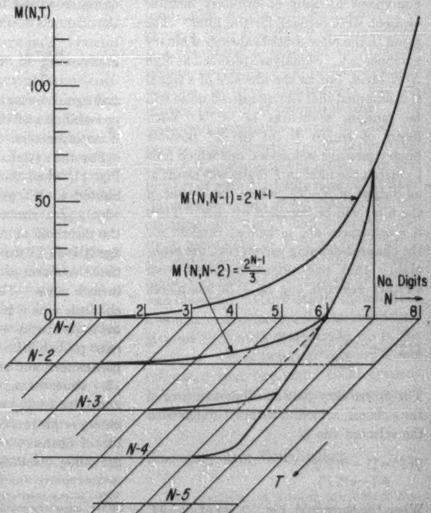

Fig. 13. Number of binary sequences M(N, T) in a set whose correlations are less than +T versus N the number of digits in the sequence

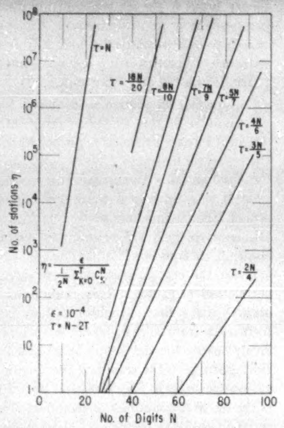

Fig. 14. Number of randomly selected binary sequences selectable without exceeding a probability ϵ of having a pair of them nonseparable with threshold parameter $\tau=(N-2T)$, $\epsilon=10^{-4}$

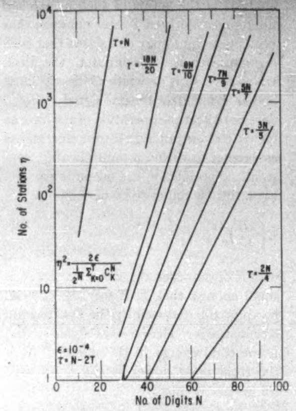

Fig. 15. Number of randomly selected binary sequences selectable without exceeding a probability 2ϵ of having any pair of the sequences be nonseparable with threshold parameter $\tau=N-2T$, $\epsilon=10^{-4}$

interest, Shuey's report considered the problem of how many binary sequences could be randomly selected and still cause interference with low probability. The specific model of a system considered, consisted of a 2-level quantizer preceding such a tapped delay line filter. It is clear that except for timing requirements, this is equivalent to using an ordinary bistable element shift register for the filter. The input to the filter consists always of binary symbols ± 1. Signals are received at high S/N ratio, but in the absence of a signal it is assumed that the quantized noise will be random sequences of ± 1's. With filters of length N, of the 2^N possible binary message sequences, one which fails to match the filter in T digits will result in an output of $N-2T$, where the output of the filter will be bounded by $\pm N$. Then if η sequences are picked at random for the channel-defining waveforms, the probability that one sequence differs from another selected one in T or less places is

$$P(T)=2^{-N}\sum_{k=0}^{T}C_k^N$$

The probability that no other sequence of the η chosen coincides within T digits with the selected one is

$$Q(T)=[1-P(T)]^{\eta-1}$$
$$\doteq 1-\eta P(T)$$

When the threshold, Fig. 10, set at $N-2T+\Delta$, at the output of the filter is exceeded, interference* takes place and the probability of this interference is

$$P(i)=1-Q(T)=\eta P(T)$$

Thus for a given probability of interference $P(i)=\epsilon$, η can be calculated with N and T as parameters.

The probability of interference in any of the channels because of any other of the channels would be given by

$$P_{tot}(i)=\frac{\eta(\eta-1)}{2}P(T)$$

and again, η can be calculated for a given probability ϵ of interference, with N and T as parameters.

For the system as described, shown in Fig. 11, when the random noise is bandlimited to W cps, then sequences occur which give rise to false alarms (exceed the threshold at $N-2T+\Delta$) on the average $2W\ P(T)$ times per second; $P(T)$ is the false alarm probability for the system in such noise. The maximum number of channels η as a function of the length of the sequences N were calculated with various probabilities of error ϵ and T as parameters, and are given in Figs. 14 and 15. Here we see that such a system of multiplex coding using randomly selected binary sequences can provide a large number of channels with low probability of providing insufficient channel separation if the length of the sequence is 50 to 100 digits.

This analyis is intended only to answer the access question by putting bounds on the number of channels which can be defined by this system of multiplex coding. Clearly the system could not utilize all channels simultaneously, but would operate with reasonably low equivocation only at a very low system duty cycle. Such practical questions have been ignored as to how actual interchannel interference caused by simultaneous reception of two of the binary waveforms with some degree of overlap would affect the rate of transmission. With a 2-level quantizer, preceding the filter, a stronger signal from one channel will swamp out a weaker one. In receiving the weaker one, on the average only half the overlapping digits will be in error, so if the filter and threshold detector can allow T errors, an overlap of $2T$ digits would be allowed on the average without causing interference. More overlap of signals would cause interference. If the filter is not preceded by a quantizer, a modified approach to the problem of rate of transmission would be required. In this case, the S/N ratio varies as $\sqrt{N}$ since interference is like a random walk problem.

SYSTEMS USING FILTERS MATCHED TO WHITE NOISE

The possibility of using very long samples of random noise for defining channels arises.[5,12] For a very long sample of such a waveform, e.g., a segment of white Gaussian bandlimited noise of duration T seconds, limited to a band of W cps, the autocorrelation is effectively of the form

$$\frac{\sin 2\pi W(t-n/2W)}{2\pi W(t-n/2W)}.$$

Such a function has only one nonzero sample value, and can be considered to be the ideal short-time autocorrelation function.[8] Such a waveform could be used to represent a binary symbol in one channel. The noise waveforms and their matched filters can be specified by their $2TW$ (random amplitude) sample values. The various waveforms would be of nearly equal energy, and interference would be additive Gaussian, so that such a system of matched filters would constitute a system of optimum detectors in the Woodward sense of maximizing inverse probability of the signal if each signal is transmitted with equal probability.[7] Although there is an infinite number of such waveforms, only about $N=2TW$ of them can be in the transmission medium simultaneously, for then the output signal-to-noise ratio of a matched filter is reduced to unity. There is nothing in this systems idealization which prevents a single waveform from being transmitted repetitively N times in the interval T, and being correctly received, so long as no other transmissions take place simultaneously and the proper reception can take place at the unity signal-to-noise ratio.

---

* This is not interference in the strict sense, but rather misinterpretation of the received signals, i.e., thinking station S_{tk} transmitted when it was S_{jl}.

Only in the limit of infinitely long noise sequences are the cross correlations always zero. The practical question should be considered of how fast the correlation functions approach these optimum forms as the lengths of the sequences grow. Specifically, the rate at which the trading of redundancy for equivocation can take place in such a system as the length of the waveform segments is increased should be evaluated. This would require at least probabilistic knowledge of the envelope of the autocorrelation functions in order that a proper evaluation of the probabilities of error can be made.

Systems in Which Decoding Is by Pulse-to-Pulse Computation

Several papers have appeared recently in which coding theory analyses of specific systems are presented. The following general assumptions are usually adopted: Channel-defining binary codes are selected. Interference rejection is based on Hamming distance concepts or some other pulse-to-pulse computational requirement. Such a code will be used to transmit binary-coded information. Decoding with small probability of error requires very high signal-to-noise ratio, so that very low system duty cycles are required. This in turn implies that only very low channel rates will be afforded by such systems. Every channel is assumed to be the same as any other, and the binary information is transmitted at random instants. P. M. Lewis[13] considered a quantized binary channel operating at high signal-to-noise ratio. The signals to interference ratio is set by the duty cycle of each channel d, the length of the channel defining codes L, and the number of possible and actually used channels p and m, respectively. Average system performance was calculated in terms of the expected number of errors for a given choice of parameters p, m, L, d. For specified p and m, L and d were varied to maximize the total rate of transmission. The analysis proceeds by assuming L digits of a code are sprinkled at random throughout n digit spaces, whence $d=L/n$. Part of the L digits are some that are added to attain a specified low probability of false alarm, P_f. Using Hamming distance concepts coupled to the expected number of errors, values of L and d required to maximize the system rate of transmission H are found. Lewis' results are summarized:

$$d_{\text{opt}}=\frac{1}{2m}$$

$$H=\frac{1}{2L}$$

$$n=2mL$$

$$L=4e\log_e 2p+\log_2\frac{1}{P_f}$$

Two ranges for system specifications are of interest, and optimum "expected value" performance of such a system may be summarized by the following table:

System Specification	$p=25$ $m=10$ $P_f=10^{-8}$	$p=5{,}000$ $m=10$ $P_f=10^{-8}$
L	70	130
H	0.0077 bits/digit space	0.0038
n	1,400	2,600

The disturbing feature of this system is the large value of n required and the small system rate of transmission as well as the much smaller channel rate of 1 bit/n digit spaces.

Many of the disadvantages of this system are due to the quantizer at the receiver input, required by the postulated system of error detection decoding which allows only two received symbols. The requirement that the L code elements be randomly distributed among the n digit spaces implies that there be n digit storage available at the coding and decoding devices.

Noble[14] analyzed binary-pulse systems from the point of view of information theory, calculating the probabilities necessary for obtaining Shannon's information rate. The distinction was made between "symbol information rate," which measures rate excluding the effects of message coding, and "message information rate," which is the information rate available with the associated message coding constraints. For the pulse systems, the optimum symbol rate is exactly that given by White,[1] 0.7 bit/pulse width, while the application of the message coding constraints (equal number of 1's and 0's in the message were assumed) cuts this down to 0.2 bit/pulse width. The message coding is clearly an error-detecting system which makes no attempt to correct errors, and the loss of information rate caused by possible errors is surprisingly large. Error-correcting codes can increase the information rate by minimizing such loss. For a system using matched-filter coding to represent the binary symbols, an optimum symbol rate was found to be about 0.5 bit/sec/unit bandwidth-equivalent to 0.25 bit/pulse width in a bandlimited pulse system.

Experimental Evaluation of a Channel Synchronized System

A channel-synchronized asynchronous system, suggested by R. L. Shuey, utilizing delta modulation,[15,16] was simulated by E. R. Schultz[9] as a 2-channel system. Delta modulation is a form of pulse code modulation in which information is carried by the presence or absence of a pulse, or equivalently by pulse polarity in a constant *prf* pulse train. The pulses represent the change in the modulating waveform between sampling instants. Either a single or a double integration of the pulse train can be used as an approximation to the information waveform in the coding or decoding process. The outstanding advantage of the delta modulation system is the simplicity of the decoding equipment, consisting of the integrating circuits. The disadvantage lies in the very high sampling rate required for good signal-to-noise ratio (about 100-kc *prf*'s were used by Schultz).[9] Each channel of the multiplex system was distinguished by its unique pulse-repetition frequency. The advantage of using such a system for multiplexing, as pointed out earlier, is that a synchronization problem which can be solved is substituted for a coding problem whose solution is not known.

The 2-channel experimental system used pulse widths and *prf*'s which give about a 10% probability of interference, and simulated a practical multiplexing system operating with perfect synchronization between transmitters and receivers, i.e., perfect demultiplexing. The noise and interference were of three expected characteristic types: heterodyne, cross talk, and quantizing noise. The first two types were markedly dependent upon the relative values of *prf* used by the two channels, and were found experimentally to be minimized by a 20-kc difference in *prf* assignments. At this point a maximum S/N ratio of about 25 db (decibels) was observed. Calculations showed that a similar system having six channels would give an S/N ratio of about 11 db in the channels. As a practical matter, it was estimated that one could build systems having about 10 channels for use simultaneously.

Summary and Conclusions

The question of finding statistical distributions for signals which will maximize the rate of transmission of information in an asynchronous multiplexing system has been considered. A study of the general nonorthogonal system which uses Gaussian noise like coding, and that of the channel-synchronized asynchronous systems shows that such systems are inefficient from the information rate point of view compared to orthogonal systems such as frequency division multiplex. Such studies attempt to answer the question: What is the optimum asynchronous system, and how can its performance be measured? From the standpoint of information capacity, the answer to these questions would give a yardstick by which any practical system could be measured.

Lacking a complete answer to the questions, one is forced to consider specific systems. The coding theory analysis of various fixed-length block-coding schemes have been made for two purposes; for measuring the optimum information rate, and for finding the number of channels made available by the coding scheme. The question of how well finite-length matched-filter coding systems solve the access problem requires further study of the interference produced by the overlapping of channel signals in time of transmission.

The analysis presented here of the interference effects in binary systems treats only the case of video pulses, and will be changed if other transmission methods are postulated, such as for example, a binary frequency shift system. For very long binary sequences, new practical considerations arise, e.g., concern for local oscillator stability, since alphabet symbols ±1 imply phase sensitive detectors when a common r-f band transmission is used. These and other practical considerations have not been treated here.

Ultrasonic Frequency Power Generator Using Transistors

YIN-MIN WEI
NONMEMBER AIEE

INCREASED USE of ultrasonic energy in industrial applications has created a greater demand for ultrasonic frequency power supplies. Most of these power supplies are constructed with vacuum tubes as the conversion devices. However, power supplies, which are made with transistors operated as high-current switches,[1] can be made higher in power conversion efficiency and more compact for the same power rating. Described in this paper will be the circuits which have been utilized in the generation of ultrasonic frequency power.

Methods of Generation

Two-Transistor Oscillator

The first circuit to be considered will be a 2-transistor push-pull oscillator utilizing a series tuned feedback circuit as shown in Fig. 1. This circuit which uses switching transistors was suggested by R. P. Putkovich as a means of providing a stable frequency oscillator. The operation of this circuit may be explained in the following manner. Assume transistor Q_1 is conducting. The voltage across power transformer T_1 primary equals $2E_B$. This same voltage appears across the feedback circuit of L_1, C_1 and feedback transformer T_2 primary (see Fig. 2). Initially the inductor L supports almost all the voltage (assume the feedback circuit has high circuit Q). As the inductor current increases, the voltage across T_2 primary rises. Feedback transformer T_2 secondary voltages are such as to keep transistor Q_1 conducting and transistor Q_2 cut off. As the condenser C_1 charges, the voltage across T_2 drops. T_2 secondary voltage drop causes Q_1 to start swiching OFF. The capacitor then begins to discharge through primary of T_1 and the voltage across T_2 is reversed. This initial reversal of voltage causes Q_2 to conduct and Q_1 to cut off, and the previous half cycle is repeated for Q_2 conducting. Frequency variation can be controlled by varying L_1 or C_1 or both. This oscillator can be used to drive a low-power load directly or to drive another higher powered inverter.

Four-Transistor Bridge

Another type of power inverter consists of a 4-transistor bridge circuit[2] (Fig. 3) which is driven by some lower powered oscillator. Drive signals appear at four separate, but identical, secondary windings (designated *a-b-c-d*) of drive transformers T_3 with polarities selected such that transistors Q_3 and Q_5 are driven into

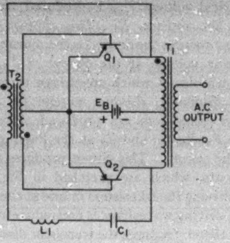

Fig. 1. Push-pull oscillator

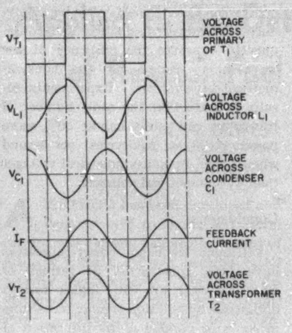

Fig. 2. Voltage and current waveforms in Fig. 1

conduction while Q_4 and Q_6 are driven to block. When transistors Q_3 and Q_5 are conducting, the input direct current flows from A to B in the primary of output transformer T_4. When transistors Q_4 and Q_6 are conducting, the input direct current flows from B to A in the primary of T_4. Thus, alternating voltage at the drive frequency is available at the secondary of output transformer T_4. Because each nonconducting transistor has to block the input direct voltage, the magnitude of the input direct voltage is limited by the maximum V_{Ce} rating of the transistor.

SERIES-CONNECTED BRIDGES

Because of the difference in switching speed, each of the transistors which are connected in series to operate from a direct voltage may take a peak voltage equal to the full supply voltage. Thus, series operation of transistors is not generally feasible. In order to accommodate higher input direct voltages, two or more transistor bridge circuits can be connected in series across the direct voltage input as shown in Fig. 4. The four transistors numbered *3*, *5*, *7*, and *9* are driven ON simultaneously by signals fom T_3, while transistors numbered *4*, *6*, *8*, and *10* are driven OFF simultaneously by opposing signals from T_3. When the signals from T_3 change polarity, transistors *3*, *5*, *7*, and *9* are driven OFF while transistors *4*, *6*, *8*, and *10* are driven ON. Thus, an alternating square-wave voltage is obtained at the output transformer T_4. Since the voltage across a condenser cannot change instantaneously, the condensers C_2 and C_3 help to equalize the direct voltage across the bridges in case the transistors in one of the bridges should turn ON or OFF sooner than the other because of differences in transistor switching times. Again, with the addition of the diode bridge at the center of each transistor bridge, the circuit would continue to work even if one of the transistors is disconnected from the circuit. Assume Q_3 is taken out of the circuit. When the odd numbered transistors are driven ON only the lower bridge works and supplies the output power from condenser C_3 through the primary winding P_2 of transformer T_4. This makes the voltage of C_3 lower than that of C_2. But when the drive voltage changes polarity, only the even numbered transistors are conducting and both the transistor bridges work. This time, the voltage from C_2 through the upper bridge to winding P_1 of T_4 is higher than that from C_3 to P_2 through lower bridge. Since P_1 and P_2 are identical windings on the same transformer and have the same polarity, C_2 actually supplies the output power and charges C_3 through P_1 and P_2 and diodes D_6 and D_8 to equalize the voltage of the two condensers It is understood that this same action through the primary windings of the output transformer also tends to maintain equal voltage across C_2 and C_3 when the voltage difference is caused by some other factor, such as the d-c leakage of the two bridges In addition, the diode bridges provide a path for the continuous flow of current carried by an inductive load such as an ultrasonic transducer, when the transistors are turned OFF.

System for Power Generation

Combining the oscillator of Fig. 1 with the bridge-type power inverter of Fig. 4, a system for the generation of a-c power was obtained and is shown in Fig. 5. The frequency control oscillator provides a

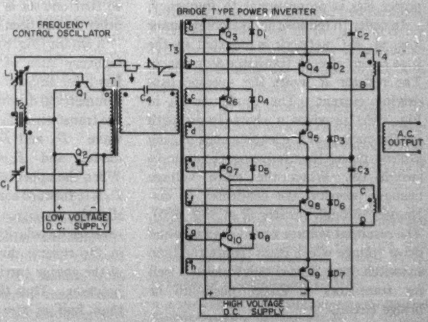

Fig. 5. System for power generation

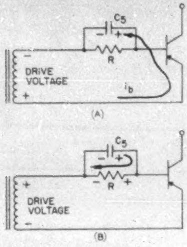

Fig. 6. Base biasing circuit

square-wave output at T_1 which has good frequency regulation with respect to load impedance changes and power supply fluctuations. The frequency is controlled by L_1 and C_1 in the oscillator feedback circuit. The oscillator output provides drive signals through C_4 and transformer T_3 for power inverter transistors Q_3 through Q_{10}. The polarities of T_3 secondary windings are such as to drive transistors Q_3, Q_5, Q_7, and Q_9 ON and transistors Q_4, Q_6, Q_8, and Q_{10} OFF alternately. Output transformer T_4 sums the two primary inputs and provides a-c power at any desired voltage at its secondary terminals. Good regulation and filtering of the high-voltage power supply is required for reliable operation of the power inverter due to the voltage limitations of the power transistors.

Circuit Improvements

R-C Network in Base

The transistors in the system described are operated in the switching mode to minimize power dissipation in each transistor. As the operating frequency increases, the power loss during switching becomes a substantial part of the total power dissipation because switching power loss is proportional to frequency.

In order to reduce this switching power loss, an *R-C* network is inserted in the base circuit of each transistor as in Fig. 6. The resistor R limits the average base driving current. The condenser C_5 in Fig. 6(A) provides a short-circuit path for the current at the leading edge of each driving pulse, thus reducing the time to switch ON. When the drive voltage changes polarity, the condenser C_5 discharges through resistor R of Fig. 6(B). The resultant voltage across R adds to the drive voltage which helps reduce the time to switch OFF. This circuit functions well for transistors in either push-pull or bridge circuits.

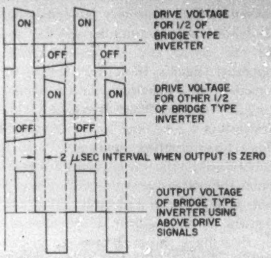

Fig. 7. Nonsymmetrical drive waveforms

Capacitance Drive Circuit

It has been shown by Moll[3] that for equal driving current transistors are switched ON faster than OFF because of the minority charge carriers stored in the base region. The *R-C* network in the base circuit helps to reduce switching time both ON and OFF. However, a condenser C_4 in series with the driving transformer as shown in Fig. 5, produces an exponentially decaying driving voltage, thus minimizing the base charge carrier storage to reduce the switching OFF time. This, in turn, reduces the conduction time of all transistors and helps reduce the instantaneous short circuit which appears across the d-c supply twice each cycle.

Nonsymmetrical Driving

In a push-pull or bridge circuit, the d-c power supply will be instantaneously short-circuited twice each cycle when all the transistors are in the ON state because they are switched on faster than off. This periodical, temporary short circuit produces high-power dissipation in the transistors. To guard against this short-circuit situation, the two sets of transistors, which are operated ON and OFF alternately, may be driven separately by nonsymmetrical voltage waveforms (Fig. 7) so that one set is switched off before the other set has been switched on.

A circuit (Fig. 8) which makes use of the recovery time of semiconductor diodes[4] has been employed to generate the nonsymmetrical driving signal. The input to the transformer T_5 is a symmetrical square wave. D_9 and D_{10} are identical silicon diodes and $R_1 = R_2$, $R_3 = R_4$, $C_6 = C_7$. When the upper terminal of T_5 is positive, D_9 is in forward conduction and V_{AB} is only slightly positive. As the input voltage reverses its polarity the diode D_9 conducts in the reverse direction intially because of the charge carrier storage in the diode junction. Thus the diode conducts more than half of the time and a nonsymmetrical voltage V_{AB} is produced across the the resistor R_3. This voltage, in turn, produces the desired nonsymmetrical driving voltage at the output of T_6 for the transistors which are driven through C_6. Similarly, driving voltage for the other transistors are produced through D_{10}, R_2, R_4, C_7, and T_7 at the lower part of the circuit. This circuit produces two outputs, which are sketched in Fig. 7, for driving the transistors in bridge circuit. The driving waveshape is nonsymmetrical and thereby reduces the transistor dissipation during switching.

The addition of diodes D_{11} and D_{12}, as indicated by the dotted lines to shunt R_1 or R_2 when D_9 or D_{10} is reverse biased, reduces the power dissipation and consequently improves the efficiency of the waveshaping circuit for the nonsymmetrical drive voltage. Experimental results indicate that the same number of transistors can safely handle 50% more power at 20 kc (kilocycles) per second when driven by nonsymmetrical voltages than by symmetrical voltages.

Conclusions

Ultrasonic frequency power generators have been constructed at ratings of 50 watts to 1 kw with higher ratings obtainable by addition of more transistors in series or parallel or by utilization of transistors having higher voltage and current ratings.

The frequency of these germanium transistor units is a function of temperature, supply voltage, and load. The frequency stability obtained from transistorized power generators is shown as:

1. 1% frequency change for 10 F (degrees Fahrenheit) temperature change.
2. 1% frequency change for 10% supply-voltage change.
3. 0.02% frequency change from no load to full load.

A 1-kw unit having dimensions of 20 inches width, 9 inches height, and 15 inches deep has been constructed. It weighs less than 50 pounds and has a d-c

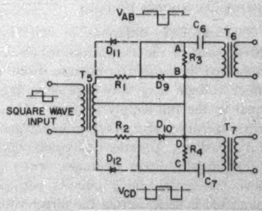

Fig. 8. Nonsymmetrical drive voltage shaping circuit

Vol.
Pt. 1
1959

to a-c power conversion efficiency of about 85%. A generator of the same power rating using vacuum tubes may be three times its size and weight and only about one-half as efficient. At the present time, the cost of transistor units is higher than vacuum tube units; however, this situation is expected to improve when higher power transistors become available. As a matter of fact, laboratory sample of silicon transistors rated at 300 volts and 20 amperes are made by Westinghouse Electric Corporation.

Delayed Neutron Detection Methods Applied to the Detection and Location of Reactor Fuel Element Failures

R. A. DEWES
NONMEMBER AIEE

J. C. CHILDS
NONMEMBER AIEE

A METHOD has been developed and demonstrated to detect and locate reactor fuel element failures by means of primary coolant delayed neutron (DN) activity measurements. The initial development, done at the Knolls Atomic Power Laboratory,* applied to a high-temperature, pressurized, recirculating water-cooled reactor system. However, it can be applied to a variety of other types of reactor systems, including air-cooled types. By this method, the state of reactor fuel integrity can be continuously and simply monitored. The actual location of fuel element failures can also be determined; in some instances this location can be accomplished without the necessity of shutting down the reactor.

In brief, the method consists of measuring the neutron activity of a flowing sample of primary coolant fluid as it passes through a DN detection station. The presence of neutron activity above a certain predetermined background level indicates the presence of fission product emitting surfaces in the reactor system. This indicates the presence of a failed fuel element. The neutron activity arises from the DN emitting fission product isotopes I-137 and Br-87 which enter the coolant stream by recoil from an exposed fuel surface.

In order to locate the failure within a multicellular reactor core, either of two methods may be employed. The first of these involves auxiliary equipment which permits continuous flow of primary coolant samples from selected portions of the reactor core through individual sampling lines. A measurement of the neutron activity of the effluent from each of these lines indicates the location of the failure within the resolution of the sample line intake location. A second, less complicated, method has been found to be usable in this application and may be applicable to most reactors. This method, termed the "flux depression method," utilizes the local reduction in flux which accompanies the insertion of one or more control rods at constant average reactor power. Such a rod manipulation depresses the specific fissioning rate in the region of the inserted rod(s), with the spatial extent and amount of flux depression depending upon many parameters. If a failure is present in the region of the depressed flux zone, the average neutron activity of the primary coolant as measured by the permanently installed delayed neutron detecting station is found to decrease. The failure is thus located within the resolution of the flux depression pattern of various rod movements.

Discussion

Failure Detection

In a reactor system, fission product isotopes may enter the primary coolant system from fuel surfaces that are exposed to the coolant because of a failure, from fissionable atoms in or on the reactor construction materials or fuel cladding surfaces, or from fissionable atoms in solution in the primary coolant. Of the many fission products released, only a few emit neutrons. Of these, it is necessary only to consider the DN emitters given in the following:

Isotope	Fission Yield	Neutron Transition Fraction	Half Life
Br-87	0.027	0.02	56 sec.
I-137	0.049	0.06	22 sec.

These isotopes are the most important because of half-life. The other DN emitters have half-lives on the order of 5 seconds or less, and so have decayed to the point that they are not detectable by the time they have arrived at the detecting station mentioned in the previous sections.

There are various mechanisms associated with the release of fission product isotopes: gaseous diffusion, erosion, corrosion, and fission recoil. Of these, only the recoil mechanism is important in establishing the level of DN activity in the coolant of a reactor which has high integrity fuel. Fissionable atoms in solution may also contribute neutron activity; however, the contribution is negligible in a reactor primary system which has a normally efficient purification system and low corrosion and erosion rates. Thus, measurement of the neutron activity of a primary coolant sample is directly related to the magnitude of exposed fuel surfaces. A certain base level of neutron activity exists because of the presence of fissionable atoms on or near the surfaces of the core construction materials.

The use of the bromine and iodine DN emitting isotopes as a basis for this measurement provides many advantages over other methods of failure detection. Their

R. A. Dewes and J. C. Childs are with the General Electric Company, Schenectady, N. Y.

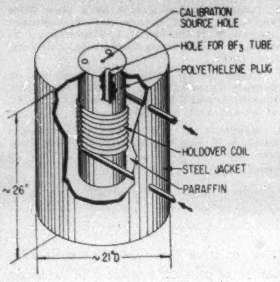

Fig. 1. DN detection station

short half-life means that an up-to-date picture of reactor conditions is available at all times, and laborious corrections for past reactor history need not be undertaken. Further, the neutron level is an unambiguous indication of fission product activity; there is no confusion with competing nonfission-product coolant activities that exist in, say, gamma analysis. Also, no primary coolant sample need be removed from the primary system nor handled in any manner; only the activity of a small leg with a holdover vessel need be measured.

The mathematical relation which governs the fission product release is fairly simple to evaluate. The activity per unit coolant volume of any isotope released is

$$B=\frac{ryp\sigma S\phi f\rho hA}{VM}\left[\frac{\lambda}{\lambda+d+\beta+l}\right](1-e^{-\lambda t}) \quad (1)$$

where

r = fission product isotope release factor = nuclei entering stream/nuclei produced ~0.25 for recoil mechanism
y = fission yield
p = neutron transition fraction
σ = U-235 fission cross section at reactor temperature
S = area of failure (exposed fuel)
ϕ = thermal neutron flux density (average)
f = fraction by weight of U-235 present in meat
ρ = fuel meat density
h = fission product recoil range in fuel meat
A = Avagadro's number.
V = active system volume
M = gram molecular weight of U-235
λ = decay constant for isotope
d = deposition removal constant for isotope
β = system purification constant
l = system leakage constant

In the case of the halogen DN emitters, the values of l, β, and d are negligible compared to λ. Also, at equilibrium $e^{-\lambda t}\sim 0$; thus

$$B=\frac{rypo\sigma S\phi f\rho hA}{VM} \quad (2)$$

The count rate (CR) observed at the detection station to which the sample takes T seconds to travel, having a volume v, and a detection efficiency ϵ, is

$$\mathrm{CR}=(Bv\epsilon)e^{-\lambda T} \quad (3)$$

The background in this detecting system is caused by environmental neutrons at the detecting station and by the previously mentioned DN's produced by the recoil nuclei from natural uranium impurities in the reactor core surfaces (of the order of a few parts per million unless contaminated). The only other neutron activity present is that caused by N^{17}; this isotope is produced by the $O^{17}(n,p)$-N^{17} reaction of the oxygen in the primary coolant. Since the half life of this isotope is 4.14 seconds, a transit time of a minute or so to the DN detecting station allows the N^{17} to decay to a negligible amount.

Failure Location

The multisampling system mentioned in the first section for purposes of failure location can be as extensive as required.[1] In general, the number and location of sampling lines is determined by an analysis of: probable failure zones; the number and location of discreet, replaceable sections of the core; the maximum error in location that can be tolerated; the probable primary system activities that can be tolerated in the event of a failure; and reactor flux distribution. These considerations, among others, also determine the importance attached to a given size of failure. The sampling lines, led through a multiple valve manifold, enable known areas of the core to be surveyed, and the location of the failure is denoted by the highest reading sample line. The line which samples effluent from the region containing a failure will produce the highest reading because of the presence of freshly added DN fission products from the failure location. The other lines will sample the highly diluted activity which returns through the circulating primary system to these other lines. (The relations describing these details have been analyzed and are given in references 2, 3.)

The flux depression method, also mentioned in the first section, is a powerful tool. Eliminating the need for a complex sampling line system, the location procedure can be carried out rather quickly, an advantage arising from the short half-life of the isotopes involved. Only a short wait, of the order of 5 minutes, is necessary for the system to come to equilibrium after a control rod maneuver. The performance of this test demands an approximate knowledge of the flux contours produced by a given rod insertion. A map of flux versus location within the reactor for each rod(s) movement enables one to see the areas of overlap from adjacent rod movements. The extent of the reduction of neutron activity of the primary coolant with a given rod(s) insertion can be correlated with the map for that rod(s) movement. The area of the failure is then located with some precision. By these methods of failure location, costly radiochemical tests are eliminated, and only the fuel in the indicated defective zone need be replaced if replacement is deemed necessary.

The presence of generally distributed surface contamination can be distinguished from a fuel failure by the failure location procedures, which will reveal that no localized source of activity such as a fuel failure is present.

Measurements have been made on the reactor to which this system has been applied to gather information on the nature of the flux plots previously mentioned. These measurements revealed that the flux was depressed an average of 50% in a well defined area about each control rod in moving the rod from the fully withdrawn to the fully inserted position. Little confusion arose from manipulation of adjacent control rods. Although in some cases manipulation of one rod causes measureable flux changes in the region of adjacent rods, the greatest changes are confined to the region of that one rod, so that good resolution is obtained.

Other Reactor Systems

There are no essential differences that exist if one considers this system in terms of air-cooled reactors or boiling-water reactors. Provided that the construction of the reactor enables some form of channeled coolant flow about the fuel units, sampling of air or water can be ac-

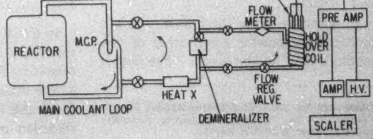

Fig. 2. Outline of DN detection system for fuel-failure detection. This system is also used for failure location with flux depression procedure

Vol.
Pt. 1
1959

complished as previously outlined. A boiling-water reactor, for example, presents no special problems because the reactor core is essentially covered to its full depth with flowing water (a fraction of the upper part of the core contains a steam-water mixture, with water predominant). Any steam included in the withdrawn sample, if sampling procedures are used, would readily condense in the sampling lines; background levels and signal levels would be realtively the same as for nonboiling water systems.

Flux depression techniques, of course, can be applied freely to these other reactor systems, subject to the same criteria.

Description of Equipment

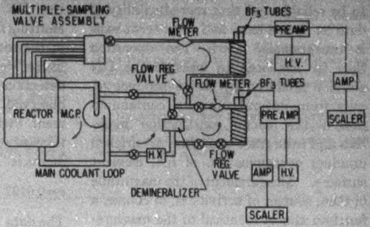
Failure Detection Equipment

The DN detection station which is used is illustrated by Fig. 1. Primarily, it consists of a $3^1/_4$-inch-diameter helical coil of 3/8- by 1/4-inch stainless steel tubing having a total volume of 150 cubic centimeters (cm). Within the coil is a cylindrical polyethylene plug containing three equally spaced holes for the location of neutron counters. Anton Electronics Laboratory type *370-E* proportional counters with 2-mil-diameter anodes are used. The counters are filled with $B^{10}F_3$ to a pressure of 60 cm of mercury and are about 1 inch in diameter and $11^3/_4$ inches in length. A fourth hole located on the axis of the polyethylene plug is used for insertion of a calibration source, nominally 5 millicuries of polonium-beryllium. The source is 1/4 inch in diameter and is attached by a threaded connection to a 1/4-inch-diameter insertion rod. A calibration count rate of the order of 5,000 counts per minute is produced by this source.

In order to shield the counters from ambient neutrons resulting from leakage through the reactor shield, the coil is surrounded by $1^1/_2$ inches of paraffin, 1/8 inch of cadmium, and an additional $6^1/_2$ inches of paraffin.

As shown in Fig. 2, the DN station is connected to the reactor primary coolant system by connection to the coolant purification system. Since the coolant purification loop joins the main coolant system at the inlet and outlet of the primary coolant pumps, a large hydraulic head is available to produce flow through the DN detection station. Also the water in the purification loop is cooled prior to entering the demineralizer and presents the advantage of cooled water for delayed neutron monitoring. The DN detection station is located outside the radiological shielding; therefore, suitable isolation valves are used between the piping outside the shield and the purification loop.

Fig. 3. Outline of DN detection system for fuel failure location by multiple sampling procedure



A high-pressure variable-area-type flow indicater, Brooks Rotameter model no. *FV-1110-VH-BTP*, is used as a reference for regulation of flow to the DN detection station. The flow rate to the station is adjusted to a fixed value which produces a coolant transit time of approximately 2 minutes from the reactor to the DN station. This transit time allows for decay of the short-lived nitrogen-17 neutron activity which is inherently present in water-cooled reactor systems, leaving only bromine-87 and iodine-137 activity present within the coil of the DN detection station.

The counting circuitry is also shown in Fig. 2. It consists of an Atomic Instruments linear preamplifier, model *219;* Atomic Instruments linear amplifier, model *218;* and a Radiation Instruments Development Laboratory scaler, model *49-10.* A Radiation Counter Laboratories count-rate meter, model *15-Mark 15,* and a Foxboro EMF Dynalog recorder are also provided for use when continuous recording is desired. A John Fluke, model *405,* high-voltage power supply is used to provide approximately 2,200 volts to the three counters. Simplex low-noise coaxial cables are used for the high-voltage and input signal cables.

Over-all system gain is set so that the majority of output pulses from the linear amplifier fall in the range of 70–80 volts. This is established with a calibrated scope or a pulse analyzer. The discriminator setting is 20 volts.

Failure Location Equipment (Sampling System)

The equipment used for fuel element failure location by the multisampling technique is auxiliary equipment, installed only at the time of its use. As illustrated by Fig. 3, 19 external sampling lines are connected to 19 sampler receptacles on the reactor pressure vessel. Each sampler receptacle provides a point of connection to a sampler rake installed within the reactor. Each rake provides a representative sample of coolant effluent from a discreet section of the core.

The 19 sampler lines of 3/8- by 1/4-inch stainless steel tubing are led to a multiple valve-manifold assembly which was manufactured by Autoclave Engineers, Inc. This unit permits the selection of coolant effluent from one sampling line at a time for DN monitoring and also regulates the flow rate in the sampling line. Flow from the valve manifold passes through a Graham heat exchanger, model *12X4C-12,* and the cooled water than enters the DN station where the level of DN activity is measured. Outflow from the DN station passes through a Brooks variable area-type flow indicator which is used as a reference for adjustment of flow in the system. From the flow meter, the water then returns to the reactor primary system via a canned-motor centrifugal pump. This pump provides the hydraulic head to obtain a flow rate consistent with a 2-minute transit time of the coolant from the reactor to the DN station. Suitable isolation valves are used to isolate the failure location equipment from the high-pressure reactor primary system.

In operation, the neutron activity of each sampling line is compared to the reactor coolant average activity. Each sampling line is monitored by the DN station for a fixed period of time. The resulting CR observed is compared to the CR produced by the permanently installed primary system DN detection station. Abnormally high neutron activity of a sampler line, compared to the reactor average, indicates the location of the failure within the portion identified with that line.

Results

Failure Detection

Operating experience with the previously described equipment has shown it to be reliable and that reproducibility of data on both a long- and short-term basis is exceptionally good. The operation thus far has been to measure the DN activity produced by fission product recoils from natural uranium contamination in the reactor construction materials and from trace quantities of enriched uranium contamination of fuel element surfaces. Measurement of the magnitude of these sources of activity is, of course, a function almost identical to the measurement of exposed fuel alloy in the core in the instance of a failure.

Microphonic or electronic background with the power plant equipment in operation has been found to be negligible. Background due solely to leakage of environmental neutrons through the detecting station shielding has been approximately 30 counts per minute at full reactor power.

To obtain precision when taking DN measurements on an operating plant, it is necessary that reactor power and coolant transit time between the reactor and the detecting station be maintained constant during each counting interval and that these values be accurately known from one counting interval to another. For the application in question, counting intervals of 15 to 20 minutes were normally used. With meticulous care taken to maintain constant flow and power level, and with standard shipboard gages and flow indicators as references, a fractional standard deviation of less than 3% was obtained in each of two sets of data of 18 and 24 points, taken under two different sets of operating conditions. In another instance, data taken by several different persons unfamiliar with the equipment, under less constant conditions of flow and power level, produced a total of 16 points with a fractional standard deviation of 7%.

Calibration of the measuring system by reference to the decay curve of a nominal 5 millicurie polonium-beryllium calibration source showed less than 1% change in calibration over a period of 4 months.

The absolute counting efficiency, ϵ (see equation 3), of a detecting station was determined in an experiment conducted at the thermal test reactor (TTR) at the Knolls Atomic Power Laboratory.[4] The DN station used in this experiment was of identical construction to that used on the reactor plant, and the results were applied to the measurement made on the pressurized water reactor system. The experiment was designed to provide a continuous recirculation of water containing U-235 in solution through a region of the thermal column of the TTR and thence to the DN detection station. The DN emitting fission product isotopes produced in the reactor thermal column by U-235 fission were therefore carried to the DN detection station where their activity was observed. The data taken in this experiment yielded nine separate determinations of ϵ; the average of these measurements is

$$\epsilon = 0.0127$$

The data had a fractional standard deviation of 2.0%.

If desired, the counting sensitivity of the detecting station described herein could be increased, without significant increase in its over-all size by increasing the diameter of the tubing used in forming the hold-over coil, and by a slight increase in the diameter of the coil. For example, an increase in tubing inner diameter from 1/4 to 3/8 inch would increase the volume of the hold-over coil by a factor of 2.25. An increase in the diameter of the coil to $4^{1}/_{4}$ inches would increase this volume by an additional factor of 1.3 and would also increase the space within the coil for the location of counters and associated moderator by a factor of 1.7. This would permit use of five rather than three neutron counters to monitor the coil. Thus, the over-all sensitivity to coolant delayed neutron activity could be increased by about a factor of 5 with only a 1 inch increase in over-all diameter of the detecting station.

Using the absolute counting efficiency obtained in the TTR experiment, the DN counting data obtained from the pressurized water power reactor were used to calculate the total amount of U-235 in the core which was contributing to the system fission product activity. This amount was compared to the amount determined by radiochemical analyses performed on extracted samples of primary coolant, by which the concentrations of many fission product isotopes were determined. The results, normalized to the value calculated from the DN counts, are shown in the following:

	Relative Amount of U-235
DN value	1.00
Radiochemical value	0.55

The DN value represents one calculation based on the average of 24 measurements with a fractional standard deviation of 3%. The radiochemical value represents the average of 19 individual measurements and calculations based on a total of 11 different isotopes. The fractional standard deviation of the radiochemical values is 60%.

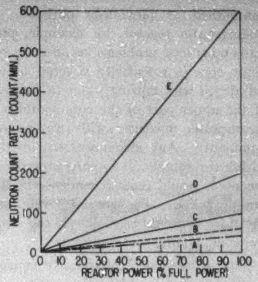


Fig. 4. Typical DN system output from reactor source contributors

A—Ambient background contribution
B—Normal 2 ppm contribution
C—Total background (A+B)
D—Total signal: 1 cm^2 failure
E—Total signal: 5 cm^2 failure

Conditions:
Full power thermal flux 10^4
2-minute delay to detector
2% counting efficiency
400 cm^3 holdover volume
10% U-235 fuel content

To illustrate the relationship and magnitude of the data obtainable from a DN detecting station to other plant parameters, Fig. 4 has been prepared. Fig. 4 is based on the following hypothetical system and counting station parameters:

v = detecting station volume = 400 cm^3
ϵ = detecting station counting efficiency = 2%
V = active primary system volume = 5×10^6 cm^3
ϕ = thermal flux density in core (average) at full power = 10^{14} n/sec-cm^2
f = fraction by weight of U-235 present in fuel alloy = 10%
ρ = fuel alloy density = 5 grams/cm^3
h = fission product recoil range in fuel meat = 10^{-3} cm
S = area of failure (exposed fuel) = 1 cm^2 and 5 cm^2

The foregoing values are substituted in equations 2 and 3 along with the standard constants involved in these equations to calculate the DN activities produced by the counting station. Typical values for counting station background caused by environmental neutrons and to 2 ppm (parts/million) natural uranium contamination in the core mechanical structure are also shown on Fig. 4.

It may be concluded that the DN method of fuel element failure detection is reliable and precise, and that it is a simple technique to apply and operate.

Used in conjunction with sampling systems or flux depression methods, it also represents a very promising approach towards the location of fuel element failures. Since the initial development and application of this system at the Knolls Laboratory, the method has been applied to several other reactor plants.

The Effect of Flux Distribution on Iron Losses

M. J. SCHINDLER
NONMEMBER AIEE

Synopsis: The classical formula used to compute eddy-current losses in magnetic sheet steel is derived from Maxwell's field equations based on the conditions of constant permeability. This condition of constant permeability is unfounded since in each cycle the permeability of modern materials will undergo changes of at least 1 to 100. Large differences between actual losses and the losses computed according to the classical formula have been noted. These differences could be attributed to the assumption of constant permeability. This paper attempts to determine approximate solutions for Maxwell's field equations under the condition of variable permeability that will lead to a modified formula for determining the eddy-current losses. Since rough approximations were used, final conclusions cannot be made. However, the results indicate that the error in the classical formula (the assumption of constant permeability) accounts for only a small part of the discrepancy between calculated and actual eddy-current losses. Experiments were conducted that confirmed the concept of changing flux distribution. These experiments also indicated that other mathematical approaches could be used for more accurate approximations.

THE losses in magnetic materials at low frequencies are generally divided into two parts: the hysteresis loss and the eddy-current loss. The hysteresis loss is attributed to the energy consumption of the flux reversal and is determined by plotting the hysteresis loop at a very low frequency.

The eddy-current loss is due to resistive heating by eddy currents, and can be computed if the flux distribution and the material properties are known throughout the magnetization cycle. In the past, the flux distribution has been found by solving Maxwell's field equation on simple geometric configurations based on the assumption of constant permeability. The solution of these equations is known as the classical formula.

This approach has resulted in very considerable differences between the calculated and actual figures; Stewart in one instance found the eddy-current loss to be three times the calculated value.[2] This difference is called the eddy-current anomaly. However, it is based on a formula known to be incorrect. Therefore, it seems reasonable first to estimate where the classical formula is in error and in what direction. It appears that the error may be caused by basing the computations on constant permeability.

This paper attempts to find approximate solutions for Maxwell's field equation under the condition of variable permeability that will lead to a modified equation for the eddy-current losses.

Flux Distribution

The classical formula has been derived under the condition of equal flux distribution across the thickness of the sheet. Whether this assumption holds true can easily be estimated by computing the so-called penetration depth. Since, as far as eddy currents are concerned, the most critical moments during the magnetization cycle are the ones corresponding to the steep parts of the hysteresis loop, it is necessary to use the maximum value of the differential permeability in the penetration equation

$$\delta_{[cm]}=50.33\sqrt{\frac{\rho}{\mu f}}$$

For hot-rolled silicon steel this approach yields figures between 1,000 and 5,000, leading to penetration depths of 0.5 to 1 mm (millimeter).

Because the thickness of normal transformer sheets lies between 0.3 and 0.5 mm, equal flux distribution can be assumed and the classical formula should give fairly accurate values. However, modern textured materials have loop slopes of up to 10^6 or more. A typical value (Armco Trancor *3X*; see Fig. 1) is 3×10^6 which gives a penetration depth of approximately 0.04 mm. According to the classical theory, the magnetic field decreases exponentially with

M. J. SCHINDLER is with the Radio Corporation of America, Harrison, N. J.

The author wishes to express his gratitude to the Wright Air Development Center for the opportunity of working on this project, as well as for permission to use the material for this paper, which is based upon work done while the author was employed at the Metallurgy Branch, Aeronautical Research Laboratory. The material, containing the mathematical deductions in detail and a description of the low-frequency generator used for the experiments, was reported in 1958.[1]

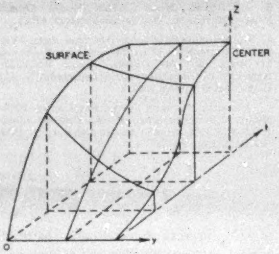

Fig. 2. Flux variations for sinusoidal flux change and exponential distribution

$$H_{(Y)}=H_0E^{-y/\delta}$$

In the center of a sheet 0.16 mm from the surface, the field would therefore be only 0.02 of the surface field. This result is definitely far enough from homogeneous to render the classical theory invalid.

To describe the actual process more accurately, it is necessary to compute the eddy-current losses under the condition of nonhomogeneous flux, exponentially decreasing toward the center plane. But this is not enough. Only during the time of magnetization reversal, when the induced eddy-current voltage is highest, can this high-screening effect be expected. As the material approaches saturation, the flux becomes more and more equally distributed over the whole cross section as the differential permeability decreases. This flux distribution causes the penetration depth to decrease. Furthermore, as Rusbüldt[3] points out, positive and negative magnetization may exist within the specimen during field reversal since the eddy currents screen off the interior from the outside field, thus sustaining the old magnetization direction in the interior. In the extreme, this situation would lead to a model in which two huge domain walls move from the surface toward the center, reversing the induction from plus to minus saturation, or vice versa, as they pass. The true state lies somewhere between these extremes, but where cannot be predicted without solving the field equations.

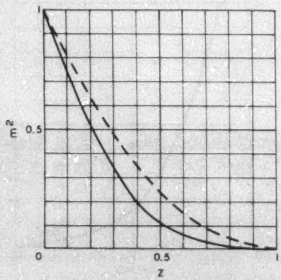

Fig. 3. Solid curve: normalized curve of Fig. 1. Dotted curve: approximation by m=1−Z

Exponential Flux Distribution

GENERAL CONCEPT

Since the distribution of flux or induction across the thickness is not known, another assumption must be made. The new theory should come closer to actuality than does the classical theory if it is assumed that the permeability will be uniform across the whole sheet at any given moment, but that the permeability will be a function of the average induction at this time. In other words, the flux decrease toward the center plane will be highest at low inductions and will approximate zero with saturation, where the differential permeability becomes very small. Of course, in a model of this kind there will be one direction of flux only, at any time, over the whole cross section, and the simultaneous existence of both directions at the time of flux reversal cannot be accounted for.

In the case of sinusoidal induction, this approach would lead to a distribution over time and cross section, as shown in Fig. 2, causing formation of harmonics on the surface as well as in the center region and a higher average induction on the surface than in the center region.

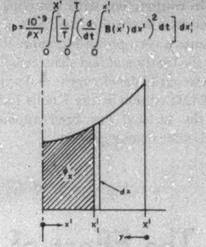
To facilitate computation it is necessary to find a suitable approximation for $m=\sqrt{\mu}$ as a function of the induction B. Fig. 1 shows u as a function of B for Armco Trancor *3X*, showing the maximum of 300,000 at $B=0$, and the approach toward zero at saturation induction B_{sat}. To make this function independent of the absolute values of B and μ, it is convenient to introduce a "normalized" induction $z=B/B_{sat}$ and replace the relative permeability by m^2. This step immediately points toward a very simple approximation of the function, namely

$$m=1-Z$$

which, as Fig. 3 shows, comes fairly close to the measured values.

COMPUTATION OF EDDY-CURRENT LOSSES

To find the energy consumed by the eddy currents in unit volume, it is necessary to compute the differential energy in an infinitely thin layer and integrate over



$p=\frac{10^{-9}}{\rho X'}\int_0^{X'}\left[\frac{1}{T}\int_0^T\left(\frac{d}{dt}\int_0^{x_1'}B(x')dx'\right)^2dt\right]dx_1'$
ϕ_x
dx
x'
x_1'
x'
y

Fig. 4. Flux contributions to eddy currents in plane x_1'

the sheet thickness, dividing the result by the thickness. For reasons of symmetry, however, only one half of the sheet is considered, integrating from the center layer toward the surface. This procedure can be simplified by using x' instead of y for the local variable, counting x' from the center plane rather than from the surface; see Fig. 4.

The power per unit volume will be

$$p=\frac{10^{-9}}{\rho X'}\int_0^{x'}\left[\frac{1}{7}\times\int_0^T\left(\frac{d}{dt}\int_0^{x_1'}B(x')dx'\right)^2dt\right]dx_1'$$

or, using $B=B_{max}\sin\omega t$ and D for the total thickness $2X'$:

$$p_c=\frac{10^{-9}}{6\rho}\pi^2f^2B^2_{max}D^2$$

which is the classical formula for the eddy-current losses.

For the present purpose, the normalized induction z is substituted and, to simplify computation, a modified local variable $x=x'/\Delta$. This substitution

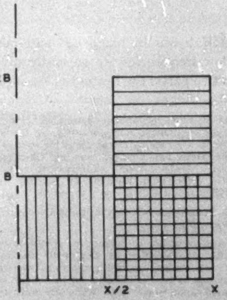


Fig. 5. Vertically hatched area—uniform flux distribution. Horizontally hatched area—flux concentration on surface

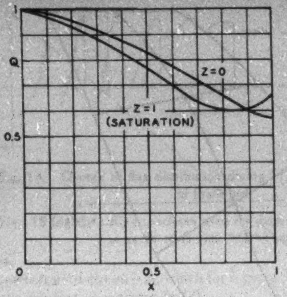

Fig. 6. Loss ratio for improved linear approximation

means that the thickness is measured in penetration depths rather than in centimeters thereby making it independent of the geometrical configuration. The final equation for the losses then reads

$$p=\frac{10^{-9}}{\rho}\Delta^2 B_s^2 \frac{1}{X}\times \int_0^{x}\left[\frac{1}{T}\int_0^T\left(\frac{d}{dt}\int_0^X z\,dx\right)^2 dt\right]dx$$

This equation shows that, if the time function z is a sequence of harmonics, the time integral will be the sum of the integrals of its members. Therefore, an increase must be expected in the loss figures if harmonics are generated; see Fig. 2.

It is now possible to calculate roughly what influence the second factor, namely, higher average induction in the surface layer, will have on the total loss figure. This calculation can be made easily by comparing the losses for the two different cases of flux distribution given in Fig. 5, where the vertically hatched area is a homogeneous flux which leads to the classical formula, while the horizontally hatched area denotes a distribution that would be the extreme of the situation in Fig. 2. Both areas are equal, and since a pure sinus is used as time function in both cases, there will be no difference in the magnetic behavior of the two sheets. As long as the induction $2B$ is not higher than saturation, it is not known which situation really exists.

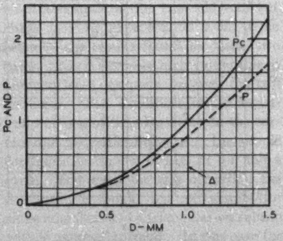

Fig. 7. Loss figure p (nonuniform flux) compared with classical result p_c

To compute the loss for the second case (concentration of the flux in the surface region), the lower integration limits are changed from 0 to $X/2$, and the induction B is replaced by $2B$. The former introduces a factor of 1/8, the latter of 4, giving a final result of $p=1/2\ p_c$. This result (decrease of the losses to half the original value) may, at first sight, look surprising. However, it is quite evident that the flux in the center region contributes most to the eddy currents since a flux path using two symmetrical planes at the distance d from the center will induce a voltage only in layers with greater distances than d, while the space between the flux-carrying layers will be free from eddy currents.

These preliminary considerations may be summed up by stating that there will be a loss increase due to the harmonics and a decrease due to the unequal flux distribution without evidence as to which will be greater.

LINEAR APPROXIMATION

The loss computation for an exponential flux distribution turns out to be impractical. A fairly simple approximation must be used, and for better understanding of the procedure a straight line is chosen which corresponds to the first two terms of the sequence for the exponential function

$$\epsilon^{-mx}=1-mx+\frac{1}{2}m^2x^2\ldots$$

Following the steps outlined above reveals that

$$p=\frac{10^{-9}}{6\rho}\pi^2 f^2 Z_0^2(2\Delta X)^2 Q=p_c Q$$

Consequently, the result can be written as the classical formula multiplied by a factor Q. Since the classical formula will give correct results if the sheet is thin enough, this conclusion was expected. The factor Q is given by

$$Q=1-\frac{1}{4}X-0.23X^2+0.05X^3+0.03X^4+ Z_0^2(-0.45X^2+0.15X^3+ 0.43X^4)+0.025X^4Z^4$$

which is plotted in Fig. 6.

This result can be approximated roughly by $Q=1-0.3X$ resulting in a modified formula for the eddy-current loss

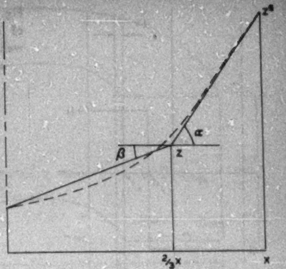

Fig. 8. Composed linear approximation of exponential flux decrease

$$p=\frac{10^{-9}}{6\rho}\pi^2 f^2 B^2 D^2\left(1-0.3\frac{D}{2\Delta}\right)$$

This equation was compared with the classical formula in Fig. 7 for a Δ of 1 mm and, although it definitely gives no account for the eddy-current anomaly, the modified equation points out that with varying sheet thickness the eddy-current loss will not change as much as the classical formula predicts.

This has been observed before but it was usually attributed to surface layers of allegedly poorer magnetic qualities. This explanation may be true to some extent but since the penetration depth usually is of the same order of magnitude as the sheet thickness (no one uses thinner material than is strictly necessary), the conditions of Fig. 7 will usually prevail. It must not be forgotten that p is the loss factor per unit volume which should be expected to decrease, if only part of the cross section is being magnetized, as is the case in thicker laminae. (See the considerations referring to Fig. 5.)

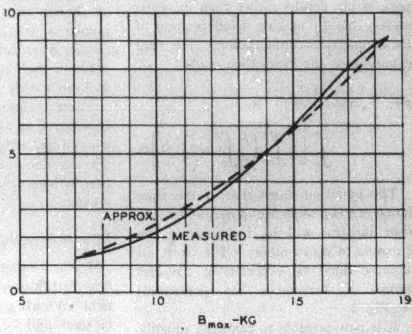

Fig. 12 (right). Hysteresis loss versus maximum induction for cold-rolled steel

COMPOSITE LINEAR APPROXIMATION

Admittedly the linear approximation used will not describe the exponential induction decrease very well. A better approach may be to divide the model into two parts using a different linear approximation in each one, as shown in Fig. 8.

Due to the better approximation, it is now reasonable to expect a wider permissible range for X which, following the procedure used before, is found to be $X_{max}=2$. Consequently, sheets can be covered up to a thickness of four times the penetration depth now, where, according to the equation, the center field will only be 0.02 of the surface value.

The calculation now leads to the result

$$Q=1-0.11X-0.03X^2+0.002X^3+Z_0^2(0.006X^2+0.002X^3)$$

which is plotted in Fig. 9 and shows no appreciable difference from Fig. 6 except that the decrease is now slower and reaches approximately the values at $X=2$, as was found for $X=1$ in Fig. 6. This result points out that the approximation is not very critical as long as the general distribution between zero and maximum is covered.

The conclusion so far is that an exponential decrease of the induction from the surface of a sheet toward the center will not lead to an increase in eddy-current losses and that a different approach is necessary.

Movement of a Huge Domain Wall

As mentioned in regard to flux distribution, it is reasonable to expect magnetization of the positive and negative signs simultaneously during field reversal which in the extreme would lead to a model in which two huge domain walls move from the surface toward the center. The nomenclature of Fig. 10 has been chosen to simplify computation and it therefore deviates somewhat from that used in the previous sections.

The thickness of the model would be $4d$ but only one half of the cross section is shown in the figure. The surface is at the right side where the domain wall movement starts with $y=d\cos\omega t$, giving a total flux as depicted in Fig. 10(B), if the local variable x equals d. In any other location the flux will change only during part of the cycle, as shown for $x=0$, remaining constant until the domain wall enters the region for which it is to be computed. This is the case at the time

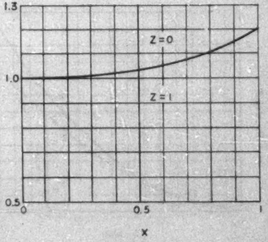

Fig. 13. Dynamic hysteresis loss versus sheet thickness

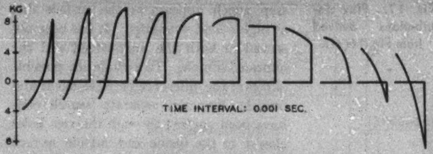

Fig. 14. Change of flux distribution during 1/2 cycle in sheet model of Brailsford

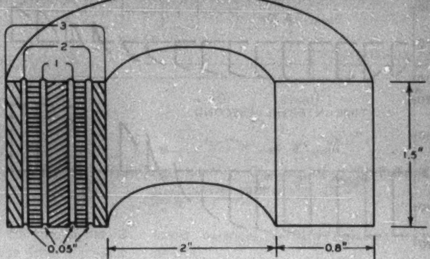

Fig. 15 (right). Ring specimen used for determining flux distributions as depicted in Figs. 16(A) and (B)

t_1 when $y = d \cos \omega t_1 = x_1$, which for t_1 gives the solution $\omega t_1 = \arccos (x_1/d)$.

For any layer, therefore, it is necessary to compute the time integral between this value and $t = 1/4f$ only, because no voltage will be induced at any other time; see Fig. 10(B).

Following the same steps used in the previous sections, it is found that

$$p = \frac{1}{2d}\int_{-d}^{+d} dP = \frac{10^{-9}}{\rho}\, 4\pi f^2 B^2 d \times$$

$$\int_{-d}^{+d}\left[\pi - \arccos\frac{x}{d} - \frac{x}{d}\times\right.$$

$$\left.\sqrt{1-\left(\frac{x}{d}\right)^2}\,\right]dx = \frac{10^{-9}}{\rho}\, 4\pi^2 f^2 B^2 d^2$$

and, as the classical formula for a thickness of $4d$ gives $P_c = (10^{-9}/\rho)\pi^2 f^2 B^2 (4d)^2$, the final result reads

$$Q = \frac{p}{p_c} = 1.5$$

Although this result would indicate higher losses as compared to the classical formula, it must not be forgotten that no commercial sheet material provides the conditions under which a huge single wall would form. Rather, it must be expected that the true figure will lie somewhere between this result and the one found previously.

Swinging Flux Distribution

Knowing that the true flux distribution would have to lie between the two previous assumptions, the true eddy-current losses may be expected, as well, to lie between the results found for these two cases. Still, it would be highly desirable to know at least one point between the two extremes. The condition would essentially be one of time lag between the surface and the center fluxes, e.g., the simple configuration shown in Fig. 11 for half a cycle. But even for this condition the computation would not be simple for sinusoidal flux, and a triangular waveform will be assumed instead. In this case the induced voltages are constant, which simplifies the problem considerably. On the other hand, the deviation from the sinus is not very great and any change in loss values, due to different flux distributions, should be about the same in both cases.

It will be assumed that the slope of the distribution line changes sinusoidally, and the steps used in the earlier calculations will be followed. It is found that

$$p = \frac{16}{3}\, 1.37 Z_0^2 f^2 X^2$$

which must be compared to the result for $z = Z = Z_0(4ft-1)$. This is simply given by the first member of the solution for p, being

$$p_c = \frac{16}{3} Z_0^2 f^2 X^2$$

thus leading to the final result $Q = 1.37$.

Dynamic Hysteresis Loss

One fact often overlooked is that the hysteresis loss, too, may change under a-c conditions. If, for instance, exponential flux distribution is assumed, the center parts of the sheet will never reach the induction which would be expected from the total flux, while the surface layers will reach higher values. To calculate this error, a mathematical expression for the hysteresis loss as a function of induction is required. Fig. 12 shows this function for a cold-rolled material. In the practical range of between 7 and 17 kilogausses it follows fairly accurately a square law.

Introducing the flux distribution into the formula for the hysteresis loss

$$p_h^* = \frac{1}{X}\int_0^X L_h Z_{\max}^2 dx$$

reveals that

$$p_h^* = \frac{1}{X} L_h Z_0^2\left[X + (1-Z)^2\left(1+\frac{1}{2}X\right)^2 \times\right.$$

$$\left.\left(\frac{1}{3}X^3 - \frac{1}{2}X^3 + \frac{1}{4}X^3\right)\right]$$

or, because the static or d-c hysteresis loss $p_h = L_h Z_{\max}^2$,

$$p_h^* = p_h\left[1 + \frac{1}{12}(1-Z)^2\left(1+\frac{1}{2}X\right)^2 X^2\right]$$

$$= p_h Q_h$$

Q_h is plotted in Fig. 13. The maximum possible increase of the hysteresis loss would be less than 20%, and this would be at very low inductions and for a sheet in which the center is practically completely free from magnetic flux.

Experimental Results

To simulate conditions in a magnetic sheet, Brailsford[4] built a model using a stack of transformer steel strips, on which he put loaded windings to act as eddy-current paths. He found that, although the total flux in the stack was sinusoidal, the flux in the center appeared peaked, while on the surface the curve was flattened. This result is in accordance with Fig. 2. Furthermore, a time delay

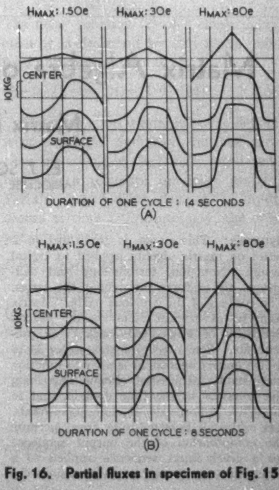

Fig. 16. Partial fluxes in specimen of Fig. 15

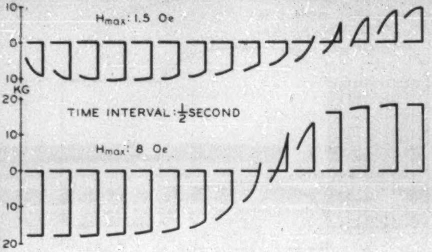

Fig. 17. Flux distributions derived from Fig. 16(A)

in the center part can be observed. From his curves the flux distribution at different moments have been derived in Fig. 14. They show clearly the generally logarithmic lag toward the center of the sheet during flux changes, and the simultaneous existence of positive and negative inductions. The sequence shown in Fig. 14 more or less resembles a damped traveling wave and could probably be treated mathematically as such.

While at power frequency only a model can be used to gather information about the flux distribution, this detour may be avoided by using very low frequencies. Fig. 15 shows part of a ring through which holes of 0.05-inch diameter have been drilled in such a way as to make the differently hatched areas equal. Three search coils of 30 turns each have been wound as indicated by the braces 1, 2, and 3. Coil 1 will then give the flux in the central part. The differential voltage between 2 and 1 gives the flux in the intermediate section and, for the surface layer, 3 is connected in counterphase with 2. This sample has been magnetized by a very-low-frequency generator capable of delivering 500 *W* peak triangular current at less than 0.05 cycle per second. The output voltages of the search coils have been integrated electronically, with the use of a Reeves d-c amplifier with capacitive feedback, and plotted on a Librascope.

Fig. 16 displays the flux in the three sections of the sample (center, intermediate, surface) at three different field values. The duration of one cycle is approximately 14 seconds in Fig. 16(A) and approximately 8 seconds on Fig. 16(B). From these, Fig. 17 has been derived showing the flux distribution at time intervals of one second. They are in agreement with those of Fig. 14, if the triangular field is considered against the sinusoidal flux used by Brailsford.

A few words should be added about the step which appears in the surface flux at higher field strengths. It has been observed in both the unannealed and the annealed sample. To exclude any possible effects of the difference between inside and outside diameter, separate search coils have been applied through the two holes closest to the inside and outside surface and the flux plotted for both. Although a time lag can be observed because of the higher inside field strength, the step is present in both cases. It is caused by the fact that the surface layer has already reached a flat part of the hysteresis loop when the center enters the steep portion, and therefore takes over practically all the change in the total flux. Only when the center, too, has reached the flat part of the loop will the surface flux increase simultaneously with the center flux, as may be seen from the charts. This effect will be emphasized by a rectangular loop. A noticeable increase has been observed after annealing of the sample.

Matrix Algebra of Sequential Logic

Matrix Logic III

E. J. SCHUBERT
ASSOCIATE MEMBER AIEE

Synopsis: This paper is the third in a series on matrix algebra applied to logical design. Notation, terminology and definitions are uniform throughout the series. The content of the previous parts, "Matrix Analysis of Logical Nets"[1] and "Matrix Synthesis of Highspeed Logic,"[2] is prerequisite. The object of this paper is to derive matrix operations similar to function matrices for sequential circuits describing the behavior in the time domain, and to introduce appropriate algebraic operations. The approach, believed to be novel, permits the computation of the output sequence for a given input sequence applied to a sequential circuit and in its inversion, the computation of a function matrix required to produce a certain output sequence from a given input sequence.

DIGITAL DATA processing implies the extensive use of sequential logic, which is a combination of static logic and memory functions. An output from static logic depends solely on the combination of inputs irrespective of time. Memory functions in the abstract sense imply the preservation of a state or a signal for a certain length of time without any logical operation on the signal. Feedback loops may be provided to control the inputs or the outputs of memory elements, depending on previous states.

Static or combinatorial logic is frequently represented in the space domain as a Venn diagram or in its abstracted form called a Veitch-Karnaugh chart. This approach becomes impracticable with increasing complexity. Because any logical proposition may be expressed as a system of linear forms in canonical minterms, matrix algebra has been advanced in two previous papers.[1,2] This paper is

Paper 59-204, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 1–6, 1959. Manuscript submitted January 23, 1958; made available for printing July 3, 1959.

E. J. Schubert, formerly with the Burroughs Corporation, Paoli, Pa., is now with Monitor Systems Inc., Fort Washington, Pa., subsidiary of Epsco, Inc.

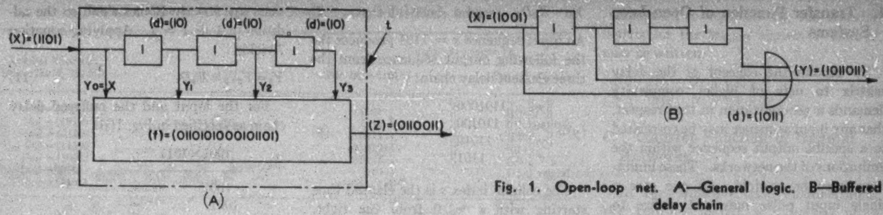

Fig. 1. Open-loop net. A—General logic. B—Buffered delay chain

the third part in the same series and deals with sequential logic. It is written in direct continuation of the previous papers in order to avoid repetition.

Logical multiplication and solution of simultaneous equations by a degenerated type of matrix inversion are feasible. The simplicity of the matrix algebra in sequential logic appears to be advantageous over other presently known concepts.[3–5]

1. Information Content of a Sequential Word

Any input sequence (x_q) may be expressed by a matrix wherein $_q$ refers to the elapsed time increments. The length of a sequence has an upper bound p depending on the over-all system but within this limit it may be defined by the number of bits from the least to the most significant one. The implication of this definition is that a specified sequence of zeros as such cannot be recognized in a single channel unless at least a single ONE has been transmitted as a start signal, and sampling at a given rate is provided.

This fact influences directly the information content of a sequential word of length p. The number combinations for a word with p digits radix b are b^p, e.g., for $b = 2, 2^p$. For sequential words, only those combinations are valid which are distinguishable with respect to the least significant ONE occurring first, i.e. a sequential word of p bits yields 2^{p-1} combinations only.

Because of this reduced information content of an input sequence length p there are not more than 2^{p-1} distinguishable output sequences. This upper limit cannot be exceeded independently of the logical design as long as the coding is binary.

2. Time Differential of a Function

The change of a logical function in time becomes of such significance in this context that a more specific symbol is desirable. Referring to the signal Z in particular the change from its value Z_1 to Z_2 during the transition from time increments T_1 to T_2 can be formulated even for an infinitely short transition from T_1 to T_2. The change of Z may be expressed by a difference Z_2-Z_1, considering that there are three alternatives.

No change:

$$Z_2=Z_1 \qquad \dot{Z}_1=\dot{Z}_1{}'=0 \tag{1A}$$

Switch on:

$$Z_1=0;\ Z_2=1 \qquad \dot{Z}_1=1 \tag{1B}$$

Switch off:

$$Z_1=1;\ Z_2=0 \qquad \dot{Z}_1{}'=1 \tag{1C}$$

To describe the transition of a binary signal requires a ternary notation accordingly. Such a difference Z_2-Z_1 with respect to an infinitely short interval resembles a differential quotient of analytic functions and may be denoted by a similar symbol $\dot{Z}$.[6] If a time index for $\dot{Z}$ is required, the suffix of the first time increment shall be used.

To employ binary coded ternary notation the following convention is established:

States		Binary Coding		Ternary Notation
Z_1	Z_2	$\dot{Z}_1{}'$	$\dot{Z}_1$	
0	0	0	0	0
0	1	0	1	1
1	0	1	0	2
1	1	0	0	0

(2)

States at time T_1, T_2 are related to the differentials and any general logical condition as follows:

$$Z_2=Z_1{}' \quad \dot{Z}_1=Z_1{}' \quad A$$

$$Z_2{}'=Z_1 \quad \dot{Z}_1{}'=Z_1 \quad B \tag{3A}$$

By cancelling identical terms the differentials may be obtained directly:

$$\dot{Z}_1=A$$

$$\dot{Z}_1{}'=B \tag{3B}$$

If $\dot{Z} + \dot{z}'$ is referred to, particularly in larger matrices, ternary notation may be used.

3. Delay Matrix

Sequential logic may be treated somewhat similarly to combinatorial logic as linear forms in the time domain. Corresponding to the minterms in combinatorial logic are time increments. The latter are denoted by an index e for the elapsed time with respect to a zero reference time. The behavior of a delay element is described by the output signal Z_s during the time increment s, depending on the applied input sequence X_q:

$$Z_s=X_qD_e \quad (z)=(x)(d) \quad s=e+q \tag{4}$$

The delay circuit is completely defined by the delay matrix (d) as the output signal following a unit pulse at time zero. Because of the digital nature the output levels are discrete and restricted at present, to binary signals.

To refer to a specific example, in Fig. 1 three delay elements are provided in a chain similar to a shift register with the individual outputs (y_1), (y_2), (y_3). The delay function (d) of a single delay element is described by two terms only for a unit pulse at time 0:

$$D_0=0;\ D_1=1 \quad (y_1)=(1\ 0)=(d)$$

The convention is established to denote with the least significant bit the zero time increment in the binary word representing a sequence or delay matrix. For the second delay element the input occurs at time 1. Accordingly, the output signals are

$$D_0=0;\ D_1=0;\ D_2=1 \quad (y_2)=(1\ 0\ 0)$$

It will be noted that the sequence (y_2) must be obtained according to equation 4 as the product of an input sequence (y_1) in a delay element (d).

$$(y_2)=(y_1)(d)=(d)^2;\ (y_2)=(1\ 0)^2=(1\ 0\ 0)$$

Cascading the signal (y_2) into a third delay element (d) eventually yields the output y_3:

$$(y_3)=(y_2)\ (d)=(d)^3 \quad (y_3)=(1\ 0\ 0\ 0)$$

4. Transfer Function of Open-Loop Systems

To expand the concept of the delay matrix to nets of higher complexity demands a generalization in that respect, that any input sequence may be correlated to a specific output sequence within the limitations of the networks. These limitations may be twofold. In one case a single input pulse may not suffice to generate any output. In the other extreme the length of the input sequence might considerably exceed the number of delay elements. A sequence may be regarded as a vector in binary notation, and accordingly the affine transformation of the input sequence into a specific output sequence implies a tensor of somewhat degenerated form. This transfer function is closely related to a composite truth table with time increments as added parameters.

Transitions of states and outputs may be combined into a single matrix describing the transfer function of a net. Similarly to the continuous relation between input and output in servosystems, the transfer function of a digital system defines the output sequences as a function of input sequences. To derive the matrix of a transfer function the following approach is contemplated.

The concept of the transfer function may be derived from the elementary case shown in Fig. 1(A). The network comprises several delay elements d connected to a combinatorial logic with the function f but without any feedback loop. This latter feature is significant and emphasized by the designation of an "open-loop net."

In this example the static logic is combinatorial for four inputs and is completely described by the function matrix f.

$$Z_s = N_{si}F_i \quad (z)=(n)(f) \tag{5}$$

N_{si} are the combinations of the delayed inputs y, depending on the input sequence x and the elapsed time. The set of intermediate outputs is described by the delay matrix d representing any shift register or delay chain by the unit matrix.

$$(d) = \left\|\begin{matrix} 1 & 0 & 0 & 0 \\ & 1 & 0 & 0 \\ & & 1 & 0 \\ & & & 1 \end{matrix}\right\| = I \tag{6}$$

The first pulse X_0, passing through the delay chain, causes the outputs as in equation 4. Any following input X_q will be shifted in time and will accordingly generate outputs y with increasing delay e, depending on the length of the chain.

$$Y_{es} = X_q D_e \quad s=q+e \quad (y)=(x)(d) \tag{7}$$

An input sequence $x = 1101$ produces the the following output sequence from the three element delay chain:

$$(y) = \left\|\begin{matrix} y_3 \\ y_2 \\ y_1 \\ x \end{matrix}\right\| = \left\|\begin{matrix} 1101000 \\ 110100 \\ 11010 \\ 1101 \end{matrix}\right\| \tag{8}$$

The column index s is the elapsed time starting with $s = 0$ from the right. The row index e designates the output line of the delay chain. Each column represents a specific input combination N_{si} during the increment s, wherein i is the binary word formed by the column with the least significant bit at the bottom. According to previously established conventions, the dummy index i is expressed in octal notation representing as matrix the sequence of minterms at the input of the static logic. $(y)^*$ denotes the transpose of (y).

$$(i)=(10, 14, 6, 13, 5, 2, 1)=(y)^* \tag{9}$$

An output Z_s is restricted to those combinations N_{si} of the intermediate variables Y_s for which the logic is operative; therefore $F_i = 1$. For any possible input sequence (x) the appropriate sequences (i) are essential in order to obtain (z). Because of the restrictions for (x) as stated in section 1, 2^{p-1} combinations have to be evaluated only. According to equations 7 and 9 the inputs into the logic (f) are described by the minterms N_{si}, wherein (i) may be computed directly from equation 10 with the use of a suitable subroutine depending on the digital machine available.

$$(i)=(xd)^* \tag{10}$$

The computer routine requires only that the function matrix (f) is stored internally or accessible at the input for any (i) in order to print the output sequences (z). Input sequences may be generated with another subroutine for the binary expression:

$$x=2n+1 \quad 0 \leqq n \leqq 2^{p-1} \tag{10A}$$

A special case of considerable significance is a chain of delay elements feeding a buffer. The delay matrix d is by definition the output sequence for a unit pulse at zero time. Because no gates are contained in the circuit and no other signal is fed into the buffer than the taps of the delay chain the delay matrix is sufficient to define the circuit. The shift in time for each subsequent input X_e corresponds to the shift operation in a multiplication. No carry as in binary arithmetic is applicable because all operations are strictly Boolean and so the addition of $1 + 1 = 1$. Applying equation 7 yields

$$Y_s = Y_{q+e} = X_q D_e \tag{11}$$

For the input and the buffered delay chain as specified in Fig. 1(B)

$$\begin{array}{r} 1001\times1011 \\ \hline 1001 \\ 1001 \\ 1001 \\ \hline \end{array}$$

$$(y)=1011011$$

5. Closed-Loop Systems

The previous section points out that the input sequence passes through a delay chain which virtually acts as a buffer to store the input sequence in parallel fashion at the inputs into combinatorial logic. In this sense the network behavior was evaluated without internal storage elements.

Closed loop systems imply feedback. A feedback loop is a connection from an output of a logical net to an input of the same net. In this context the loop comprises delay or storage elements but no logical elements. The outputs of these internal storage elements define the state of the net similarly to the Moore-Mealy concept.[3,4] Transition from one state to another is possible in two different modes either requiring a separate reset signal as for a flip-flop element, or without reset as in dynamic delay elements similar to those used in the National Bureau of Standards Eastern Automatic Computer and described by a delay matrix. To discriminate between the two different types of storage elements and the mode of transition, the first one will be called "static storage" and the second one "dynamic storage" or, briefly, "delay."

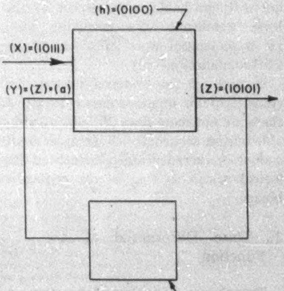

Fig. 2. Dynamic feedback

Table I. Operative Logic with Single Dynamic Feedback Loop

Logical Function (h) = (H₀ H₁ H₂ H₃)	(x) = (1)	Output Sequence (z) For (x) = (:01:)	Output Sequence (z) For (x) = (:1:)
$(h_2) = (0100)$	1	(:01:)	(:01:)
$(h_5) = (1010)$	111110	(:10:)	(:0:) trivial
$(h_6) = (0110)$	(:1:)	(:0011:)	(:10:)
$(h_8) = (1110)$	(:1:)	0101011	(:01:)
$(h_{11}) = (1001)$	(:10:)	(:0110:)	(:0:)
$(h_{12}) = (0101)$	1	(:01:)	(:1:) trivial
$(h_{13}) = (1101)$	(:01:)	(:01:)	(:1:)

Some elementary requirements for the design of such nets may be derived from a basic circuit. In the primitive case of Fig. 2 a sequential input (*x*) and the output (*y*) of a dynamic delay element is connected into a static logic with the function (*f*). Its output (*z*) is fed back into the delay element (*d*). To compute the output signal (*z*) the expansion theorem[2] may be used. A logic with two inputs (*x*), (*y*) is restricted to one of sixteen function matrices (*h*); see equation 2(C) of reference 2. The primitive circuit has two states only defined by the output signal Y_e of the delay element. Accordingly, the output signal (*z*) is correlated to the same states due to the feedback loop.

$$Z_e = f(H, X_e, Y_e) \tag{12A}$$

$$Y_e = Z_{e-1} \text{ for } (d) = (10) \tag{12B}$$

$$Z = H_0X'Y' + H_1XY' + H_2X'Y + H_3XY \tag{12C}$$

$$Z = Y'(H_0X' + H_1X) + Y(H_2X' + H_3X) \tag{12D}$$

Substituting for *Y* equation 12(B) and referencing in time yields

$$Z_e = Z'_{e-1}(H_0X_e' + H_1X_e) + Z_{e-1}(H_2X_e' + H_3X_e) \tag{12E}$$

The equation may be split into two wherein the first describes the condition for switching the signal (*z*) ON, and the second determines the condition to switch (*z*) OFF. For the latter relation some transformation is required.

$$Z_e = Z_{e-1}'(H_0X_e' + H_1X_e) \tag{12F}$$

$$\begin{aligned} Z_e' &= Z_{e-1}(H_2X_e' + H_3X_e)' \\ &= Z_{e-1}[(H_2' + X_e)(H_3' + X_e')] \\ &= Z_{e-1}(\cancel{H_2'H_3'} + H_2'X_e' + H_3'X_e + \cancel{X_eX_e'}) \end{aligned}$$

$$Z_e' = Z_{e-1}(H_2'X_e' + H_3'X_e) \tag{12G}$$

The first term $H_2'\,H_3'$ is irrevalent because function coefficients cannot operate one on another. Equations 12(F) and 12(G) specify the transition from one state into another because the signal Z_{e-1} is the input into the delay element and its state is delayed for one time increment only. Applying equations 3(A) and 3(B) to the paired equations yields eventually

$$\begin{Vmatrix} \dot{Z}_e \\ \dot{Z}_e' \end{Vmatrix} = \begin{Vmatrix} H_0 & H_1 \\ H_2' & H_3' \end{Vmatrix} \begin{Vmatrix} X_e' \\ X_e \end{Vmatrix} \tag{13}$$

This matrix is called transfer matrix and must comprise in each row of the (*h*) matrix at least a single ONE. The implication is of such significance that it is regarded as design criterion 1.

This restriction limits the number of useful functions of two variables to seven only as listed in Table I. Any other logic performed in a circuit according to Fig. 2 is either redundant or inoperative with respect to *Z*.

A sequence (*z*) may be computed with the aid of equation 13 by means of two equations only because of the single input (*x*) being either 0 or 1. The first line in Table I comprises the logic (h_2) = (0100) in the order of the function coefficients. H_2 and H_3 has to be complemented in equation 13 and it yields equations 14(A) and 14(B). Colons within brackets denote periodic sequences.

$$X = 1: \quad (\dot{z}) = \begin{Vmatrix} 0 & 1 \\ 1 & 1 \end{Vmatrix} \begin{Vmatrix} 0 \\ 1 \end{Vmatrix} = \begin{Vmatrix} 1 \\ 1 \end{Vmatrix} = \begin{Vmatrix} \dot{Z} \\ \dot{Z}' \end{Vmatrix} \tag{14A}$$

$$X = 0: \quad (\dot{z}) = \begin{Vmatrix} 0 & 1 \\ 1 & 1 \end{Vmatrix} \begin{Vmatrix} 1 \\ 0 \end{Vmatrix} = \begin{Vmatrix} 0 \\ 1 \end{Vmatrix} = \begin{Vmatrix} \dot{Z} \\ \dot{Z}' \end{Vmatrix} \tag{14B}$$

Z will be switched off for $X = 0$ and on or off for $X = 1$.

A feedback loop as shown in Fig. 3 comprising a static storage element as a flip-flop requires a set signal $\dot{Y}$ and a reset signal $\dot{Y}'$. Each signal may be generated by a separate logic *g* and *h*.

$$\dot{Y} = Y'(G_0X' + G_1X) + Y(G_2X' + G_3X) \tag{15A}$$

$$\dot{Y}' = Y'(H_0X' + H_1X) + Y(H_2X' + H_3X) \tag{15B}$$

The set signal $\dot{Y}$ is irrelevant for Y = 1 and similarly $\dot{Y}'$ for Y′ = 1. Higher reliability of the feedback loop will be assured for the condition $G_2, G_3, H_0, H_1 = 0$, which is stated as design criterion 2:

$$\begin{Vmatrix} G_2 & G_3 \\ H_0 & H_1 \end{Vmatrix} = 0 \tag{15C}$$

Similarly to equation 13, the transfer matrix for the trigger signals $\dot{Y}$ and $\dot{Y}'$ may be written

$$\begin{Vmatrix} \dot{Y} \\ \dot{Y}' \end{Vmatrix} = \begin{Vmatrix} G_0 & G_1 \\ H_2' & H_3' \end{Vmatrix} \begin{Vmatrix} X' \\ X \end{Vmatrix} \tag{16}$$

6. Transfer Function of General Networks

In the primitive case demonstrated, the transfer matrix is obtained as a 2-dimensional operator for the input variable *X*; it yields the differentials or trigger signals for a single storage element only. It has been shown, in equation 18 of reference 1, that the function matrices as such are the necessary and sufficient expressions for the behavior of a net and that the states or combinations are properly defined by the dummy index *i*. This concept gives the required flexibility to deal with nets of higher complexity.

For a general network as shown in Fig. 4 a set of independent inputs *X* and dependent inputs *Y* originated in feedback loops are considered. The conversion of a sequential input (*x*) into parallel is not significant in this context. The static logic has one set of exterior outputs *Z* and another set of interior outputs or trigger signals $\dot{Y} + \dot{Y}'$ controlling storage elements in the feedback loops. The logic (*f*) operates solely on the instantaneous combinations of all inputs *X* and *Y* to generate both sets of outputs $\dot{Y} + \dot{Y}'$ and *Z* respectively.

The dummy index *i* specifies the combination of all inputs $X + Y$, and accordingly the output, e.g.,

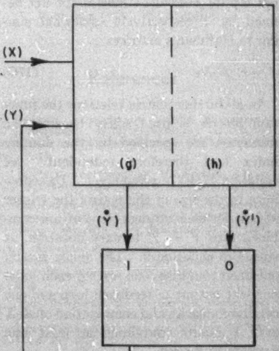

Fig. 3. General net

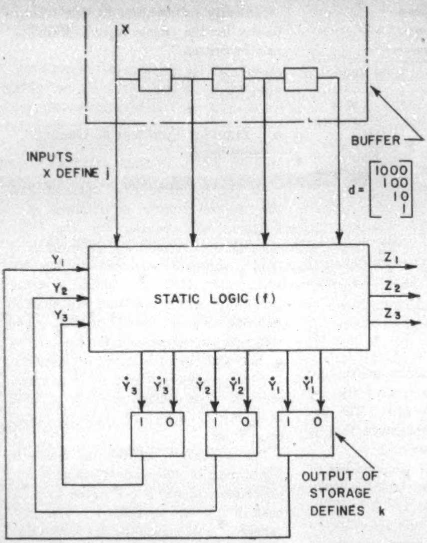

Fig. 4. Feedback with static storage element

$$Z_r = F_{ri} N_i \qquad (17A)$$

The minterm N_i may be divided into one minterm related to the independent input combination of X and another N_k for the dependent combination of Y.

$$N_i = N_j N_k \qquad (17B)$$

For convenience i may be written in such a form as to preserve the numerical terms for j, k. This allows the direct correlation to the states of the independent inputs X or the states of the net defined by Y respectively somewhat similar to Huffman's matrices.

$$Z_r = F_{rj} N_j N_k \qquad (17C)$$

In all further matrix relations the function matrix is used solely because the minterms are specified by the dummy index and therefore redundant; see equation 17(B) of reference 1. To economize in the size of the matrix the trigger signals for each storage element are combined into $\dot{Y} + \dot{Y}'$ ternary notation, as stated in equation 2. The single matrix obtained comprises one row for each independent output or feedback loop and one column for each valid combination of all X and Y inputs containing at least one nonzero coefficient.

A transfer function matrix of this type is the complete description of a sequential logic for its outputs and states depending on the imposed input conditions. The complete sequence of states and output signals may be derived from this matrix by operating on the dummy index $i = j,k$ according to each column. By writing the sequence of (i) similar to (9) the sequence of states is already specified by the section (k) of (i).

To demonstrate the method a frequently quoted problem has been chosen. It concerns the design of an indicator for the direction of rotation with a coded disk. Departing from the conventional concept of three segments, two half-circular arcs are contemplated displaced 90 degrees. From the brushes or photocells two pulse trains will be available and should cause a distinct signal Z for the direction denoted as negative.

Value of x	Positive Direction	Negative Direction
x_1	$=(:0110:)$	$=(:0110:)$
x_2	$=(:0011:)$	$=(:1100:)$

(18A)

The colon within the brackets may indicate that the pulse trains are periodic. According to the convention the least significant bits refer to an arbitrary zero-time increment. Its length depends on the speed of the disk and is irrelevant for a logic of ideal response. As an aid for discussion the individual inputs X_1, X_2 are listed below the index j.

$$i = \begin{cases} k = 0\,0\,0\,0 \;\; 1\,1\,1\,1 \\ j = 0\,1\,2\,3 \;\; 0\,1\,2\,3 \end{cases} \quad \begin{array}{c}\text{column}\\ \text{index}\end{array}$$

$$\begin{aligned} X_1 &= 0\,1\,0\,1 \;\; 0\,1\,0\,1 \\ X_2 &= 0\,0\,1\,1 \;\; 0\,0\,1\,1 \end{aligned}$$

$$Y = 0\,0\,0\,0 \;\; 1\,1\,1\,1$$

$$\left\| \begin{matrix} \dot{Y} + \dot{Y}' \\ Z \end{matrix} \right\| = \left\| \begin{matrix} 0 & 1 & 0 & 0 & 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \end{matrix} \right\| \qquad (18B)$$

One state j must be chosen to switch a storage element Y on, e.g., for $j = 1$, $\dot{Y} = 1$. Depending on the direction of the disk two sequences may be written as follows:

Positive direction:

$$(i+) = \left\| \begin{matrix} k \\ j \end{matrix} \right\| = \left\| \begin{matrix} :0\;0\;0\;0\;1\;1: \\ :0\;2\;3\;1\;1\;0: \end{matrix} \right\| \qquad (18C)$$

Negative direction:

$$(i-) = \left\| \begin{matrix} k \\ j \end{matrix} \right\| = \left\| \begin{matrix} :0\;0\;1\;1\;1\;0: \\ :0\;1\;1\;3\;2\;2: \end{matrix} \right\| \qquad (18D)$$

The behavior of the net is therefore completely described by the two rows of the transfer matrix; see equations 18(B). Redundancy elimination by means of the r-matrix (equation 9 of reference 2) is directly applicable. In conventional form the final design equations may be rewritten from the transfer matrix as follows:

$$\dot{Y} = X_1 X_2'$$

$$\dot{Y}' = X_1' X_2'$$

$$Z = Y X_2 \qquad (18E)$$

A circuit of this kind flashes a signal for the negative direction of the disk. If a permanent signal occurs the disk is at still stand with X_2 on.

7. Synthesis by Inversion

The ultimate goal of the previous analysis is a direct routine for synthesis of a network in order to produce a certain output sequence for a specified input sequence. A sequence (x) passing through a delay chain may always be substituted by the minterms (n) as presented to the logic (f). For each minterm N_{si} the output Z_s is already specified for the time increment s and may be transcribed directly. Only where contradiction exists a decision has to be made for the proper value of F_i. Expressing the process in matrix notation for the coefficients involved yields an inversion eventually. The operator : denotes an inversion. In this case it indicates that Z_s has to be referenced to N_{si} or the index (i) proper.

$$Z_s = N_{si} F_i \qquad (19A)$$

$$F_i = Z_s : N_{si} \qquad (19B)$$

$$(i) = (y)^* = [(x)(d)]^* \qquad (19C)$$

As an illustrative example a problem similar to the foregoing is used with the restriction that a single channel is available only to transmit a pulse train. The pulse train shall generate a signal for the sequence (x) and no signal for the reversed sequence $(x)^-$. According to Section 1 the sequence of minimum length must be found which is distinguishable from its reverse. Because the first and necessarily the last bit must be ONE, at least two more bits of complementary value must be inserted. Following are the desired output sequences (z):

$$(x)=(1101) \qquad (x)^-=(1011)$$

$$(z)=(11111) \qquad (z)'=(00000)$$

$$(i+)=\left\| \begin{array}{ccccccc} 1&1&0&1&&& \\ &1&1&0&1&& \\ &&1&1&0&1& \\ &&&1&1&0&1 \end{array} \right\| =(\mathit{10}, 14, \mathit{6}, 13, 5, 2, \mathit{1})$$

$$(i-)=\left\| \begin{array}{ccccccc} 1&0&1&1&&& \\ &1&0&1&1&& \\ &&1&0&1&1& \\ &&&1&0&1&1 \end{array} \right\| =(\mathit{10}, 4, 12, 15, \mathit{6}, 3, \mathit{1})$$

Comparing the sequences $(i+)$ and $(i-)$ three common terms *10*, *6*, *1* as italicized will be noted. The first and last one are irrelevant but *6* will be disallowed for (z) and therefore for this circuit the compromise for (z) = (10111) must be considered. Deriving the function matrix (f) connected to three delay elements from $(i+)$ and $(1-)$ is straightforward. Any *Fi* not relevant is marked — in order to indicate freedom in minimization.

$$(f)=(0010010-\ 0-0110-\!-)$$

Conclusions

Referring to the work by others on sequential circuits, Huffman is primarily concerned with asynchronous logic similar to relay circuits[5] while Mealy deals with synchronous systems related to electronic data processing.[4] Synchronism, literally speaking, implies coincidence in phase and pulse rate in that respect that pulse form, timing of pulse edges, and duration must conform to the standards established for the system. With increasing distances among the units of digital systems the phase condition cannot be maintained and has to be eventually abandoned. Remote inputs can be sampled locally but either the system must be able to process such data on line or buffer storage will be required. Open loop systems with delay chains are related to the broader concept of synchronous systems without phase restriction. Phase-controlled operation relieves the restriction specified in section 1.

Matrix algebra applied to the design of sequential logic has the advantage of a complete and explicit representation of a net adaptable to computer routines. The scope of the method is general enough to utilize multilevel logic and any type of operation either asynchronous or synchronized. Methods for analysis of matrix logic, the expansion by added input variables and the reduction routines derived previously, are directly applicable for sequential operations.

The examples used in the different phases were chosen for illustrative purposes only and are elementary. Actual design problems with the usual order of more than ten inputs and several feedback loops are definitely beyond the scope of this paper and depend on the available computer facilities. Desirable are binary computers with subroutines for logical operations and individual access to several 10,000 bits storage. Computers of low speed and restricted capacity may be improvised with sets of paper tape punches and readers with a separate counter for each unit recording the indexes i, j, and k. Subsequent papers are in preparation dealing with matrix routines for symmetric logic and simultaneous equations for logical functions.

Appendix. Glossary of Terms and Symbols

Symbols and notations used in this series on matrix algebra are compiled and referenced with respect to references 1 and 2, and to this paper. In the process of standardizing the symbols throughout the series some modifications were unavoidable and have been marked with an asterisk following the reference.

b=base or radix of positional notation.

(d)=delay matrix of coefficients D_e; output sequence of delay circuit during time increment e for a unit pulse as input at zero time; see equation 4.

e=time index for elapsed time increment since zero time in delay matrix (d) or transfer function; see equation 4.

(f)=function matrix of coefficients F_i defining the output of combinatorial logic for input combination N_i; see reference 1, equation 13.

$(f)'$=complement of (f); $(f)+(f)'=(1)$; $(f)^-{}'=(f')^-$; see reference 1, equation 13.

(g)=expanded function of coefficients G_i, G_j; see expansion theorem; see reference 2, equation 3.

i=dummy index denoting the coincidence condition of p binary inputs with each bit corresponding to one input; for binary inputs preferably in octal notation; see reference 1, equation 9(A).*

(i)=sequence of i; see equation 9.

j=dummy index similar to i; preferred for independent inputs; see reference 1, equation 11.

(j)=sequence of j; see equation 17(B).

k=index for states similar to i; see equation 17(B).

(k)=sequence of states; see equation 17(B).

(n)=minterm matrix for all coincidence conditions N_i of all inputs into combinatorial logic as defined by i; see reference 1, equation 8.

N_i, N_j, N_k=specific minterms; see equation 17(B).

p=number of input variables; see reference 1, equation 11; length of a sequence; see section 1.

q=time index in an input sequence; see equations 5 and 7.

r=row index; see equation 17(A).

(r)=redundancy matrix; see reference 2, equation 9.

s=time index of output sequence; mostly $s=e+q$; see equations 5 and 7.

$Y_s=F_{si}\times N_i$=matrix notation in Einstein convention; mostly dot product if not specified otherwise; see reference 1, equation 4(A).

(y)=function matrix for combinatorial output Y; see reference 1, equation 18.

$(y)^*$=transpose of (y); see equation 9.

$(y)^-$=reverse of (y); see reference 1, equation 14.*

$\dot{Y}$, $\dot{Y}'$=transition of logical function; see equation 2.

transfer function=composite matrix of trigger or transfer outputs into feedback loops and external outputs; see equations 13 and 16.

: =inversion; mostly referencing Z_s with respect to i as specified by N_{si}; see equation 19(B).

(: . . . . :)=periodic sequence; see equation 18(A).

( )=short notation for matrix in lieu of bold face type; see equation 4.

Simultaneous Logical Equations

Matrix Logic IV

E. J. SCHUBERT
ASSOCIATE MEMBER AIEE

Synopsis: A new method for reducing logical problems of higher complexity based on matrix logic is presented. Sets of propositions related to a set of constraints are transformed into minimum form without iterative simplifications. The savings in design effort and hardware for the eventual circuit are demonstrated in a reference problem.

THE DESIGN of a control unit of a digital computer with a minimum of hardware is a typically logical problem. The conditions to be satisfied are given in a table of control signals versus instructions. These control signals may be regarded as constraints and the instructions as propositions.

A constraint is said to be compulsory/disallowed if the proposition is affirmative/negative for this particular constraint.

In a recent publication, the fact has been contemplated that the total number of constraints be a valid measure for the complexity.[1] In that concept, propositions are divided arbitrarily into two groups, the first including propositions with a greater number of constraints and the second group including the remainder. The first group only is said to be correlated to minterms in one-to-one correspondence to constraints.

The object of this paper is to demonstrate a simpler algorithm without iterative simplifications, which may be most efficiently applied to any combinational problem of higher complexity. The matrix notation used throughout the paper has been derived in previous papers. Compared with any other notation, matrix logic offers the most explicit presentation directly correlated to complete truth tables, and it may be adapted to computer routines for problems of higher complexity.[2–4]

Merging of Sets

The design of digital machines implies the mechanization of decoders and encoders similar to control units with free choice of the instruction code. Any instruction corresponds to a proposition or a declarative statement specifying a subject in reference to a set of constraints or gating signals. Eventually the propositions have to be reduced to logical nets which perform equivalent logical functions on input signals. The advantage of matrix notation has been demonstrated as a concept for processing complete truth tables efficiently. Such truth tables define a certain coincidence condition of the input variables by the index i of a minterm N_i, and express the binary output Y_z by the dot product of coefficients F_{zi} and N_i.

Propositions Y_z may be defined with respect to the constraints Z_k by a matrix of coefficients C_{zk}. The difference between logical functions and propositions is the fact that the latter are governed by ternary sets. The purpose of the proposed method is the correlation of ternary set functions c defining the outputs Z_k with respect to the inputs Y_z.

Any problem may be stated in sets of outputs Z_k depending on a set of encoding inputs Y_z. The solution implies a set of simultaneous equations of unions.

$$Z_k = \bigcup_z C_{kz} Y_z \tag{1}$$

The merits of the design depend on the correlation between m and k or the eventual transformation T_{km} of Z_k into Z_m.

$$Z_m = \bigcup_z C_{mz} Y_z \tag{2}$$

$$C_{zm} = C_{zk} T_{km} \tag{2A}$$

$$(c_m) = (c_z)(t) \tag{2B}$$

To find a suitable transform (t), the matrix (c) must first be defined.

The outputs Z_k, Z_m are binary signals similar to the input Y_z. These logical functions Z_k must satisfy the propositions Y_z in such a way that all constraints C_{zk} are met. Frequently a number of constraints is irrelevant in some of the propositions. This irrelevance of constraints is an additional but single state over the b states the logical functions may assume. Therefore a base $b+1$ is necessary and sufficient to describe propositions in terms of C_{zk} in a system of linear forms with the use of matrix algebra.

Consistent with numbering conventions the following symbols are proposed for binary logic and the corresponding ternary constraints:

Symbol	Binary Logic	Ternary Logic
0	false	false
1	true	true
2		irrelevant

To process ternary coefficients, operators have to be defined as in binary logic. Besides the three basic operations NOT, AND, and OR, the IDENTITY operation is introduced and denoted by $\equiv$.

NOT

C	C'
0	1
1	0
2	2

(3A)

AND

AB	0	1	2
0	0	0	0
1	0	1	1
2	0	1	2

(3B)

OR

$A+B$	0	1	2
0	0	1	2
1	1	1	2
2	2	2	2

(3C)

IDENTITY

$A-B$	0	1	2
0	1	0	1
1	0	1	1
2	1	1	1

(3D)

For any contradiction the identity function is zero, $A \equiv B = 0$.

Theorem I: Constraints common to several propositions may be merged into a single constraint, providing there is identity in the individual terms.

An output Z_k depending simultaneously on several propositions Y_z may be regarded as a vector with the components C_{zk}. Because of the peculiar feature of irrelevance any component denoted by the symbol 2 is not defined and constitutes a degree of freedom. Those components with values 0 or 1 are fixed. Any two vectors may be merged into a single one as long as the components in k are either identical or at least one of the components has the value 2.

The convention is established that the matrix is written with the column index k numbering the constraints and the row index z denoting the individual propositions. This z-by-k matrix of coefficients

C_{zk} of radix $b+1$ is called the (*c*) matrix of constraints.

Theorem I implies that any two columns of (*c*) may be merged providing that all elements in the columns satisfy equation 3(D) or

$$C_k \equiv C_{k+j} = 1 \qquad j \geq 1 \tag{4A}$$

Therefore the shifted index $k+j$ is discarded and the merged coefficients $\bar{C}_k$ are governed by ternary operations:

$$\bar{C}_k = (C_k \equiv C_{k+j}) \bigcap_z C_{kz} C_{(k+j)z} \tag{4B}$$

This reduced matrix should be reordered from C_{kz} into C_{mz}.

Similarly one instruction might be the subset of another, and therefore superfluous. Accordingly the matrix C_{mz} must be transposed and processed in the same way towards C_{rm}; r is the new order superseding z. The restored matrix C_{mr} is a reduced form and should comprise a lesser number of coefficients than the original matrix C_{kz}.

Nonredundant Encoding

To establish an algorithm for an optimum binary code of Y_z requires a measure for the significance of useful coefficients C_{mz} or C_{kz} respectively. Eventually the logical functions $Y_d = Y_d(X_d)$ are found which provide a unique code.

Theorem II: A nonredundant code for redundant words comprises the bits with the highest entropy only.

The entropy H_k describes the probability distribution of ZERO's and ONE's in the set C_{zk} for i_k ONE's in the total number of n words.

$$H_k = p_k \log p_k + (1-p_k) \log (1-p_k); \quad p_k = i_k/n \tag{5A}$$

This function has a maximum at $p = 0.5$:

$$dH = 0 = \log p - \log (1-p)$$
$$p/(1-p) = 1; \; p = 0.5 \tag{5B}$$

A more convenient relation with a maximum of the same value is

$$p_k(1-p) = i_k(n-i_k)/n^2 \tag{5C}$$

Because n is constant, the numerator suffices:

$$D_k = i_k(n-i_k) \tag{6}$$

Theorem III: The sole measure for the significance D_k for decoding purposes, called rank of a bit k, is the number i_k of ZERO's or ONE's in bit k, whichever is less. Bits of rank zero are trivial.

In a function (*f*) the number of nonzero terms may be denoted by $|F|$. If (*f*) depends on p variables then the total number of terms either true or false is given as

$$|F| + |F'| = 2^p \tag{7}$$

where $|F|$ is the number of coefficients $F_i = 1$.

Any function requires for its realization not more minterms/maxterms than the number of ONE's/ZERO's.[3] Accordingly, the number of required terms eventually depends on the lesser of $|F|$ or $|F'|$. The statement of equation 7 is true for the whole system and indistinguishable for any function. Therefore the sum of constraints in any proposition is irrelevant for any classification of one proposition with respect to another.

An order d of the bits k (or m) can be established corresponding to the rank D_k in such a way that the bits are sorted properly as to their significance for decoding. Most significant bits may be placed to the leftmost side of the words; the least significant bits are expected to be irrelevant or redundant.

Theorem IV: Any set of coded words is uniquely distinguishable, if discrimination within the pairs of "most similar" words is possible. Two words are most similar if they are adjacent in numerical order, and if they are considered as numbers written in order of rank D_k.

Sufficient for proper discrimination is a difference in at least a single bit of two most similar words. If there is a difference in more than one bit, the discrimination in the bit of highest rank is preferable. This rule will assure that bits with highest probability or significance will be considered for the nonredundant code of Y_z or Y_r.

Optimization of Implicit Codes

A set of words with some unspecified bits may be designated as an "implicit code." This code is ternary according to matrices 3(A), (B), (C), and (D). Discrimination of two such code words is possible only if, for at least one bit k, the identity function 3(D) vanishes.

d	2	3	1	7	6	4	5

* maximum value for D_m possible

$$\bigcap_k C_{kz} \equiv C_{k(z+j)} = 0 \tag{8}$$

A quantitative discrimination depends on the algebraic relation

$$\sum_k 1 - C_{kz} \equiv C_{k(z+j)}) = E_{z:z+j} \tag{9}$$

Providing one of the words C_z comprises several irrelevant bits $C_{kz}=2$, E may be increased by replacing in these bits 2 by 0 or 1 according to equation 10.

$$\bar{C}_{kz} = (C_{kz} \equiv C_{k(z+j)})(1 - C_{k(z+j)}) \tag{10}$$

Theorem V: In an implicit code with some bits unspecified in some words, a bit k must be considered as possibly of highest rank if neither the number of ZERO's nor ONE's exceeds half of the number of words.

The significance of any bit k was previously defined by D_k in equation 6. If a bit or column k comprises at least irrelevant entries 2, then the upper bound for D_k is

$$\text{for } t \geq n/2 - i_z > 0;\ D_k \leq n^2/4 \tag{11}$$

Depending on system requirements for the final code, any 2 may be replaced by 0 or 1 to improve discrimination in equation 9. It is therefore possible that the eventual distribution of 0's and 1's yields the maximum D_k. In some cases, where the instruction code must operate the gates directly without any auxiliary control units, all the bits must appear in the instructions.

Application to Design of Control Unit

Based on theorems I through V, the following steps are suggested for the solution of logical design problems involving simultaneous propositions related to a larger number of constraints. The prime objective is to establish and maintain consistent orders throughout all steps.

1. Formulate the propositions Y_z in matrix coefficients C_{zk} with respect to the constraints Z_k.
2. Merge constraints by the operation described in equation 4(A) and (B), transforming C_{zk} into C_{rm}, correlating r to z and m to k.
3. Determine ranks of variables X_d by equation 6, correlating d to m to k.
4. Reorder C_{rm} into C_{rd} and sort as sequence of ternary numbers.
5. Determine difference of adjacent words in the most significant bit d only.
6. Retain for code of Y_z or $Y_r = Y(X_d)$ only those bits d in which a difference occurs.
7. The remaining outputs Z_m must be formed as logical function $Z_m = Z_m(X_d)$.

To evaluate the merits of this approach, a design problem is taken from a recent publication and described in Table I.[1] Ten instructions Y_z ($z=1, \ldots 10$) are given with respect to 20 gating signals Z_k ($k=1, \ldots 20$). Irrelevant conditions are entered as 2.

In Table II all columns are evaluated taking two columns at a time with respect to identity 4(A). Starting from the left, the columns $k=1$, 2 remain isolated. Column $k=3$ can be merged with all other columns marked $m=\bar{3}$. Merged coefficients according to equation 4(B) have to be entered accordingly. This procedure reduces the 20 original columns in order k to 7 columns on order m. This process is repeated for the rows in Table III and eliminates $z=9$, 10 by $r=\bar{6}$, $\bar{7}$ respectively.

To determine the significance of the bits m for decoding purposes a count of 0's and 1's is made in Table IV. Whenever theorem IV applies, an asterisk is inserted for D_m. The rank is the highest for $D_3=16$ ($m=3$), and accordingly assigned to $d=1$. Those bits marked by an asterisk are possibly of highest rank also, and are therefore placed in consecutive order $d=2, \ldots 5$.

Table VI. Minimum Code

	INPUT			OUTPUT			
d	1	2	3	4	5	6	7
s= 1	0	0	0	.	0	0	0
2	0	$\bar{1}$	0	.	.	1	0
3	0	$\bar{0}$	$\bar{1}$	1	1	0	0
4	0	1	1	0	0	0	0
5	1	0	0	1	.	0	0
6	1	1	$\bar{0}$	1	.	0	0
7	1	1	1	0	0	1	1
8	1	$\underline{0}$	$\underline{1}$	1	.	1	0
m	3	1	2	6	7	5	4
k				1	2	1	
	3	1	2	9	0	7	4
				Z_m			

After reordering in d corresponding to their ranks in Table V, the words are sorted according to their similarity. Index $s=1$ designates the word $r=5$ as the lowest binary number.

The final matrix C_{ds} may be adapted to comply with system specification for the input code proper. For a minimum code for eight words, with three bits $d=1$, 2, 3, some additional entries $\bar{0}$, $\bar{1}$ are essential, as shown in Table VI. The inputs will operate the output signals $m=1, 2, 3$ directly. Remaining outputs must be formed in an encoder matrix.

If systems specifications demand a given code, e.g., Teletype for the instructions, the first five bits $d=1, \ldots 5$ may be matched with appropriate Teletype symbols. Then, two additional outputs $m=4$

Table VII. Matched Code

(Five-Bit Teletype Code)

	INPUT					OUTPUT		TELETYPE CODE
d	1	2	3	4	5	6	7

6	1	1	$\bar{0}$	0	$\bar{1}$	0	1	W
7	1	1	1	0	0	1	1	U
8	1	$\underline{1}$	$\underline{1}$	1	$\underline{0}$	1	0	K
m	3	1	2	6	7	5	4	
k				1	2	1		
	3	1	2	9	0	7	4	
						Z_m		

Vol.
Pt. 1
1959

5 are required only, because the inputs are identical with five outputs, as illustrated by Table VII.

Conclusions

Drastic reductions in simultaneous logical equations can be achieved by merging constraints without contradiction. These reduced forms may be coded efficiently, depending on the symbol distributions within the code bits. Direct applications of this approach are the design of control units or code translators.

The explicit algorithms are easily adaptable to computer programs for logical design routines with a modest demand on memory capacity.

Further improvements of this approach are under investigation, particularly to establish a unique order in k and z prior to merging. These orders are related to the distribution of the coefficients C_{zk}.

Symmetric Switching Functions

Matrix Logic V

E. J. SCHUBERT
ASSOCIATE MEMBER AIEE

Synopsis: Symmetric logical functions are classified in ordinary and threshold function. The first class is defined as being operative for only k of p inputs being active. Threshold functions are operative for at least k of p inputs. Ordinary symmetric and threshold functions are mutually related and one class may generate functions of the other class. Transistor circuits are already extensively used to perform threshold functions in form of resistor-coupled nonlinear amplifiers. Recently a new logical element has been conceived which performs ordinary symmetric logic. To evaluate the merits of these logical elements efficiently a method has been developed which may be adapted to logical design by computer routines. Solution of problems involving up to ten variables is feasible without the aid of computers.

COMBINATIONS of inputs which are irrespective of any preference or relative position of one input to another are commonly known as symmetric switching functions. A typical logic of this type is an output depending on any two out of five inputs.

The significance of these logical functions was due to the economy in the design of relay networks using transfer contacts.[1] High-speed logic based on solid state components has no direct equivalent to the transfer contact and therefore the concept of symmetric functions has been neglected.

Ordinary Symmetric Function

A symmetric function depending on k and only k active inputs, out of the total number of p inputs, may be called ordinary, and corresponds to the combinations of p different things, all different, taken k at a time:

$$_pC_k=\binom{p}{k}=\binom{p}{p-k} \tag{1}$$

Conventional logic elements are described by the primitive relations for which one and only one combination is unique. The mathematical interpretation for C is correct for both extremes $k=0$ and $k=p$ respectively. The first case describes the inhibited buffer, the second case the operative gate.

In the canonical form any function Y_z may be represented by the sum of minterms or the product of maxterms. A minterm N/maxterm M is any one of the 2^p distinct AND/OR conditions of all p variables X, in which these variables are or are not complemented in any of the 2^p possible ways.[2] The suffix i of N or M is the octal equivalent of the binary number formed by writing ZERO for each complemented variable and ONE for each uncomplemented variable, in the order of their appearance.

In the preferred matrix presentation functions are sums of minterms.[3] A binary coefficient F_i indicates if the minterm N_i is applicable for the function Y_z, or expressed in matrix notation:

$$Y_z=F_{zi}N_i \qquad (y)=(f)(n) \tag{2}$$

To recognize an ordinary symmetric function in this form depends on two conditions to be met by the suffixes i:

Rule 1: The number of minterms involved must be equal to a binomial coefficient as defined in equation 1.

Rule 2: In this set of minterms one and the same input must occur as often as any other input.[4] The subset of minterms comprising one and the same input are the combinations of $p-1$ things, taken $k-1$ at a time, or

$$_{p-1}C_{k-1}=\binom{p-1}{k-1} \tag{3A}$$

As a typical example a function of five variables is given in the form

$$Y=N_{17}+N_{27}+N_{33}+N_{35}+N_{36} \tag{3B}$$

For convenience the suffixes are written in octal notation and easily converted into binary:

$$\begin{array}{ll} 17\ (\text{o}) & 01\ 111 \\ 27\ (\text{o}) & 10\ 111 \\ 33\ (\text{o}) & 11\ 011 \\ 35\ (\text{o}) & 11\ 101 \\ 36\ (\text{o}) & 11\ 110 \end{array} \tag{3C}$$

Only two binomial coefficients of a set, $p=5$, are equal to the number 5 corresponding to the number of terms:

$$\binom{5}{1}=\binom{5}{4}=5 \tag{3D}$$

The occurrence of active inputs is obtained as the sum, digit 4 in rule 2, from the foregoing tabulation of the binary suffixes. Only the second binomial coefficient satisfies equation 3(A):

$$\binom{5-1}{4-1}=\binom{4}{3}=4 \tag{3E}$$

Accordingly it can be stated that the function describes an output being operative for four out of five inputs. To express this relation in short form the bino-

	10	1	10	45	120	210	252	210	120	45	10	1

mial coefficient is suggested to be used as a function symbol:

$$Y=\binom{p}{k}X \qquad (3F)$$

The complexity of a symmetric function is characterized primarily by the term k. Referring to a symmetric function by its degree specifies the term k irrespective of p.

Threshold Function

A function describing an output being operative for any combination of at least k out of p active inputs is called a threshold function. It is a composite function comprising a number of ordinary symmetric functions. A corresponding binomial coefficient yields

$$T=\binom{p}{\geq k}X=\binom{p}{k}X+\binom{p}{k+1}X+\ldots+\binom{p}{p}X \qquad (4)$$

Solid-state circuitry lends itself to threshold functions. To form an ordinary symmetric function by means of threshold functions, equation 4 is transformed as follows:

$$\binom{p}{\geq k}X=\binom{p}{k}X+\binom{p}{\geq k+1}X \qquad (5A)$$

Substituting for the threshold functions T_1, T_2 respectively, and S for the ordinary symmetric function, yields

$$T_1=S+T_2 \qquad (5B)$$

$$T_1T_2'=ST_2'+T_2T_2' \qquad T_2T_2'=0$$

$$S=T_1T_2' \qquad (5C)$$

After manipulating on equation 5(B) and substituting in equation 5(C) the equation for the ordinary symmetric function generated by threshold functions is obtained:

$$\binom{p}{k}X=\binom{p}{\geq k}X\binom{p}{\geq k+1}'X \qquad (5D)$$

Equation 5(D) describes the coincidence of a threshold function of at least k of p inputs with the complemented threshold function of at least $k+1$ of p inputs to produce the ordinary symmetric function of k out of p inputs.

Matrix Algebra

Any function of p variables may be expressed by equation 1 wherein i is within the bounds of 0 and $2p-1$. The principles of matrix algebra modified for logic have been published previously and are therefore considered as known for the derivation to follow.[3, 5]

A symmetric function may be written in matrix notation:

$$\binom{p}{k}X=F_{ki}N_i \qquad (6)$$

$$F_{ki}=1 \qquad \text{if } k=0, \qquad \text{then } i=0 \qquad (6A)$$

$$\text{if } k\neq 0, \quad \text{then } i_q=\sum_q 2^{n}q \qquad (6B)$$

$$1\leq q\leq {}_pC_k \qquad (6C)$$

$$0\leq n_q\leq p-1 \qquad (6D)$$

According to the definition of the symmetric function the suffixes i are the binary numbers obtained by combining k ONE's in a p bit word. Table I contains the binomial coefficients for $p\leq 10$ to determine the number of terms and/or suffixes to be calculated.

A threshold function differs in its matrix in the equation for the suffix only according to the definition that the binary number is necessarily the combination of at least k ONE's in a p bit word.

$$1\leq q\leq \sum_r {}_pC_r \qquad (7A)$$

$$k\leq r\leq p \qquad (7B)$$

The conditions for unequal exponents n_q and their bounds are as in equation 6. In Table II the sum of the binomial coefficients similar to 4 is listed as a check for the total number of terms and/or suffixes involved.

In Table III the matrices for a set of four variables are listed. The suffixes are written in octal notation, ZERO's are deleted whenever possible. Lines 1 through 4 contain the states of the variables. With respect to the ordinary symmetric function in line 8, the function coefficient F_{ki} must be ONE for any two but only two input variables being ONE.

NEGATION

A proposition being true for any combination of p things taken k at a time may still be satisfied for another proposition of $p-k$ things taken at the same time. Coincidence is definitely excluded for one proposition being true for p things taken k at a time and another proposition taking $p-k+1$ things at the same time. This logical statement is directly verified by "reversed" function matrices and may be stated in terms of threshold functions.[3]

Vol.
Pt. 1
1959

$$\binom{p}{\geq k}' X_p = \binom{p}{\geq p-k+1}^{-} X_p$$

$$= \binom{p}{\geq p-k+1} X'_p \quad (8)$$

The significance of this relation is in the equivalence of two threshold functions of different degree. In another paper the need for symmetric functions of the lowest degree has been demonstrated.[6]

In Table I, line 13, is the threshold function for at least two of four active inputs X. Its complement is line 16, and it is the reversed function of at least three of four active inputs (line 12) or equivalent to the threshold function of at least three of four complemented inputs.

$$\binom{4}{\geq 2}(X_4X_3X_2X_1) = \binom{4}{\geq 3}^{-}(X_4X_3X_2X_1)$$

$$= \binom{4}{\geq 3}(X_4'X_3'X_2'X_1') \quad (9)$$

AND Operation

Two ordinary symmetric functions of the same set but of different degree are disjoint because any minterm can be a combination of only k of p things at a time:

$$\binom{p}{k}X_p\binom{p}{m}X_p = 0 \quad k \neq m; \quad 0\ldots\text{false} \quad (10)$$

On the other hand, any threshold function gated against an ordinary symmetric function yields the latter only if the first one is of higher degree:

$$\binom{p}{\geq k}X_p\binom{p}{m}X_p = \binom{p}{m}X_p \quad k \geq m \quad (11)$$

This relation is directly obtained from equation 4.

OR Operation

Because ordinary symmetric functions of the same set but of different degree are disjoint, the union is nonredundant. The test of the suffixes of such a union of two ordinary symmetric functions would satisfy rule 1 but not rule 2.

Normalized Symmetric Matrix

Any symmetric switching circuits designed for k of p inputs will perform properly for the specified number of k inputs irrespective of p. Accordingly the number k may be mapped into the minterms designated by the dummy index i similar to equation 1.

Table III. Symmetric Function Matrices (F_{ki})

\end{array}$$

$$\|P_{ki}\| = (0112 \;\; 1223 \;\; 1223 \;\; 2334)$$

It has been shown previously that symmetric functions of different degree are disjoint or that each minterm occurs in a single symmetric function only. Instead of writing five matrices for different k's a single matrix, $\|P_{ki}\|$ may be formed by designating each minterm with the appropriate value of k. A significant feature of this matrix $\|P_{ki}\|$ is its symmetry if written in quadratic form.

$$|P_{ki}| = \left\|\begin{matrix} 0 & 1 & 1 & 2 \\ 1 & 2 & 2 & 3 \\ 1 & 2 & 2 & 3 \\ 2 & 3 & 3 & 4 \end{matrix}\right\| \quad \text{normalized symmetric matrix} \quad (13)$$

The $\|P_{ki}\|$ matrix has been developed for $k=10$ and is shown in Table IV. It is essentially a truth table of symmetric functions with $p=10$, independent variables replacing the true value ONE for the appropriate value of k. The reference frame in i_x and i_y is in octal notation wherein the two pairs of octal digits are interchangeable because of the symmetric feature of the $\|P_{ki}\|$ matrix.

Expansion of Symmetric Functions by Cascading

Two logical blocks are considered, the first with p inputs and a function (f), the second one with $q+1$ inputs and a function (h). The output (f) of the first block is connected to one input of the following block. The output (g) of the second block must be a Boolean function of $p+q$ variables.

A cascade of two symmetric functions implies that an output (g) from the second block will be possible under following conditions only:

$$\text{for } \binom{p}{k_1} = 0 \qquad \binom{q}{k_2} = 1$$

$$\text{number of active inputs: } k_2 \quad (14A)$$

$$\text{for } \binom{p}{k_1} = 1 \qquad \binom{q}{k_2-1} = 1$$

$$\text{active inputs: } k_2 - 1 + k_1 \quad (14B)$$

$$(g) = \binom{p}{k_1}'\binom{q}{k_2} + \binom{p}{k_1}\binom{q}{k_2-1} \quad (14C)$$

In the first case, equation 14(A), the number of active inputs required is k_2; in the second case, 14(B), the output from the first block is operative with k_1 and therefore k_2-1 active inputs into the second block are permissible. The resulting output (g) does not represent a symmetric function any more.

It has been shown that a basic matrix relation called the expansion theorem exists for any cascade of logical functions.[5]

$$(g)=(h)\left\|\begin{matrix} f' \\ f \end{matrix}\right\| \tag{15A}$$

In a particular example two symmetric functions (f), (h), may be cascaded by using the relation 15(A).

$$(f)=\binom{3}{2}=(00010110)$$

$$(h)=\binom{3}{1}=(01101000)$$

$$(g)=\left\|\begin{matrix} 0 & 1 \\ 1 & 0 \\ 1 & 0 \\ 1 & 0 \end{matrix}\right\| \left\|\begin{matrix} 11101001 \\ 00010110 \end{matrix}\right\| = \left\|\begin{matrix} 00010110 \\ 11101001 \\ 11101001 \\ 11101001 \end{matrix}\right\| \tag{15B}$$

The cascaded output (g) is an unsymmetric function as predicted.

Reduction of a Function Matrix by Symmetric Logic

Function matrices are complete truth tables in an orderly notation. Routines for processing, analyzing, and generating such function matrices have been derived elsewhere.[7, 8] Any function matrix (f) is the sum of other matrices (s), (t), (u); wherein (s) represents ordinary symmetric functions, (t) threshold functions, and (u) the remaining unsymmetric functions.

$$(f)=(s)+(t)+(u) \tag{16}$$

To extract the part $(s)+(t)$ from (f) all coefficients F_{zi} must be inspected and compared with the normalized symmetric function. If for a certain value of k all or most of its coefficients $P_{ki}=k$ coincide with some F_{zi}, then this part of (f) may be efficiently covered by a symmetric function $\binom{p}{k}$. Equations 4 and 5(A) among threshold and ordinary symmetric functions should be considered if applicable. A typical problem for six variables is solved in the Appendix.

As repeatedly shown, the function matrix should be specified to the extent only as 0's and 1's are significant. Irrelevant combinations of i should therefore be designated requiring a ternary notation for (f). In the Appendix irrelevant states are denoted by x. (For an exact treatment of binary function matrices and ternary propositions see reference 8. In this context the loosely defined ternary notation is used only to explain reduction methods.)

The dot product of $(f)\ \|P_{ki}\|$ is governed by the following relation:

$$\frac{F_i=0,1}{(f)\|P_{ki}\|=\cancel{k},k}$$

Conclusions

An extensive study of symmetric functions reveals their merits for solid-state logic and in particular for logical elements performing threshold functions. Cascaded symmetric switching circuits do not perform symmetric functions.

The generalized method is applicable to large-function matrices and permits, eventually, the evaluation of symmetric functions for problems of up to ten variables without the aid of computers. Computer routines for automation of logical design are the subject of continuing investigations and will include programs for the reduction of function matrices by means of symmetric logic.

Appendix. A Design Problem

A logical function (f) of six variables is given. x in the matrix denotes irrelevant combinations which may be either 0 or 1. Because there are fewer 1's than 0's the coefficients being 1 are multiplied with the normalized symmetric matrix $\|P_{ki}\|$.[3]

$$\begin{array}{cc} & \begin{matrix} 0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 \end{matrix} \\ (f)= & \left\|\begin{matrix} 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 \\ x & 1 & 1 & 0 & x & x & 0 & x \\ 0 & 1 & 1 & x & 1 & x & x & x \\ 1 & 0 & 0 & 0 & 0 & 1 & 1 & 0 \\ x & x & 1 & x & x & x & x & x \\ 1 & 0 & 0 & 1 & 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 & 0 & 0 \end{matrix}\right\| \begin{matrix} 0 \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \end{matrix} \end{array}$$

$$(f)\|P_{ki}\| = \left\|\begin{matrix} & & & 2 & & 2 & 2 & \\ & 2 & 2 & & & & & \\ & 2 & 2 & & 2 & & & \\ 2 & & & \cancel{4} & & 4 & 4 & \\ & & 2 & & & & & \\ 2 & & & 4 & & 4 & 4 & \\ 2 & & & 4 & & 4 & 4 & \\ & 4 & 4 & & 4 & & & \end{matrix}\right\| \begin{matrix} 0 \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \\ 7 \end{matrix}$$

In the result one term is disallowed as indicated by $\nmid$. The term may be readily identified as the minterm N_{33} from the octal indexes of row and column. By definition the minterm N_{33} is the short form of the input coincidence 011011≡33 in octal notation. Accordingly the function (f) may be regarded as the sum of two symmetric functions with the restriction of N_{33} on $\binom{6}{4}$

$$(f)=\binom{6}{2}+\binom{6}{4}N_{33}'$$

Some Multihorned Dilemmas in the Magnetic Field

F. AVČIN
NONMEMBER AIEE

ENGINEERS do not like problems in units and dimensions if the discussion of them is likely to upset the concepts they learned in school. They usually shrug off such matters as "metaphysical." Unfortunately, there are enough theoretically minded scientists and engineers who insist on thinking and talking about such things to produce a continuing situation well represented by an old proverb: *Quot capita, tot sententiae* (From many heads, many opinions).

Nowhere is this better demonstrated than in the deliberations of Technical Committee 24, Electric and Magnetic Magnitudes and Units, International Electrotechnical Commission (IEC), particularly in relation to fundamental quantities that describe the magnetic field. The author has been closely involved in recent deliberations and has observed the epidemic of the malady *oersteditis acuta* which has spread among national committees.

It is the author's hope that the discussion which follows may clarify some of these problems, particularly with respect to those concerned with the magnetic field intensity H and its various cgs (centimeter-gram-second) and mksa (meter-kilogram-second-absolute) units, the oersted in particular. Perhaps there is here a lead to the cure of the disease. *Ne spes me faleret!* (Perhaps my hope might not deceive me!)

For this purpose it is necessary to adhere to a process of simple, careful exposition with numerical examples; complicated presentation, intricate logic, and especially lack of practical examples are to be avoided.

Background

Early experiments with magnetized needles led to Coulomb's equation defining the forces acting between point magnetic poles p:

$$\mathbf{F}=\mathrm{k}\frac{p_1p_2}{r^2}\mathbf{r}_0=p_1\mathbf{H} \tag{1}$$

where quantities are indicated in italics, measures in roman, and vectors in boldface. This equation also defines the magnetic field intensity H (also called, to the confusion of several generations of students, magnetic field strength and magnetizing force). This definition of $H=\mathrm{k}p/r^2$ is associated with the concept of "action at a distance," operating on a pole without the intermediary of the surrounding medium, like gravitation according to early concepts.

For magnetic fields produced by electric currents, equation 1 has its counterpart in the classical definition:

$$\mathbf{H}=-I\nabla\Omega \tag{2}$$

where Ω is the solid angle subtended, at the point where H is observed, by the current loop with current I. From equation 2 the value of H at the center of a long, uniformly wound solenoid can be directly derived:

$$H=4\pi\frac{NI}{l} \tag{3}$$

where N/l is the number of turns per unit length.

In 1882, Oliver Heaviside, a revolutionary in many areas of physics, mathematics, and engineering, realized that it is confusing (should we invent a word: "unrational"?) to find the factor 4π, which derives from spherical symmetry, in equation 3, which is concerned with a problem that might be called linear. He noted similar anomalies in other cases, both in electrostatic problems and electromagnetic problems. Therefore, he wrote equation 3:

$$H=\frac{NI}{l} \tag{4}$$

and, proceeding backward,

$$\mathbf{F}=\mathrm{k}\frac{p_1p_2}{4\pi r^2}\mathbf{r}_0 \tag{5}$$

This apparently arbitrary procedure leads to an interesting idea. From equation 5 it appears that

$$\mathbf{H}=\mathrm{k}\frac{p_2}{4\pi r^2}\mathbf{r}_0$$

represents the pole p_2 as having a (uni-

Paper 59-1187, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted December 3, 1958; made available for printing August 11, 1959.

F. Avčin is with the University of Ljubljana, Ljubljana, Yugoslavia.

The author is greatly indebted to Dr. Francis B. Silsbee, Chief, and Irwin L. Cooter, Raymond Sanford, and Chester Petersen, staff members, Electricity and Electronics Division, National Bureau of Standards, as well as to Dr. Carl C. Chambers, vice-president for Engineering Affairs, University of Pennsylvania, with whom he has discussed much of the Technical Committee 24, IEC, problems, and to Dr. S. Reid Warren, Jr., who gave this paper a digestible form.

This paper is derived from presentations at two colloquies held April 26, 1957, at the Moore School of Electrical Engineering, University of Pennsylvania, Philadelphia, Pa.; and April 29, 1957, at the National Bureau of Standards, Washington, D. C.

form) influence over a sphere of radius r; i.e., this is representative of the modern field concept involving the active participation of the medium, as contrasted with the obsolete action-at-a-distance concept.

Since the force $\mathbf{F}$ is the same, regardless of whether equation 1 or equation 5 is chosen, something has to give. Heaviside simply charged the units of magnetic pole strength by the factor $\sqrt{4\pi}$. In the cgs electromagnetic system, the unit pole in equation 1 is 1 cm (centimeter)$^{3/2}$-gm (gram)-second^{-1}, if k is dimensionless. Heaviside used the unit pole in equation 5 as $\sqrt{4\pi}$ cm$^{3/2}$-gm$^{1/2}$-second^{-1}, with k dimensionless. This was the first case of what is now called "rationalization by units."

Crux of the Problem

Now the trouble begins.

From equation 2 the classical definition of H gives $[H]=1$ abampere-steradian per centimeter (where [] is used to mean unit of), which, since there are 4π steradians in a unit sphere and 1 abampere equals 10 amperes, reduces to $10/4\pi$ ampere per cm. This nonrationalized unit of magnetic field intensity H is called the "oersted" by the majority of engineers and scientists, and so in most textbooks one finds:

$$1 \text{ oe (oersted)} = 10/4\pi \approx 0.8 \text{ ampere per cm (or ampere-turns per cm)}$$

This type of oersted may be called the "people's oersted" because of its popularity. It is dimensionally inconsistent with the fundamental units: centimeter-gram-second of the cgs system.

The dimensionally consistent and rationalized cgs unit of magnetic field intensity is 1 cm$^{-1/2}$-gm$^{1/2}$-second$^{-1}=10$ amperes per cm (or 10 ampere-turns per cm); it is 4π times larger than the people's oersted. It is believed that the IEC named this unit (10 amperes per cm) the "oersted" in 1930; however, eyewitnesses to that meeting differ in opinions except to agree that Oersted's name was bestowed upon the unit of the quantity "magnetic field intensity H," whatever it was or is.

Today we are led by modern concepts to look upon Coulomb's law of forces between magnetic poles as a useful approximation because we accept the hypothesis of equivalent Amperian currents rather than discrete magnetic poles. The reasons are clear: magnetic poles cannot be exactly located; they appear always in pairs; magnetic fields of elementary particles (including neutrons!) are always dipole fields; the forces on a magnet are spread throughout its volume; ferromagnetic polarization is primarily the result of electron spins, etc.

Thus it follows that H is, a priori, a theoretical mathematical tool. It is a figment of the imagination, in an important sense. It is true that whatever we do, we finally measure, not H, but

$$\mathbf{B}=\mu\mathbf{H}$$

the magnetic flux density (or magnetic induction) B, related to the magnetic field intensity H by the permeability μ. In the cgs 3-dimensional system of units, μ is a pure (dimensionless) number; in the mksa 4-dimensional system, μ is a physical quantity with measure and dimensions.

The torque $\mathbf{T}$ exerted on a magnetic dipole moment $\mathbf{m}$ can be written in two ways:

$$\mathbf{T}=\mathbf{m}_H\times\mathbf{H} \quad \text{or} \quad \mathbf{T}=\mathbf{m}_B\times\mathbf{B}$$

Now, if the magnetic moment $\mathbf{m}_H$ is defined in terms of the first relation, its unit is weber-meters; the unit of pole strength is webers, and this relation is, therefore, typical of the obsolete concept of point charges. On the other hand, the second relation gives $\mathbf{m}_B$ in ampere-meters^2, typical of the modern concept of Amperian currents (current loop).

Analysis of polarizable media likewise supports the concept that B is the realizable physical quantity, rather than H. In the rationalized system:

$$\mathbf{B}=\mu_0\mathbf{H}+\mathbf{J}$$

in which $\mathbf{J}$ is magnetic polarization (or intrinsic induction B_i). Whenever $\nabla\times\mathbf{J}$ exists there is an increase at a surface in the tangential component of $\mathbf{B}$. What is often called the demagnetization owing to an air gap in a magnetic circuit, is expressible, in this case, as the effect of the magnetic potential drop (ampere-turns) in the gap.

On the contrary, attempting to describe this situation in terms of H meets with logical difficulties. It then appears that poles on the ferromagnetic material, at the air gap, send $\mathbf{H}$ lines in one direction through the material and in the opposite direction through the air gap. Then the poles are attributed to $\nabla\cdot\mathbf{H}$, which produces an increase in the normal component of $\mathbf{H}$ in the air gap. The process of demagnetization is thus less easily understood.

The B field can be calculated from the distribution of uncanceled Amperian currents. The H field is computed from the corresponding distribution of pole strength. Mathematically, both concepts are equivalent; physically the B concept is the only reality, if anything of our descriptions of nature's behavior can be considered to be "real" for men's senses. But as the character of physical theories is essentially tentative and subject to experimental proof, only such quantities as can be measured have full claim on "reality."

All this may prove the intrinsic physical nonreality of the H. This is the first difficulty with, and the main objection to, the quantity "magnetic field intensity H."

The role of H is essentially that of an intermediary between the cause, the geometrical distribution of the exciting currents whether it is conductional or Amperian uncanceled, and the final effect, the physically real induction B. The excitation, the total current, alias the magnetic potential drop NI (ampere-turns) is, in some countries, such as Germany and Switzerland, denoted by the symbol Θ. Let the specific or linear excitation NI/l be symbolized by θ, for the purpose of this paper at least. With it we can write $H=\mathrm{k}\theta$, k being 4π in the nonrational and unity in the rational case. Using $B=\mu H$ we obtain:

$$B=\mu\mathrm{k}\theta$$

Equal causes, i.e., equal linear excitations θ, must naturally give equal magnetic effects and equal inductions B regardless of the definitional changes of the two intermediaries k and μ.

The logical step would be to try to live without such a trivial quantity as H, as the electrical engineer does. He plots his magnetization curves simply in the form $B=\mathrm{f}(\theta)$: gauss or kilolines per square inch versus the ampere-turns per inch or centimeter (see Proceeding *a*, Table I), according to an equation:

$$B=\mu\theta$$

where θ is defined as being $\theta=NI/l$ for solenoid or toroid. More precisely it is the vector quantity:

$$\bar{\theta}=\oint\frac{I\,d\mathbf{s}\times\mathbf{r}_0}{4\pi r^2}$$

for more complicated current geometrics of the conduction and/or Amperian currents I. This $\bar{\theta}$ corresponds to the rationalized vector $\mathbf{H}$.

One argument in favor of H is its beautiful parallelism with the electric field strength $\mathbf{E}$ as defined from Coulomb's (Priestley's) law for electric point charges. But this parallelism is only a nice fiction, really only useful for freshmen in physics. The more elaborate theories of the electromagnetic field exhibit the relations $B-E$, $H-D$, instead of the parallelism $B-D$, $H-E$. This is particularly pertinent in

the relativistic Lorentz transformation and for the elegant Minkowski 4-dimensional vector presentation of the electromagnetic field, where, in Maxwell's equations, the pair $\mathbf{B}-\mathbf{E}$ appear as part of one vector equation and the pair $\mathbf{H}-\mathbf{D}$ as part of another. Thus both experiment and advanced theory confirm the correlation of B with E. The equations in media may thus be written in the form $D=\epsilon_0 E+p$ and $H=B/\mu_0-M$ (with $M=J/\mu_0$ being the magnetization).

The American Association of Physics Teachers suggests that the basic way to develop the theory of the magnetic field is to start with the electromechanical interaction between current elements. The corresponding vector force equation:

$$d\mathbf{F}=I d\mathbf{s}\times\mu_0 \oint \frac{I' d\mathbf{s}'\times \mathbf{r}_0}{4\pi r^2}$$

may be written with μ_0 appearing in the second factor instead of in the first, giving the second factor the dimension of B according to the well-known simplified equation $F=IlB$ for three mutually perpendicular directions of force, current, and field.

The factor 4π in the denominator of this rational equation for B can be shown to be the direct consequence of the same factor in Priestley's equation for point electric charges if put in motion. The attractive forces between current elements as contrasted with the repulsive forces between like charges appear to be simply a consequence of relativistic transformation of co-ordinate systems. This may serve to convince those who accept the rationally written equations in electrostatics but prefer to use the nonrational ones in magnetics. Both disciplines are too closely interlinked to permit such a differentiation. Electrokinetics, and hence magnetics, are but "electrostatics in motion."

Problem of Rationalization

The second difficulty about the magnetic field intensity is the rationalization problem. It is significant that this physical quantity H must undergo all the complications involved with rationalization procedures, even if it is "not real." In 1950 the IEC accepted the so-called total rationalization. After the voting, which created an *enfant terrible*, the question was put whether the quantity rationalization or unit rationalization had been accepted. The ensuing debate proved that there was no clear concept of what was meant by "total" rationalization and what type of rationalization is to be considered to be valid. So the 7-year-long rationalization war was started. The following paragraphs may help to settle it in its eighth year.

To understand clearly the booby traps of rationalization it is necessary at least to understand, if not readily accept, the so-called quantity equations and quantity calculus in physics. Without the quantity calculus there is no rationalization problem as it appears at present. It dwindles to a solution like that of Heaviside which has already been mentioned. Since quantity equations are not generally used in the United States at the present time but are expected to be universally accepted in due time, let us briefly explain their philosophy.

Quantity Equations and Quantity Calculus

Classically the letter symbols of physical quantities in physical equations are considered to designate their respective *measures* only, so they can be treated algebraically as pure numbers. No units are allowed to enter the equations. Thus the physical equation appear to be semi-mathematical, i e., it only expresses a numerical relation between measures of the quantities involved.

The modern approach, quantity calculus, supported by the investigations by group theory, is essentially different. The symbols are considered as designating not only the measures, but the measures multiplied by the chosen, quite arbitrary units. The units too can be treated as algebraic expressions. Examples of this appear later. The practical advantage of quantity calculus is the clearer insight into the content of equations; the control of their dimensional homogeneity simply by the units; and, in the case of using consistent units in the formal analogy between the quantity and measure equations, stripped of all units.

As the language of quantity equations is on a higher level than that of the purely algebraic measure equations, the symbols in the quantity equations require an appropriate interpretation. For example, it should be understood from the equation $I=V/R$ that the quantity electric current I is changing linearly with the quantity voltage V and inversely with the quantity resistance R and not that current simply *is* voltage divided by resistance. The equality sign is to be understood as a functional symbol.

The author's opinion on quantities is that 5 amperes and 10 amperes are the *same quantity:* the electric current, but of two different magnitudes.

One must not forget that men use physical quantities and then try to depict by images the behavior of nature, while their ultimate reality remains ever unknown. Each successive page in nature's great book is more difficult to turn. We are approaching the ultimate essence of things, it is true, but asymptotically only it seems. So, as quantity calculus is doing well, it should be accepted as an excellent working tool, without much deeper reasoning. The depths of nature are unfathomable.

Rationalization of H by Units

The reasoning involved is much like Heaviside's. If, from the nonrational measure equation, a measure H' is obtained, which is 4π times larger than that from the rational H, the nonrational unit $[H']$ must be 4π times smaller than the rational $[H]$. The quantities H and H' thus are said to be the same:

$$H=\mathrm{H}\cdot[H]=\mathrm{H}'\cdot[H']=H'$$

regardless of the way of writing the numerical measure equation of H:

$$\mathrm{H}=\mathrm{NI}/l \quad \text{or} \quad \mathrm{H}'=4\pi\mathrm{NI}/l$$

This principle, the ratio of units being the inverse of the ratio of measures, is generally accepted as if it were universally true. However, it is not valid if the quantity to which the two units belong has two different definitions as is the case with H and H'. Here H is not identically equal to H' and the consequence of the lack of identity appears in Tables I, II, and III on rationalization procedures for H. It is true that this point is generally over-looked to the detriment of the proper understanding of the problem involved. To use a rather poor example, the difference between H and H' is comparable to the difference between a surface defined by r^2 and one defined by $4\pi r^2$. Dimensionally both of them are surfaces but the first is that of a square and the second that of a sphere 4π times larger. In H and H' there are two different definitions of the same quantity: the magnetic field intensity. The dimensional equation of both H and H' is the same $[\mathrm{IL}^{-1}]$ unless one ascribes dimension to the solid angle Ω. However, H and H' should be described by different adjectives: the "rational" and the "nonrational" magnetic field intensity.

The rationalization by units results in equality in amounts of the two differently defined magnetic field intensities. It can be seen from Table II that despite the fact that both H and $H'=1$ amp/m (ampere per meter), the corresponding

1 oe $\triangleq$	$1{,}000/4\pi \approx 80$	$10/4\pi \approx 0.8$	$2.02 \approx 2$	1

flux densities B_0 are not equal, being actually $4\pi \cdot 10^{-7}$T (tesla*) and 10^{-7}T, as if there were two meanings of the unit amp/m possible (see Procedures *b* and *c* Table II). In fact, the unit "ampere per meter," cannot claim much illustriousness. Thus units rationalization cannot claim much reality in the quantity sense. Equal $H=H'$ ought to give equal B_0, but it does not.

If the rational units of H are 10 amp/cm (cgs$_m$, IEC oersted) and 1 amp/m (mksa), the nonrational and consequently nonconsistent, ones are 10 amp/4πcm (people's oersted) and 1 amp/4πm (millipeople's oersted, mksa oersted).

This type of rationalization is called rationalization of/or by units, though what is primarily rationalized is always the equations relating certain quantities.

Rationalization by Quantities

People who see true quantities in the symbols NI/l and H of the definitional equation for H, and not merely their measures in a chosen system of units, and who also use consistent units, are not in favor of sacrificing the double advantages of quantity equations used with consistent units. They prefer to leave the units of H and H' unchanged and, instead, describe the same natural phenomenon, the same magnetic field by two related-in-definition magnetic field intensities: the rational $H=NI/l$ and the nonrational $H'=4\pi NI/l$, saying that $H'=4\pi H$. (Note that in Table II the H″ corresponds to H′ here.)

With the unit 1 amp/m for both H and H', they would have, for example, $H=$ 5 amp/m and $H'=20\pi$amp/m with the *same* B_0 in both cases (Procedures *c–f* in Table II).

$$B_0=4\pi 10^{-7}\frac{\mathrm{T}}{\mathrm{Am}^{-1}}\times 5\mathrm{Am}^{-1}=10^{-7}\frac{\mathrm{T}}{\mathrm{Am}^{-1}}\times 20\pi\mathrm{Am}^{-1}=2\pi 10^{-6}\mathrm{T}$$

where A = amp. Thus the quantity, absolute permeability μ_0, must conform to the rational or nonrational H used. With $\mu_0'=(1/4\pi)\mu_0$ and $H'=4\pi H$:

$$B_0=\mu_0 H=\mu_0' H'$$

The intermediary μ_0 between the invariant reality B_0 and the auxiliary nonreal H must adapt itself to the changing definition of H.

Papers written on the subject of the comparison of rationalization by units and quantities usually discuss two equal versus two different quantities H. We have seen that in both cases the measures do change. In the first case the unit is also changed, while in the second it is unchanged. But H and $H'=4\pi H$ give equal B_0, as required, so the rationalization by "quantities" can claim physical "reality" to the extent that H can.

One of the consequences is a confusion in the equations containing the magnetic moment, a quantity particularly important in atomic and nuclear physics. We have seen that there can be a B moment and an H moment. As the latter can be combined with both the rational and nonrational magnetic field intensity the ensuing confusion in atomic constants is quite appreciable, e.g., various values and dimensions of Bohr's magneton, gyromagnetic ratios, etc. But the practical engineer always uses the B moment while calculating his electric machines. He must be quite sure of himself as his machinery must work exactly as rated.

If we, like he, exclude, in magnetics at least, the intermediary H, the linear excitation θ of conduction and/or Amperian currents and their effects, the induction in media $B=B_0+J$ (B_0 in air plus the contribution of the medium, the magnetic polarization J or the intrinsic induction B_i), all the enumerated difficulties immediately cease to exist. The free space permeability μ_0 can have but one unit and value, the rational one. However, there will always be cases when H can be very illustrative, e.g., in electromagnetic waves in the Poynting vector of power density flow:

$$\mathbf{P}=\mathbf{E}\times\mathbf{H}=\mathbf{E}\times\mathbf{H}'/4\pi$$

though this can always be written in the invariant B form:

$$\mathbf{P}=\mathbf{E}\times\mathbf{B}/\mu_0$$

With the newly accepted IEC unit of B, the tesla, T (1 T = 1 vs (volt-second)/m^2 = 1 weber/m^2 = 10^4 g [gauss]) of the mksa system, and the old cgs$_m$ unit (1 g = 1 cm$^{-1/2}$-gm$^{1/2}$-second^{-1}) and the corresponding units of θ being 1 amp-t (ampere-turn)/m and 10 amp-t/cm, the consistent unit of μ_0 is always $[\mu_0]=[B_0]/[\theta]$:

$$[\mu_0]_{\mathrm{mksa}}=\mathrm{T/Atm^{-1}}$$

and

$$[\mu_0]_{\mathrm{cgs_m}}=\mathrm{g/10\ Atcm^{-1}}$$

In the latter unit 10 amp-t/cm with 10 amps = 1 abampere (not "absolute ampere" but the current unit 1cm$^{1/2}$-gm$^{1/2}$-second^{-1} of the absolute electromagnetic cgs system) corresponds in cgs dimension to the gauss, so that $[\mu_0]=1$. If H is not omitted, the mksa and cgs$_m$ units of permeability are as presented in column *10* of Table II.

The numerical value of μ_0 is readily obtained from the current balance equation which is at the base of the definition of the absolute ampere:

$$F=\mu_0 lI^2\mathrm{t}/2\pi r$$

with $l=1$ m, $r=1$ m, $I=1$ amp, one turn (t) and $F=2\cdot 10^{-7}$, newton = 0 02 dyne (newton N = kgms^{-2} [kilogram-meter/(second)^2] = joule/m one has, as an example of the quantity calculus:

$$\mu_0=\frac{2\pi Fr}{lI^2\mathrm{t}}=\frac{2\pi\times 2\cdot 10^{-7}\mathrm{N}\times 1\mathrm{m}}{1\mathrm{m}\times 1\mathrm{A}^2\times 1\ \mathrm{turn}}=4\pi\cdot 10^{-7}\frac{\mathrm{newton}}{\mathrm{amp^2\text{-}t}}$$

or with

$$\frac{\mathrm{N}}{\mathrm{A}^2}=\frac{\mathrm{VAsm}^{-1}}{\mathrm{A}^2}\times\frac{\mathrm{m}^2}{\mathrm{m}^2}=\mathrm{Vsm^{-2}/Am^{-1}}=\mathrm{T/Am^{-1}}$$

and finally,

$$\mu_0=4\pi\cdot 10^{-7}\ \mathrm{T/Atm^{-1}}$$

corresponding to the units T of B and amp-t/m of θ in the equation $B=\mu_0\theta$. The corresponding, always rational, value of μ_0 in the cgs system is quickly obtained if the 4-dimensional mksa Giorgi system is allowed to degenerate to the merely 3-dimensional cgs$_m$ electromagnetic system. This immediately happens if the mksa units are identified with the usual decimal multiples of the corresponding cgs$_m$ units. If we put 1 amp $\equiv 10^{-1}$ cm$^{1/2}$-gm$^{1/2}$-second^{-1} and 1T = 10^{-4}-cm$^{1/2}$-gm$^{1/2}$-second^{-1} we have, with 1 m = 10^2 cm:

$$\frac{\mathrm{T}}{\mathrm{Atm}^{-1}}=\frac{10^4\ \mathrm{cm^{-1/2}\text{-}gm^{1/2}\text{-}second^{-1}}}{10^{-1}\ \mathrm{cm^{1/2}\text{-}gm^{1/2}\text{-}second^{-1}}\times(10^2\ \mathrm{cm})^{-1}}\equiv 10^7$$

and $\mu_0=4\pi$, a pure number.

---

* The IEC is making a valiant effort to establish the tesla (abbreviation T) as the mksa unit of magnetic flux density; 1 tesla is 1 weber per square meter.

The absolute ampere, the fourth basic unit of the mksa system, and all units derived from it may consequently be considered to be defined independently of the cgs system. Alternatively, if not so, one has:

$$1 \text{ amp} \equiv 10^{-7/2} \text{ kg}^{1/2}\text{-m}^{1/2}\text{-second}^{-1}$$

and the ampere becomes a unit derived from the three basic units of the mks system of mechanics. Four-dimensional systems are simpler than 3-dimensional systems, from both the mathematical and the formalistic-aesthetic points of view. Hence the equation: 1 ampere is 0.1 of the cgs_m abampere, is to be read as a correspondence only instead of an equality:

$$1 \text{ amp} \hat{=} 10^{-1} \text{ cm}^{1/2}\text{-gm}^{1/2}\text{-second}^{-1}$$

Thus the induction 1 tesla and 1 gauss, respectively, are obtained in air by a local linear excitation $\theta = B/\mu_0$ equal to, for tesla:

$$\theta = \frac{1\text{T}}{4\pi 10^{-7}\text{T/Atm}^{-1}} = \frac{10^7}{4\pi} \cdot \frac{\text{At}}{\text{m}}$$

and for gauss:

$$\theta = \frac{1\text{g}}{4\pi} = \frac{1}{4\pi} \cdot \frac{10\text{At}}{\text{cm}} \approx 0.8 \frac{\text{At}}{\text{cm}}$$

The important result is that it is 1 g which is obtained by the linear excitation 0.8 amp-t/cm, a statement so similar to the ancient equality between the classical people's oersted and 0.8 amp/cm. Tables I and II illustrate this still more clearly, with the standard solenoid used to realize the variable units of H and the stable units of B.

Realization of Units of *H* and *B* in Standard Solenoid

Quantities are our images of ultimate realities in physics. As every physical theory is of little use unless proved by experiment, quantities without a physical reality, i.e., not accessible to measurement, would be of little use. For every quantity there must be a standard permitting the quantity to be realized with the desired amount, which is often exactly one chosen unit of the quantity. Therefore, standards are material devices which must be somehow energized to produce a quantity of a certain amount for the purpose of measurements, i.e., of comparing. The international meter or, better still, the meter together with a precise length comparator, is such a material primary standard as are the current balance, the apparatus of the time service of any astronomical observatory, etc. Their precision accounts for the ultimate accuracy of measurements obtainable by such primary standards.

The standard for the magnetic field is an exactly known geometrical arrangement of wire with an exactly known current in it. "Exactly" in standards means that the tolerance in geometry and current is estimated as exactly as required, absolute certainty being the privilege of uneducated minds. The standard of the people's oersted has been suggested as the circular arc of wire of 1-cm arc length at a radius of 1 cm with two radial leads along the axis. The axial magnetic field strength at the center of the arc is then 1 oersted. If the whole circle is taken, it is 2π oersteds. This standard of the nonrational oersted has the disadvantage of being quite unrational indeed. It gives a low field and a very nonuniform one. The only rational standard, encountered in every well-equipped laboratory, is the precision-built standard solenoid of well-defined pitch l/N (length for a turn). Energized by the current I it produces the linear excitation $\theta = IN/l$ If it is sufficiently long, and uniformly and densely wound, the linear excitation and, so, the field in it, is highly homogeneous over a large volume and can be calculated. Therefore further discussion of the realization of units of H and B is based on the standard solenoid.

As stated already, the same θ will always produce the same B. H, on the contrary, will appear according to its chosen definition equation and unit; μ_0 will have to adapt itself to H in order to give the invariant B. Table I will show, if carefully studied, what is realized, and how, including the trickery of rationalization procedures on eight examples: four mksa and four cgs_m, all based on the physically advanced concept of quantity equations. The table shows:

1. The rationalization of the quantity magnetic field intensity by units: transition from the nonrational H' in rows *a–b* to the rational H in rows *c–d*, so that there is equality in magnitude $\text{H}'[H'] = \text{H}[H]$; transition from nonrational H'' in rows *e–f* to rational H''' in lines *g–h*, giving similarly $\text{H}'''[H'''] = \text{H}''[H'']$. The latter procedure, *g–h*, is never encountered, fortunately, but it is equally possible and analogous to the first. It is accordingly added as illustration. The units involved are in column *6*.

2. The rationalization of the quantity magnetic field intensity by measures (which is usually said to be rationalization of quantities): transition from the nonrational H'' in rows *e–f* to the rational H in rows *c–d*. There is no longer equality in magnitude as $\text{H}''[H''] \neq \text{H}[H]$. The two magnetic field strengths H'' and H, different in definition, do not have equal magnitudes as is the case with the two procedures for rationalization by units under item 1.

3. If the unit $[H]$ in column *6* of the quantity H as defined in column *4*, is to be "realized," the linear excitation $\theta = NI/l$ as in column *9* must be applied to an appropriate solenoid. For proceeding in row *a*, for example, we must realize the people's oersted. This is obtained if $H' = 1 \times 10$ amp/4πcm. If, in the corresponding definitional equation $H' = 4\pi NI/l$, we substitute for

$$NI/l = \theta = \frac{1}{(4\pi)^2} \cdot \frac{10 \text{ At}}{\text{cm}} ,$$

and have, using quantity procedure,

$$H' = 4\pi \cdot NI/l = 4\pi \cdot \frac{1}{(4\pi)^2} \cdot \frac{10\text{At}}{\text{cm}} = 1 \cdot \frac{10 \text{ A}}{4\pi\text{cm}}$$

as required. The same procedure is evident for all the eight cases.

We see that θ changes in the ratio $(4\pi)^2$ to 1 for the two cases of rationalization by units and in the ratio 4π to 1 in the case of rationalization by measures (quantities).

It is also noted that only with rationally written equations do the linear excitation θ and the unit $[H]$ correspond, except for the factor turn (t).

4. The induction B_0 in the solenoid, corresponding to the θ in column *9*, is evident from column *11*. Naturally B_0 goes in parallel with θ, changing in steps $(4\pi)^2$ to 1 for the two rationalizations by units and in steps 4π to 1 in the rationalization by measures (quantities).

5. The corresponding μ_0 which relates the "realized" unit-magnetic field intensities $H = 1 \cdot [H]$ to the actually physically existing inductions $B_0 = \mu_0 H$, are evident from column *10*. Their units $[\mu_0]$ are also given as the ratio $[B]$ to $[H]$. In the four cgs_m cases the pure number obtained for μ_0 is further illustrated with the unit gauss/oersted. This may imply the physically different character of B and H, even in cgs systems and free space. If B and H are recognized to differ essentially in matter, they are logically different in free space too, despite the fact that $\mu_0 = 1$ in Procedure *e*, Table II, as the transition from matter into free space can be considered continuous. Also they are always plotted on two different axes of the co-ordinate system.

6. Intercomparison of realized B while $H = 1 \cdot [H]$, both evident from column *11*, is startling. However, it clearly discloses some inherent difficulties in understanding H and its rationalization procedures.

In both rows *d* and *e* the IEC oersted $1 \cdot \text{oe}_r = 10$ amp/cm is realized. But as θ is different, B must be too. It is 4πg (gauss) and $1 \cdot$g respectively; the same is true for the $1 \cdot$amp/m in rows *c* and *f*, which gives $4\pi \cdot 10^{-7}$T and 10^{-7}T.

The proper understanding is simple. The oe_r and the amp/m are units of the two differently defined magnetic field strengths H and H'', both using the same unit, equal in magnitude but not identical in character. This is no more difficult to understand than the attempt to describe some physically real B by two amounts of magnetic field strength differing in magnitude by a factor 4π. The literature thus speaks of two "paradoxical" meanings of amp/m:

$$\left(\frac{\mathrm{A}}{\mathrm{m}}\right)^{\mathrm{i}}=\frac{1}{4\pi}\left(\frac{\mathrm{A}}{\mathrm{m}}\right)^{\mathrm{r}}$$

and comes to such conclusions, on a higher level of abstraction, as:

$$\left(\frac{\mathrm{cm}}{\mathrm{cm}}\right)^{\mathrm{i}}=\frac{1}{4\pi}\left(\frac{\mathrm{cm}}{\mathrm{cm}}\right)^{\mathrm{r}}$$

or vice versa. They no doubt require a rather high level of imagination and are indigestible to the realist in electrical engineering.

Based on the philosophy included in Table II, we can finally answer the two IEC questions: 1. What type of rationalization has been or is to be chosen? 2. What is the oersted, and how much field does it represent? All that is still needed is an insight into how the old-timers have been proceeding while calculating their magnetic fields. Their procedure may be explained by the example of the superhigh H parameter the author is designing for the Magnetic Measurements Section of the National Bureau of Standards: "20,000 oe at least are required. The gap is to be 3 cm long and 5 cm in diameter."

Old-timers have their result immediately: 20,000 oe require 16,000 amp-t/cm as 1 oe = 0.8 amp-t/cm. He who does not believe may look it up in any textbook or handbook. If you ask for the induction B, you get the answer: as $\mu=1$ in air, B is 20,000 g, naturally, 1 g being 1 oe. This is all.

If they were asked what field they obtained from 16,000 amp-t/cm, they use the measure equation $H=4\pi NI/10l$.

With $NI/l=16{,}000$ it gives 20,000. What? Oersteds naturally.

Very simple and correct, correct in its final result at least, as their machinery and apparatus prove. From the logic of quantity calculus however, there are two main flaws. The first is that by saying 1 oe = 10 amp-t/4πcm the units of two different quantities, H and θ, are being simply identified. The second is similar. By writing 1 oe = 1 g, a unit of H is identified with a unit of B. But this equation is never meant so seriously. In reality only measures are being compared: The number of gausses is equal to the number of oersteds. The classical procedure is essentially numerical and nonquantity. The so-called "technical" (nonrational) equation $H=4\pi NI/l01$ and the Gaussian (equally nonrational) $H=4\pi NI/\mathrm{c}l$, so beloved of some physicists, are typical measure equations, as the factors 10 and $\mathrm{c}=3\cdot 10^{10}$ (the measure of the velocity of light in the unit cm/second) came into them by a particular choice of units for the quantities involved, while true quantity equations are usable for all possible units if they too are treated algebraically.

In the Gaussian equations c appears in such quasi-static cases as above and disappears from equations where it should appear and represent the velocity of light c_0, e.g., for wavelength of an oscillator:

$$\text{Gaussian } \lambda=2\pi\sqrt{\mathrm{LC}}$$

$$\text{Quantity } \lambda=2\pi c_0\sqrt{LC}$$

It is absurd that in the Gaussian symmetric system all three quantities; wavelength, inductance, and capacitance, are to be measured in the same unit, the centimeter.

Let us quickly see how permeability is calculated, namely, the relative permeability μ_r, the only important one as it appears in tables, magnetization curves, etc. It tells how many times the magnetic field in matter is larger than in free space or air, equal linear excitation assumed. In the Armco Steel Corporation oriented-grain *M-6* silicon steel, $\theta=1$ amp-t/cm gives $B=16{,}000$ g.

Classical measure procedure: with 1 amp-t/cm = 1.26 oe ($1.26\approx 4\pi/10$) the relative permeability is:

$$\mu_r=\frac{16{,}000}{1.26}=12{,}800$$

Cgs quantity procedure:

$$\mu_r=\frac{B}{H}=\frac{16{,}000\ \mathrm{g}}{1.26\ \mathrm{oe}}$$

Using quantity calculus this is the pure number 12,800 only if 1 g = 1 oe, i.e., the 1 oe is the IEC oersted, so that:

$$\mu_r=\frac{16{,}000\ \mathrm{g}}{1.26\ \mathrm{g}}=12{,}600$$

Mksa quantity procedure: $B=16{,}000\ \mathrm{g}=1.6\ \mathrm{T}$ and $\theta=1$ amp-t/cm gives $B_0=1.26\ \mathrm{g}=1.26\cdot 10^{-4}\ \mathrm{T}$. So:

$$\mu_r=\frac{B}{B_0}=\frac{1.6\ \mathrm{T}}{1.26\cdot 10^{-4}\ \mathrm{T}}=12{,}800$$

and the absolute permeability:

$$\mu_0=\frac{B_0}{\theta}=\frac{4\pi\cdot 10^{-5}\ \mathrm{T}}{10^2\ \mathrm{Atm}^{-1}}=4\pi\cdot 10^{-7}\ \mathrm{T/Atm}^{-1}$$

as seen from row *c*, column *10* of Table II.

As these two examples of classical and illogical procedure have no effect on the final physical result, nobody cared much about them until 1950. But they may help to answer the two IEC questions:

1. What type of rationalization, quantity or unit, is to be chosen?

The "actual" rationalization is the transition of classical nonrational "measure" definitional equation for H, combined with nonrational nonconsistent units (Procedures *a–b*, Table II, if they were by measure equations only) to modern rational quantity (not measure) equation using rational, consistent units (Procedures *c–d*).

2. What is the oersted?

With "measure" equations this question is of little importance, provided only the measures of H and B are compared. The equation: 1 g = 1 oe, does not mean equal quantities $H=1\ \mathrm{oe}\equiv B=1\ \mathrm{g}$ but equal measures $H\equiv B$. Usually by "oersted," the unit 10 amp/4π cm (people's oersted) is meant, as the rationalization of units is usually understood to be an identification $\mathrm{H}'[H']\equiv\mathrm{H}[H]$ despite the difference in definition of the abstract quantities H' and H. So the people's oersted, from the quantity point of view, turns out to be the "people's gauss" instead.

If, on the contrary, we would like to answer the two questions from the quantity calculus point of view, it can be seen that most of the preceding classical procedure is realized in the transition from "quantity" rationalization Procedures *e* to *d*, Table II. In *e* the field of 1 g is realized by 10 amp-t/4πcm and $\mu=1$, as for the old-timer. But the magnetic field intensity "realized" simultaneously with $B_0=1$ g is 1 rational IEC oersted (10 amp/cm) as unit of H'' and not 1 nonrational people's oersted. The latter is "realized" in Procedure *a* as unit of H', but gives a different induction, namely $B_0=1/4\pi$ g, with $\mu_0=1$ also. But this 1 is more exactly 1 g/4πoe$_\mathrm{n}$. All this is further illustrated in Table I for $B_0=1$ g in standard solenoid.

The IEC Technical Committee 24 once tried to satisfy all sides with the following recommendation:

> "The equation between *units* is 1 amp/m = 10^{-3} oe. But the equation between *standards* (!) for these units is 1 amp/m = $4\pi\cdot 10^{-3}$ oe.
>
> "Oersted may be used with nonrational equations only, and amp/m with rational ones only in order to avoid confusion."

Old Pythia or the Delphi oracle could not have spoken more wisely

The solution, permitting one to avoid all these difficulties, may be pointed out in the following conclusions:

1. Instead of using equation 1 oe = 10 amp/4π cm or 10 amp-t/4π cm, say: (the induction $B_0=$) 1 g is produced by (the linear excitation θ) 10 amp-t/4π cm $\approx$ 0.8 amp-t/cm = 80 amp-t/m. Written in form of correspondence (or equation between measures):

$$1\ \mathrm{g}\triangleq 0.8\ \mathrm{amp\text{-}t/cm}$$

2. *In vacuo* (and also air practically) this (induction $B_0=$) 1 g corresponds to the nonrational magnetic field intensity 1 oe if oersted is understood in the old people's manner and equations come be-

Vol.
Pt. 1
1959

tween measures. Written again as correspondence for measures:

$1\ \text{g} \mathrel{\hat{=}} 1\ \text{oe}_{\text{n}}$

Be careful if using quantity equations for H!

3. The nonrational μ_0 of free space in this case is to be taken equal to unity ($\mu_0 = 1$).

4. The units amp/4π m, (mksa oersted), abamp/4π cm (the people's oersted), amp/m and abamp/cm (the IEC oersted), have a nonequivocal meaning and nonvarying physical effect (B_0) only if they are understood as units of the linear excitation and not as units of the magnetic field intensity H. It is better to add to them the physically illustrative "turn (t)." Units without t might be used with H only, *cum grano salis* (with a grain of salt). Ampere-turn per meter has a physical sense invoking immediately the solenoid experiment, which cannot be said of the ampere per meter.

5. The best way to get rid of these difficulties is to exclude their provocator, the hypothetical quantity magnetic field intensity H, by plotting B against θ, or, better still, against B_0 as B/B_0 gives directly the relative permeability. Many engineers do so already, the author included.

6. For the present transition period, it is highly recommended that engineers become acquainted with the problems as literature is written quite uncritically. The best way to learn the procedure is to calculate complete practical examples in all possible ways: measure and quantity, cgs electromagnetic, electrostatic and Gaussian, mks and mksa, rational and nonrational, and unit and quantity rationalization. It is the hard way, but with practice it is lots of fun and a much clearer insight into the meaning and content of physical equations of all kinds is obtained.

As seen, no high philosophy concerning electricity was used in the reasoning. But practical computations are unavoidable for proper understanding. "*Probieren geht über studieren*" (One single test [or standard] is worth a thousand expert opinions.)

The old way is simple, theoretically illogical but practically good, and the results are correct since two "false" steps cancel out.

To the young generation let us explain metrological problems correctly and systematically, especially in textbooks. Thus they will encounter less trouble in reading electrotechnical and electrophysical literature which is often not clear regarding equations, quantities, units, and measures, to the dismay of the uninitiated readers. Having had proper instruction, however, they will enjoy it and their work will be greatly facilitated. This is particularly true in magnetics where some veteran high school, and even college, teachers with outworn concepts slide over magnetism as fast as they can, without properly understanding it.

Only so the sleeping dogs will lie until they die.

Microwaves and Their Use in Power Systems

S. C. BARTLETT
MEMBER AIEE

MUCH HAS BEEN written on the subject of microwave, including theoretical considerations, characteristics, design of components, practical systems, experience, etc. Now that microwave systems have been in use for a period of years, it would seem of value to reappraise the situation from the viewpoint of the power system operator and engineer and to determine just what the true microwave characteristics are; to discuss relative costs, applications, reliability, and maintenance problems: in general, to consider how microwave can properly take its place to help carry the burden of system expansion. With such a purpose in mind the author has set down as briefly as possible those factors which have been observed in operating systems. Technical details have already been competently covered by such articles as those in the list of references; in this paper comments are confined to observed results and how well they substantiate theory.

The services rendered to the American public by the nation's electric utilities are fundamental to the existence of the American economy as we know it today; they enter every significant industrial process, and in the case of some are a major ingredient. Their benefits extend to farms, commercial establishments, and homes. Our economy with its high living standard would not have been possible without adequate and low cost supplies of electric energy. Total consumption has for many years been increasing at a rate beyond that of gross national production and there is no visible sign that this trend will not continue.

To provide all of this in the most efficient manner, larger and more efficient turbogenerators using higher steam pressures have been developed and built into vast network systems operating at ultrahigh voltage and interconnected on essentially a nation-wide basis. With this arrangement, plants may be strategically located to take maximum advantage of low cost fuel and by means of an efficient transmission system can convey energy to the load centers.

Simply the fact that there is a physical separation betweeen the dispatchers, plants, substations, interconnection points, and loads means that communications are called for in their broad sense, i.e., the transmission of intelligence in all forms from one point to another. The amount, quality, speed, and reliability of these communication systems are related to many factors of the power system, particularly its over-all size; the location of plants, lines, interconnecting points; the character of the machines and governors; and the character of the load which the customers apply. Basically a means of controlling generation is required, so that each system continually carries its own load by the most efficient means after having determined this load through observing the flow at all interconnections and adjusting generation accordingly. This involves a fast transfer of intelligence, since there may be rapid and frequent shifts of large loads and the net flow must be derived from concurrent observations. Here an automatic load controller can determine the corrective value required and transmit this information to the generating plants. The performance of such a system when provided with high-grade information channels is truly impressive and promises practical operation of a system with a margin of spinning reserve of less than 3%.

Operating the American Electric Power (AEP) System

In the AEP Service Corporation system the several operating companies acting in concert have accepted as obvious the

Paper 59-1099, recommended by the AIEE Power System Communications Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted January 15, 1959; made available for printing June 24, 1959.

S. C. BARTLETT is with the American Electric Power Service Corporation, New York, N. Y.

thinking that superior over-all efficiency can be attained if the system as a whole is considered and regulated for maximum over-all advantage, and if all the factors just mentioned are considered. To do this involved establishing a load-coordinating office near the geographic center of the system and equipping it with all facilities for load forecasting including a penalty factory computer to accomplish this purpose. For the work of this office the various readings which must be delivered to it are shown on Fig. 1; some of these are interconnections and some are indications of plant net generation, but all require the same treatment as far as communication channels are concerned. In general these signals are used by the individual operating companies, being transmitted by power line carrier, leased lines, etc., and must now be picked up or extended to the Columbus headquarters. These signals are either of the pulse-duration or the variable-audiofrequency type.

The Problem

Telemetering, though essential to system operation, is by no means the whole solution. Information must be gathered by other means, particularly Teletype and facsimile. Voice, though it is a slow means for the transmission of intelligence, has its advantages and presumably will always be used. Automatic data processing is finding new uses every day and could be employed to analyze the values of interchange power flow, net generation, fuel costs, machine efficiencies, and line loss to determine the most efficient combination of generating units and the loading on each.

In the operation of the physical plant, relaying, transfer trip, supervisory control, alarms, and remote control, in addition to voice, require means of transferring intelligence from point to point.

For the activities of administrative and nonoperating personnel, communication is required primarily by telephone and teletypewriter. Fig. 2 shows the various headquarters, division and district offices, all equipped with private branch exchanges and some with private automatic exchanges, among which the majority of the traffic flows. The loading by leased wires and long distance calls between each pair of these points must be added in, to determine which may justify either private or party lines.

The question then boils down simply to: "With these requirements, what is the most economical means of providing all of these circuits with suitable reliability, keeping in mind expected growth rates?"

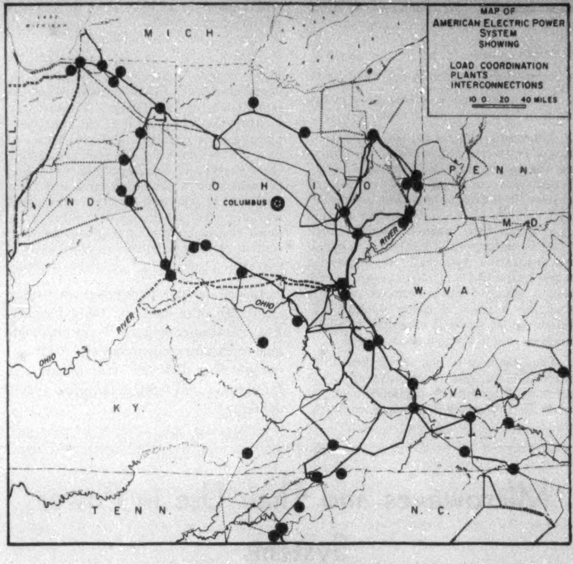

Fig. 1. Telemetering terminals

Factors Considered

A detailed study was made to determine the rate of growth of communication facilities based on channel miles from which estimates were made for the requirements for each of the next 10 years.

Table I gives the figures on which this estimate was based, and shows that 10.1% is the average annual increase for all types of facilities. In this estimate mobile radio which serves an entirely separate function from the point-to-point services has been intentionally excluded. It will be noted that the rate of growth indicated above is greater than for the power system itself, which is about 8%. This, it is felt, is realistic because of the additional functions being assumed by the communication systems. Thus appears the problem from the indicated rate of increase in channel miles, and there seems to be no indication that this trend is changing.

The next step was that of setting down the locations of all channel terminals and deciding which might be grouped or brought to assembly points to be handled by some common means such as a microwave system. The spelling out of the problem in terms of specific channels, types of intelligence to be conveyed, terminal locations, operating dates, rate of growth, etc., is complex but must be done. It would avail nothing to go into these details here since no two power systems bear more than a superficial resemblance to each other. The next step was to consider all possible tools and their relative costs. All practical means having been considered, it was found that the problem boiled down rapidly to the use of the following, either separately or in combination:

1. Power line carrier.
2. Leased wires.
3. Private telephone line.
4. Carrier on private telephone line.
5. Microwave.

To explore the economics, which are always of paramount importance, it is necessary to arrive at an evaluation of the annual costs for capital expenditures to balance against the cost of leased facilities. In the several systems considered the various components have different expected lives but the weighted average for the cost of each component and its expected life proves to be around 20 years for each entire system.

Cost Figures

Although the cost of money varies with the proportions derived from bonds, pre-

Vol.

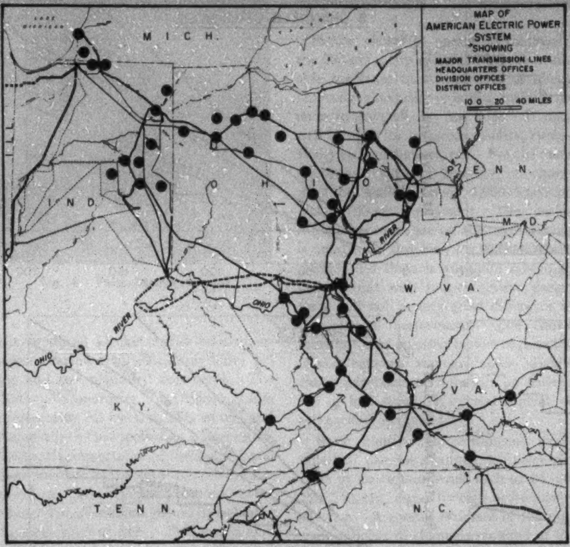

Fig. 2. System offices

ferred stock, and common stock, and the interest rates on each, it is necessary to have at least an estimating figure for engineering purposes. At the moment, these figures plus income tax on preferred and common stocks plus local property taxes, sinking fund to redeem in 20 years, and maintenance, all add to almost exactly 20% per annum on the total investment.

Making a number of assumptions, particularly in estimating the cost of building the least expensive systems, such as transmission telephone systems on wood poles along existing rights of way using long-span rural construction, phantoms wherever possible, repeaters where necessary to maintain a suitable signal-to-noise ratio on circuits with high exposure to power line noise, resulted in the series of curves of Fig. 3. The estimate for leased facilities is based on a cost of $4.00 per mile per month plus 10% tax for voice circuits with no concession in the way of a sliding scale either as a function of length or number of circuits in parallel. For a microwave system, average figures have been taken for terminal stations and repeater stations, assuming 25 miles each for the hops.

These curves indicate that power line carrier is in general the least expensive and yet, valuable as it has been to the AEP through the years, when it has been exploited to the fullest, it must be recognized that there are very definite limitations, particularly in spectrum and in practical length, the latter being restricted by the manner in which high-tension systems today are coming to look more and more like distribution networks. New techniques, circuits, tubes, and components have helped somewhat in the problem of adding channels but the limits are rigid, particularly because of the side-band requirements of voice and relay channels so that, at best, one may expect only a small percentage of additional channels to be handled by carrier. Economics dictates that power line carrier be used to the limit of its technical capabilities, particularly for short haul, feeders, etc., but other means must be found for handling the majority of channels.

Leased telephone circuits serve a valuable purpose in this business field, being available for almost any bandwidth requirements and in any number of circuits. However, they have the inherent weakness of any open-wire or cable system aggravated to some extent, probably by the fact that the AEP plants and substations are frequently in areas remote from telephone operating centers. The curves of Fig. 3 show that on a cost basis their use is very definitely in the picture, particularly where a small number of channels is required.

Table I. Requirement Estimate Basis

Type of Communication	Channel Miles 1945	Channel Miles 1954
Telephone	2,817	6,033
Relay	2,921	6,026
Telemeter	2,981	8,576
Totals	8,719	20,635

The average increment per year is 10.1%.

Private telephone systems, either metallic or by carrier, are technically no better than leased lines but may be preferred in that all equipment is under the control of the user. On the other hand, outages on leased wires may be minimized by having available circuits by alternate routing. Economically, the figures show that privately owned wire line facilities are never the solution except, possibly, in some cases requiring an unusually large number of channels in parallel.

Microwave fits in where comparatively few channels are required and its technical characteristics should be explored to determine suitability.

Carrier current being essentially saturated and private telephone systems economically unattractive, a solution must be reached between leased lines and microwave or, more likely, a combination of both. In cases where either would serve, it appears that microwave has the advantage on at least the following technical grounds:

1. Less outage time.
2. Concentration of all equipment at a small number of points.
3. Completely under user's control.
4. Ability to restore audio level at all points.

Of somewhat less importance and possibly debatable are:

1. Higher intelligibility.
2. Better signal-to-noise ratio.
3. Lower crosstalk level.

This leads to the conclusion that the true crossover between leased lines and microwave shoud be at a smaller number of channels than indicated on the basis of economic considerations only. The microwave characteristics will now be considered more in detail to determine if it is reasonable to commit many important signals to a system involving an r-f (radio-frequency) power comparable to that of of a flashlight bulb.

Microwave Licensing

In considering microwaves which in general are understood to be those fre-

E—Twelve channels
F—Twenty-four channels

quencies in the order of 1,000 mc (megacycles) and above, there are certain frequencies available for utility use, in general around 960, 1,900, 2,200, 2,600, and 6,700 mc, and consideration must be given to the propagation characteristics of these frequencies and to equipment available for operation here. Frequencies in these ranges are allocated to the power radio services on a shared basis with other industrial radio services under terms of a developmental grant only. This means that an applicant accepts the condition of a license which may be revoked at any time, that he must be aware of other users, and that he select operating frequencies after determining what other systems, frequencies, and beam directions are in use in the area. A valuable organization known as the Operational Fixed Microwave Council has been quite effective in tabulating all such information which is available to any potential utility licensee. The Federal Communications Commission

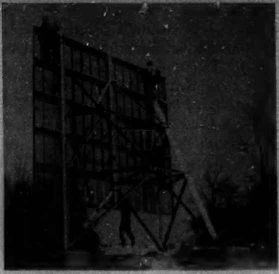

Fig. 4. Philo passive repeater

has produced Docket *11866* which considers a review of all allocations above 890 mc and has requested comments. The National Committee for Utilities Radio representing all electric, gas, water, and steam utilities has replied and, after establishing the importance of the utilities and their need for bands in the microwave frequencies, has suggested among other things that allocations should be in blocks for each class of user. This would simplify the problem of frequency allocation, particularly for the utilities, since each operates in an established franchise area. Obviously maximum utilization of the spectrum calls for careful consideration of all factors of propagation, channel loading, beam width, deviation, etc., and the objective of utility users is to establish their basic requirements and rate of expansion, and to co-operate in seeking the best solution for all concerned.

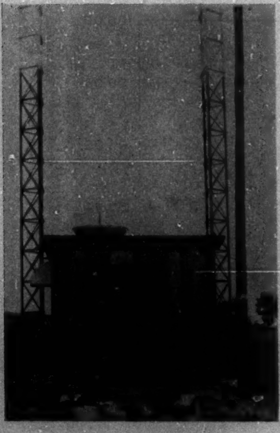

Fig. 5. Typical steel building

Systems Available

In the choice of operating frequency the 960-mc group is limited by the available spectrum to a maximum of about ten voice channels; it is also limited by noise to systems of a few hops. It may well be ideal for branches, feeders, supervisory control systems, etc. For the main microwave system, however, a choice must be made between 1,900–2,600-mc and 6,700-mc equipment. The necessary components are on the market from a number of suppliers for both of these ranges, and there is adequate reason to believe that with proper system design there will not be any great difference in the over-all performance. The choice must be based on other factors such as the choice between waveguides or coaxial cable, parabolas or reflectors on towers, full or half stand-by, crystal control, or self-excited oscillators, etc.

Basic multiplexing equipment available will provide channels for voice circuits up to certain levels such as 24, 60, 120, 240, etc., either by time or frequency division. A coreful estimate of the ultimate number of channels required at the time of amortizing the equipment must be made in order not to carry a burden of unnecessary basic equipment or to run into situations where a major change must be made in the basic multiplex equipment. If there is considerable need for drop-and-insert channels, frequency division probably has the advantage. On the other hand, long through channels may dictate time division to attain a better signal-to-noise ratio.

Although the economic and technical factors mentioned above justify full consideration of microwave, it must be realized that the high initial cost limits its use to cases where either many signals are required or to areas where lines are impractical, or where extremely wide bands such as for television must be conveyed, or for temporary installations where it would be uneconomical to build lines. In the utility business this brings up something of a new concept of investment in communication equipment: the purchase of coupling capacitors, line traps, and carrier current equipment would involve only a few thousand dollars each, whereas a microwave system involves a long-term investment which, even for a simple system, may run into six figures.

First AEP Installation

For a number of years the AEP system studied the technical characteristics and particularly the performance of microwave systems and, in fact, observed demonstrations of 960- and 4,000-mc equipment in operation during 1947. However, an extensive power line carrier system made it possible at low cost to add channels from time to time, so that it was not until 1953 that carrier saturation forced a decision regarding alternate means, and the engineering studies singled out the use of microwave as the clear-cut answer to most of the problems. By this time, microwave equipment and associated multiplexing devices had reached a relatively suitable stage of development, many of the early problems having been solved, and components improved, so that there were few misgivings. Then AEP proceeded with the first installation extending some 80 miles from Canton (Ohio power headquarters) to Philo (major generating plant) using three repeaters. The only unique feature of this first system is the large passive repeater, constructed entirely of aluminum, which eliminates a full repeater station or a long telephone cable line to get the signals into final plant about a mile away across the Muskingum River; see Fig. 4. This passive repeater, more than any other factor, dictated the use of 7,000 mc. Six voice circuits were provided, one of them being subdivided by audio tones for telemetering. Figs. 5 and 6 show a typical repeater station and its antenna system. Fig. 7 is interior of a terminal station.

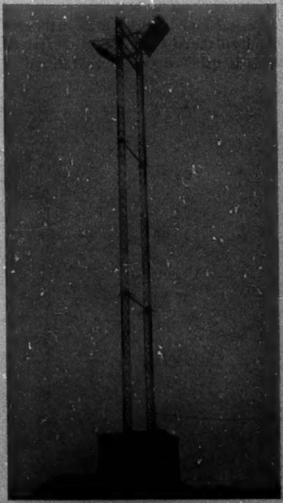

Fig. 6. Repeater with tower

Fig. 7. Terminal station interior

Results

By the end of the first year, in spite of the original errors, inexperience, and those defects which are expected to show up in the first few months, it was obvious that the system fulfilled all predictions: the cost was as estimated, the technical performance was as claimed, maintenance was less than expected, and continuity well above the guarantee.

Reliability may properly be defined in many ways, depending upon the function of the equipment, but for purposes of appraisal it is interpreted to mean the continuity of the r-f signal through the system. This is qualified to mean r-f signal of sufficient magnitude to deliver understandable signals, signal/noise = 15 db (decibels) on any voice channel. Experience shows, however, that this detail is unnecessary since equipment failures or fades seldom produce losses approaching path margins: they usually cause either a complete outage or nothing. Fig. 8 gives a record of performance extended to the present, showing continuity above 99.88% for the system or 99.97% per hop.

Microwave was thus accepted as a proper tool for the solution of problems of channel overloading elesewhere in the system. In other areas the shortage of channels was becoming acute, and restraint was required to avoid a sporadic growth of scattered microwave systems. Thus, before proceeding, it was necessary to develop a long range plan so that, as these systems were constructed they would grow together and co-ordinate in an orderly fashion. A 10-year plan was formulated, as illustrated in Fig. 9. The AEP was considered as a whole, including rate of growth, locations of generating plants, substations, loads, business offices, interconnections, etc., and the best possible estimate was made as to the location of new lines, plants, and loads.

The original Canton-to-Philo system of 1954 was followed by an extension westward to Newark (accounting headquarters) in 1956, then to Columbus (load dispatching office) in 1957; also an extension southward to Muskingum (the major plant) was made in 1956, and to Sporn (another major plant) in 1957.

Similarly, problems of channel congestion appeared in the Indiana and Michigan Electric Company which could now be solved by similar means. Here, 1,900-mc equipment was chosen, primarily on the basis that two of the five locations already had radio towers which would serve to support parabolas but would not be capable of handling the wind loading of the considerably larger reflectors associated with 6,700-mc equipment. Also, largely for comparison purposes, single side-band multiplexing was chosen, whereas frequency modulation was used in the Ohio system. The initial microwave system ran from Robison Park (load dispatching office) to Spy Run (company headquarters in Fort Wayne) to Sorenson (345-kv substation) and Deer Creek (major substation and division headquarters) in 1957.

Similarly, in the Appalachian Power Company a 145-mile system was built between Roanoke, Va. (headquarters office), and Charleston, W. Va. (division headquarters). Here again the most desirable path involved the use of a passive repeater. In this case it could be mounted on a water tank not owned by the AEP, but only if its size and weight could be held to a minimum, so that again 6,700-mc equipment was chosen; see Fig. 10. This system is unique in that no towers are used at any of its eight stations, since six of them are on mountain peaks and the terminals on office buildings (with the help of the passive repeater just mentioned). Fig. 11 shows a typical mountain top repeater station.

Fig. 9 indicates by solid lines the portion of the AEP system which is now in operation; this portion constitutes the basic backbone of the system, and it closes the gaps all the way from South Bend,

Ind., to Roanoke, Va. Although there may not be a through channel from end to end of the system, the design must be adequate to permit one or more talking circuits from Fort Wayne to Roanoke, probably by an audio patch at Columbus.

From here on, additions will be made as economic crossovers are reached, more or less along the lines of the long-range plan, which will doubtless be altered to accommodate new lines, loads, and plants which are certain to materialize.

Observations

Theoretical considerations have been adequately covered by various qualified writers; yet predictions contain differences of opinion, and the question always arises as to which of these will prove valid in practice. The manufacturer in establishing the technical advantages of his product may be expected to emphasize its good characteristics. The user is left to evaluate the importance of each characteristic in his particular application. Thus it should be of value to appraise these systems on a basis of experience and to indicate which of the characteristics are really important in the operation of electric power systems, which ones stand up in practice, and which ones may still be of debatable value because of small differences.

FREQUENCY

The proponents of 1,900- and 6,700-mc systems continue to debate as to which of these produces the less total product of depth of fade and duration; our observation is that with average good design and comparable cost either one can attain the 99.97% continuity per hop mentioned above. The argument is thus largely academic.

CHOICE OF PATH

When the operating frequency has been selected, a suitable path may be chosen. The AEP method is to work from United States Geological Survey maps, drawing tentative profiles providing 0.6 Fresnel zone plus 50 feet provided arbitrarily for trees and other obstructions. A number of paths may be plotted in seeking the best compromise between tower height and path length. Also, care must be taken to choose locations as close as possible to roads, power lines, etc. With several possible paths the next step is a field check of the sites, some of which may be found unavailable due to prior occupancy, unsuitable ground condition, difficult access or, as has been encountered the site is, in effect, missing as a result of strip mining or earth-moving operations.

The theory is well established regarding the relation between path loss and Fresnel zone, and show that there is little to be gained in going beyond 0.6 of the first Fresnel zone. If a few db are important it is better to obtain them through the use of larger parabolas. Less well established is the basic earth curvature to be used. From this company's limited experience it would appear that about equal performance results with a 1,900-mc system based on a 4/3 earth curvature or from a 6,700-mc system based on true earth curvature, each being designed for 0.6 of the first Fresnel zone.

The next step is to check by survey either on foot, with altimaters and flashing lights or by means of an aerial survey. Each has its own advantages, e.g., the survey on foot is most assuring, particularly if actual light flashing can be accomplished before the towers are built. Also, in cities, ground survey is necessary since low-flying planes are prohibited. On the other hand, radar profiling is particularly good in rough country and where dense growths are encountered There may also be some merit in obtaining the necessary information without disclosing plans to property owners.

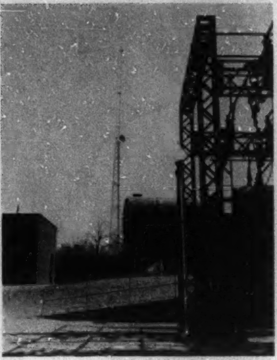

Fig. 12. Tower in station yard

ANTENNAS

Antenna gain defined as the ratio of field strength in a given direction to the field strength of an isotropic antenna, although running in the thousands, is realistic, as well as are the relations between parabola size and beams widths.

PASSIVE REPEATERS

In the use of passive repeaters, it is found that both those used at the tops of towers and those of the billboard type give very satisfactory performance. The losses with properly designed sizes and terminal parabolas based on the lengths of the two path legs are negligible and, in fact, may be slightly negative due to some focusing effect. A large-sized passive repeater such as the one mentioned above for Philo Plant, Fig. 4, costs about $10,000 installed and yet is far less expensive than an active repeater station, and certainly better than a wire line or cable for the short leg. It is felt that many applications will appear, particularly in mountainous country where at the end of a series of relay stations a short hop is required to get down into the valley to the station. These may also serve in cities for bending a beam horizontally around buildings or other tall structures; see Fig. 10.

TOWERS

When it is necessary to consider the supports for parabolas or reflectors, the choice is not hard to make. Single wood or H frames for heights up to 70 feet, and steel towers for heights above that level are entirely satisfactory. If the available area allows, guyed towers permit some saving in cost, otherwise self-supporting towers must be used. In some areas space is no problem, as in Fig. 6; in others the tower may have to be squeezed in among substation equipment as in Fig. 12, and in some cases it may be mounted on the roof of an existing building as in Fig. 13. In the electric power business it is frequently found that the stacks on generating plants, with their height and rigidity, make excellent mountings. Specifications for towers must be tailored with consideration for the wind and ice loadings in the areas where they will be used, as well as for the bend and twist limits dictated by beam widths, and for possible damage to the tower.

TUBES

To those involved in this study the only tubes which were unfamiliar, from other applications, were the lighthouse tubes used commonly in 1,900-mc equipments and the klystrons used in 6,700-mc equipment. The former, generally used in a system starting with a crystal oscillator and a series of multiplier tubes, easily attain stability well within FCC (Federal Communications Commission) tolerances, The klystron, a velocity variation oscillator, on the other hand, is more expensive and requires precision circuit design to attain the necessary stability but it is in itself the oscillator and final tube; thus its use avoids the series of multipliers. Failure of its oven or thermostat control could permit a drift beyond operating limits. Obviously nothing but tubes of the highest quality can be considered in this service and they should be subjected to preliminary aging of at least 48 hours before going into service. The spare r-f assembly, if operated hot, is an excellent place to run in these new tubes.

BUILDINGS

In the buildings both steel and concrete are used; see Figs. 5 and 11. Both have been found satisfactory and with not very much cost differential. Steel is readily assembled and easily expandable but may require special caulking and insulation. For isolated locations concrete affords some additional protection, particularly from bullets. For 6,700 mc, where antennas are normally mounted on the roof and pointed upward, it is a simple matter with the concrete building to extend the wall to form a parapet above the roof, concealing the parabolas; see Fig. 14. Naturally an existing building would be used wherever possible. Equipment could be arranged as in Fig. 15.

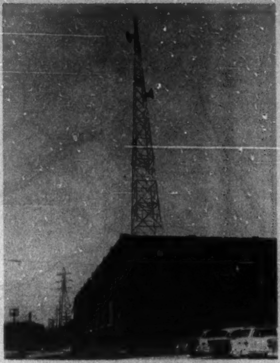

Fig. 13. Tower on building roof

R-F LINES

As far as the r-f feed system is concerned, it appears to be tied rigidly to the system chosen, namely, coaxial cable for 1,900 mc and wave guides for 6,700 mc. Wave guides having one dimension at least half wavelength are in general impractical in size and cost for use at 1,900 mc. Coaxial cable gives little trouble and the cavity blower provides a simple means of pressurizing the line. At 6,700 mc the wave guide and its low loss are ideal and universally employed. By putting the parabola at or near the transmitter there is practically no run of r-f line and no problem of maintaining cable on towers. Wave guides, being frequency selective, and having a cutoff frequency at about half operating frequency, are sometimes cited as an advantage over the coaxial cable. The ability to provide selection so far away in frequency does not make an impressive argument.

STANDBY R-F

In the matter of standby r-f equipment the individual application will dictate the rate of transfer, which in the case of relaying must be in milliseconds to those cases where only voice channels are handled and even an interruption of several minutes may be tolerated. To minimize interruptions during transfer to spare r-f equipment, hot standby is required along with fast-acting wave guide or coaxial switches or, for complete continuity both transmitters may be fed continuously to separate antennas. Those systems using only two frequencies may employ a single set of spare equipment at a repeater station, cutting it in for either direction as required. Since a simultaneous failure of both normal equipments at a repeater station is a remote possibility, there seems no error in judgment to use the so-called one-half stand-by.

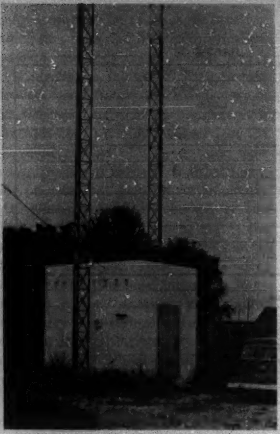

Fig. 14. Concrete building with parapet to conceal parabolas

EMERGENCY POWER

Transfer to emergency power is also designed around the requirements of the particular services rendered, and may be anything from a completely continuous supply to intentional provision of time for the line reclosers to function before starting the emergency generator. These machines give remarkable performance, particularly those operating on propane gas where heaters are provided either in the crankcase or the cooling jacket. In a matter of 1 or 2 seconds they will come up to speed and are immediately capable of picking up full rated load.

For relaying applications where outages must be strictly limited, particularly those at the instant of power supply failure, there are several approaches, all of them practical. Although diversity transmitters are not approved by the FCC it is possible to get good protection against fading by receivers spaced less than one mile. To eliminate even the momentary breaks during transfer to emergency power either battery-operated r-f or flywheel generator sets are practical.

MULTIPLES

The choice of multiplex equipment must be made between frequency division and one of the several forms of time division. Many factors will influence this choice, particularly the number of party lines, the over-all length of the system, the number of hops in a single voice path, the number of branch stations, the number of drop repeaters, and, where relaying is used, the speed of response. Unquestionably either system will, in general, give complete satisfaction, but in the AEP system frequency division was found to fit system requirements better, and it has been used both in the form of frequency modulation and single side-band modulation.

Applications

The versatility of these systems is such that with any conventional form of multiplexing it is possible to handle all forms of signals normally employed in AEP business, such as voice, telegraph, facsimile, supervisory control, load control, relaying, telemeter, alarms, etc. It seems that there will be no problem to fit in coded information such as that for data processing or the indications which may be required for systems of the future which have not yet been invented. Microwave also makes a convenient combination with mobile radio systems where the towers may be used for both purposes and the microwave system as the remote control for the radio transmitter. About the only thing which cannot be handled without special equipment and special developmental grant from the FCC is a television signal.

Although in the AEP, relaying and transfer trip are still handled satisfactorily by power line carrier, convincing indications are that no technical problem of any magnitude exists in handling these signals by microwave. The matter of obtaining complete continuity is readily solved by one of the methods mentioned above. In practically every case a microwave system must have duplicate r-f equipment and, if it is to handle relay signals, about the only change necessary is that this spare r-f must be arranged to run continuously. This involves comparatively little cost and has the additional advantage that it may be continuously monitored, giving the assurance that a transfer will never be made to a faulty spare unit. This matter of continuous supervision is itself an advantage in relaying since in general there is no continuously running signal on power line carrier and no means of determining that the channel is actually ready to function. A number of technical papers, included in the list of references, cover this subject.

Fading

Most factors in the design of microwave systems such as transmitter power, path loss, cable loss, antenna gain, and receiver sensitivity are readily measured. The exception is the factor of fading due to variations in atmospheric conditions, which must be considered largely on a statistical basis and weighed if possible by experience with other systems in the area. Although it might be theoretically possible to design a system where all fades are within the operating margin, the practical solution usually involves providing something in the order of 30 db per hop margin, which in turn produces an outage due to propagation failure of less than 0.02%. As far as one may observe, there are no reflections from the ionosphere sufficient to affect performance, and space noise from either atmospheric or man-made interference is below that of the front end thermal noise of receivers. It is not known whether fading is due to multipath propagation, refraction, atmospheric attenuation, or ducting, but each appears to have its own effect. For instance, slight signal loss in heavy rain or snow, definite loss in fog, rapid, and severe signal variations for an hour or more for no known reason, and fades for 20 minutes at a time so deep that there was no measurable grid current in the final limiter have been observed. Fortunately, only the last-mentioned case caused system outage and whole years have passed with no outage due to fading.

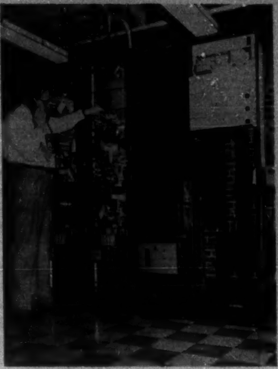

Fig. 15. Terminal equipment

Another interesting point is that such outages have always happened in paths of 20 to 25 miles in length, longer and shorter paths being affected. Also interesting is the observation that on one occasion the system was interrupted by simultaneous deep fades in two adjacent hops.

Maintenance

Routine maintenance practices must be adequate to hold systems constantly

within a few db of normal of design figures. In general it is found that, although one man can maintain about ten stations, most of his time is spent in traveling and it is more efficient to have a number of trained men available along the system for part-time work. By having men closer to the stations both outage time and traveling time are reduced.

For this work, the cost of the equipment and importance of continuous service is such that only the best men should be chosen. All suppliers offer training courses which should be taken at least by the first group of men before the equipment is received so that they will be able to make the installation, tests, and adjustments as well as take care of subsequent maintenance.

Alarm systems should be designed to convey enough information for an intelligent decision as to calling out the maintenance man immediately, the next day, or the next normal working day. It is considered important to have at each station a record of normal current and voltage readings for that particular equipment. A blank form, such as that of Fig. 16, was made up for a particular type of equipment and is valuable in that the maintenance man is frequently able to spot the trouble in a minute or two simply by observing deviations from previous readings. Section *E* on this chart is important for a check on the serviceman himself since it is not unknown for a serviceman, after completing his work, to walk off leaving some item in an inoperative condition.

On the interesting and important question of maintenance costs, a number of factors are involved, yet for all practical purposes one may reach a representative figure by imagining a typical system, say, 200 miles along with average hops and multiplexing. Such a system might use ten stations and cost about $265,000 installed. It could be maintained by the equivalent of one man, the annual cost of which, including his car, replacement parts, etc., might be $11,000, giving about 4% as an average figure. Field experience shows a cost slightly above this for the first year, and somewhat less subsequently as the equipment settles down.

Evaluation of Microwave

From field experience AEP observers have satisfied themselves that microwave has advantages over alternate means of communication for the purposes of utility operation, at least in matters of higher intelligibility, better signal-to-noise ratio, ability to restore zero db above 1 milliwatt level, lower crosstalk level, and better continuity. It also has flexibility by which it can be adapted to handling any of the many forms of intelligence required. Once the channel requirements exceed the order of six or eight voice circuits, the microwave also has economic advantages; equipment is concentrated at discrete points, which facilitates servicing. Theoretical factors stand up well

1959

in practice and details such as the causes of fading are, from the AEP point of view, academic only, since the over-all outage time results, as related to path margin derived from theory, are satisfactory in practice. Other definite tangible advantages not so readily evaluated are the increased number of long distance calls made because of inadequate other facilities or time lost waiting for a circuit. Maintenance costs per channel or per channel mile are no burden, nor is the matter of training personnel. In general the AEP feels secure in making microwave responsible for the most important functions of system operation; its apparent complexity is no serious matter since designs are made with great care to hold the number of components in the common equipment to an absolute minimum.

Microwave being normally a multichannel device may reasonably be expected to become a backbone system for long hauls to which other systems may act as local area feeders. Thus the microwave system should be engineered to high quality standards about as a toll telephone system would be, so that the signal deterioration in long hauls would be no greater than in local loops. Values in the order of 42 decibels adjusted (*F1A* weighting) should be obtainable in systems of ten repeaters without investing in more than moderate-priced equipment.

The AEP has here the basis, if desired, for setting up a full company-wide direct-dialing system by means of which it would be possible to dial any extension in any plant or office in the company. This could be done by using private automatic exchange switching machines which are now available in sizes down to those suitable for the smallest office, or by terminating on leased boards.

In the matter of terminating microwave voice circuits on leased telephone boards or continuing over leased wires, there is an agreement between the Bell Telephone Companies and right-of-way companies. The general effect of this agreement is that such connections will be made on the understanding that their use will be confined within the latter companies' right-of-way or that of neighbor companies with which it does business. The same general policy is followed by the independent telephone companies; it provides the protection which they require for their local and long-distance traffic, and leads to an increased use of leased wires and terminal facilities, which might not be justified if microwave were not available for part of the distance.

Party lines are by no means things of the past; in many cases they are valuable for alerting or transmitting information simultaneously to many substations. Also, it is logical to use the party line type of equipment for circuits to a number of unattended substations where the total traffic may readily be handled by a single circuit. Again, circuits having a simple ring-down are valuable where there is a need for direct and instantaneous contact between parties and no delays can be tolerated.

Channels of any type can be set up between any desired points, either throughout the entire system or only in local areas, and can be added singly up to the ultimate capacity. Control signals such as those used for teletype, telemeter, etc., require little channel space, and by a method of tones, 18 such signals can be applied simultaneoulsy over any voice channel.

In some cases ultimate channel requirements may be so high that consideration should be given to the maximum number of circuits which should be entrusted to any medium, no matter how nearly perfect. Although unlikely, it must still be realized that a system could be put of service for an extended period through loss of a tower or electronic equipment by tornado, fire, sabotage, or enemy action.

Conclusions

The dynamic nature of the industry must be recognized and one must be prepared to bring into use any system or method which holds promise of leading to improvements in safety and economy or the well being of the general public. Microwave should be given very thorough consideration in programs of expansions, not only as a means of handling channels for conventional purposes but for new applications, data processing, for instance and new inventions requiring the transmission of intelligence, as they may appear from time to time.

The present-day trend of seeking to obtain maximum operating and economic advantages leads to vast and complicated power networks, the efficient operation of which requires substantial increases in both the quantity and quality of communication channels. A factor in planning of considerable importance is the ultimate channel capacity required in any area. Power systems are expected to grow without limit, yet the microwave system must be designed for some ultimate channel capacity. Since the basic equipment is expensive, even though only the working multiplex is provided, it is necessary to choose a combination of microwave system and multiplexing equipment suitable for the channel loading anticipated at retirement age, say, 20 years. It is sometimes difficult to conceive of the present rate of system growths continuing indefinitely, yet this must be assumed. It is necessary to make the best possible estimate for growth in each area, designing communication systems accordingly, and if anything, leaning in the direction of making generous provisions. Although in utility work high-capacity communications systems are not generally required, it is important to watch carefully those areas of concentration such as at headquarters offices, load-dispatching centers, etc., where the microwave is originally justified; it is likely that traffic at these points will determine ultimate channel future requirements.

It is not intended that microwave should assume the full burden of communications but rather that it should take its place to share the burden with other methods, each being applied to take maximum advantage of its individual characteristics.

Ordinarily, new circuits which cannot be handled by carrier current would logically be applied to leased lines, and as the number of these circuits increased to the crossover point of 6 or 8 voice circuits in parallel, it is expected that they would then be replaced by microwave. Once the microwave is installed, it may then be used to shorten those carrier current channels which are too long, giving an over-all improvement in signal-to-noise ratio. Many new applications will appear through having additional circuits available at small cost. The AEP has in mind, for instance, management circuits either from headquarters to the various plants and divisions or as conference-type circuits to be used by all of these parties at the same time.

In the matter of guarantee, some manufacturers offer 99.95% continuity for a 4-hop system, or close to 99.99% per hop, including all equipment failures as well as fading. These are found to be realistic and practical figures which can be attained in the field without going beyond conventional designs. It is felt, however, that it is better to avoid insistance upon an over-all performance guarantee since this leads to overdesign. Instead, it seems entirely proper to hold out for simply the conventional guarantee on materials and workmanship. Part of this comes from a realistic consideration of what would be done if performance should fall short of guarantee. It is unrealistic to conceive of removing the entire system and replacing it by one of another make, or to think of completely abandoning microwave. Logically it would be expected that the design would be rechecked and components replaced to attain the desired performance. It does not seem that this could involve a cost as great as that of overdesigning the system in the first place.

In any business the efficiency of well-planned communications combined with good operating practices is a valuable asset but for electric power system operation it becomes absolutely essential as a basic "nerve system" for the complete and continuous transmission of information from remote points to central processing centers, and from there to the generating plants. The developement of communicating facilities has kept step with the expansion and increasing complexity of power systems from the original elementary telephone systems through transmission telephone circuits, power line carrier, leased wires, long-lines telephones mobile radio, and now microwave.

Although power line carrier has been a reliable "work horse" and it is appreciated that excellent service is provided by the communications common carriers, present requirements for channels are such that these means alone are insufficient. It is very fortunate indeed that microwave has attained a level of development well beyond the experimental stage, and that the rules and regulations of the FCC permit its use in utility work. This does not mean that it or any other system would be chosen to the exclusion of others but rather that each will be exploited through what is considered the right of freedom of choice to the full extent of its technical and economic capabilities. In general, the cost of communications is in the order of 1.0% of that of the total plant and its importance is so great that there is adequate reason to lean in the direction of more and better communication facilities.

Unquestionably, in times of stress and emergency, with either potential or actual system collapse, the entire cost of the communication system is justified if it performs well and gives continuous, complete, and accurate transmission of intelligence. It is here that the ingenuity of communication engineers comes into play in designing equipment to perform under the most abnormal conditions, including complete power outage. In exploiting microwave, experience indicates that since it is capable of accomplishments not previously possible, communication engineers should be urged to show the courage and vision to plan generously for the future.

◆

Discussion

G. E. Farmer (Tennessee Valley Authority, Chattanooga, Tenn.): The author is to be commended for his comprehensive and timely paper. The electric utilities are badly in need of this type of information I like the approach in respect to microwave: that it should not be expected to "assume the full burden of communications but rather should take its place to share the burden with other methods, each being applied to take maximum advantage of its individual characteristics." I should like to suggest reference 1 as an addition to the author's list.

May I comment on a few points:

Pulse-Time (PT) Versus Frequency Division. We have found PT somewhat more economical than frequency division since the latter loses the channel when it drops it at an intermediate point, whereas with PT, a new circuit may be made of the continuing section.

Signal/Noise Ratio. For us 15 db does not constitute a satisfactory circuit for one that may become a tandem circuit. *E1A* specifications recommend 35 db 97% of the time, and we use this higher figure as practically all circuits are potentially interconnectible.

Reliability. The percentage of reliability of 99.88% is remarkably good. We have not been able to approach such a figure and, as a result, do not yet consider microwave links including a repeater to be satisfactory for load control or relaying circuits. However, we are investigating the possibility of using diversity for improving this reliability figure.

Choice of Paths. We have been somewhat more conservative, using true earth's curvature on all calculations and have used full Fresnel zone clearance for paths of over 30 miles. Even with these values we still have had appreciable fading.

Stand-by Radio-Frequency. We use hot stand-by in all cases; some have 50% stand-by and others 100%, with very little difference in the relative reliability.

Emergency Power. Our propane gas engine generators have also given us excellent service. The continuous power equipment which we have used has not proved reliable and has probably caused more interruptions than it has prevented.

Channels for VHF. As our microwave repeater stations are not advantageously located, we have found it more economical to use shorter separate radio channels for this service, with voice interconnect equipment at the radio terminal.

Fading. The figure of 30 db margin is an indefinite term unless it is specific by "below the median signal or normal propagation." The industry would well be served by a more definite term.

Functional Life Tests of Apparatus as Compared with Insulation Material Tests

M. L. MANNING
FELLOW AIEE

EXPERIMENTAL WORK by users and manufacturers of electric equipment alike, has disclosed the need for an entirely new concept of insulation classification and evaluation. It is found that insulations should be classified as systems as well as materials. The manner in which the materials are applied and processed is of as equal an importance as the basic materials used. The electrical industry, working through the AIEE, developed the concept of functional evaluation of insulation systems. This concept appears in AIEE No. *1*, published in June 1957.[1]

What does the philosophy mean to users of electric equipment?

1. It recognizes the determination of insulation life by tests made in comparison with an existing insulation system in a motor or in a transformer.
2. It necessitates the re-examination of all insulation systems used in electric machinery by a manufacturer.
3. It provides assurance that the manufacturer has taken care to provide insulation systems proved by prescribed test procedures.
4. It gives more information concerning end of life of electric equipment using certain insulation systems.

Performance of insulating materials is of utmost concern to anyone using or manufacturing electric equipment. Most troubles with electric devices can be traced to limitations of insulating materials and their inability to withstand temperature, atmospheric or environmental conditions, voltage disturbances, short circuits, and overloads. Conventional books on the subject fail to keep pace with the swift progress of research, development, and applications. Courses of study in colleges and in universities have not recognized the importance of the subject sufficiently.

This paper outlines, from the viewpoint of an educator, the need for constructive thinking today, the new concept of functional testing and what it means, the organizational procedure followed by reliable companies in making insulation studies, important properties of insulation in making an analysis, and steps involved in classifying insulating materials or systems by tests. What are the objectives of functional testing; what is the AIEE doing; what is the effect of these changes on insulation standards; how are costs of apparatus affected, and what are the possibilities for stimulating the growth of better insulating materials and insulating systems?

Definitions

The following are definitions of materials, insulation systems, and functional testing.

Insulating materials include processed compositions of raw materials and commercially available combinations before they are fabricated into structures identified with electric equipment.

Insulating systems include completely fabricated and processed combinations of insulating materials with the associated parts of specific electric equipment.

Functional or prototype testing gives the means for determining the natural characteristics and behavior of insulation systems under simulated and accelerated conditions. Insulation systems of a motor or transformer can be miniaturized in model form, then accelerated test procedures can be applied to determine insulation characteristics. Logically, this teaches that apparatus life expectancy and performance are determined, not only by what insulating materials are used, but also by environment, electrical, and mechanical stresses in an application and how they affect the life and properties of insulation.

In considering insulation as related to equipment, one factor stands out. The manufacturer is interested in the development and evaluation of an insulation system, not an insulating material by itself. It is recognized that the development of an insulation system cannot proceed in orderly fashion without the prior development of insulating materials. But the evaluation of insulating materials as materials must be considered as screening tests as far as the insulation system is concerned. Repeatedly, it has been demonstrated that evaluations must incorporate all of the processes which go into insulation systems on models which are as nearly as possible like the electric machines they simulate. For large machines, this becomes more and more difficult since the cost of models increases rapidly with size. A development program cannot overlook an insufficiently developed and evaluated system.

Organizational Procedure

The following procedures are used by reliable companies in developing insulation and corresponding systems:

1. *The research department* makes the fundamental studies in the chemistry and physics of dielectrics which result in new components.
2. *The development or long-range planning group* evaluates the materials, develops processing techniques and makes model studies; disseminates information to other departments.
3. *The application or design department* has the basic design responsibilities for applying the insulation system to equipment; must help to establish shop procedures.
4. *The service performance and maintenance department* provides the information on the insulation system in electric equipment under normal or abnormal conditions. It often recommends adjustments or changes in processing procedures.

An insulation manufacturer should basically follow the organizational procedural step numbers 1 and 2. Commercially, his success depends on steps 3 and 4, application and performance.

Properties of Insulation of Importance in Making Analysis

Mechanical: 1. Tensile strength
2. Tear resistance
3. Resistance to abrasion
4. Flexibility
5. Bond strength
6. Resiliency
7. Stability

Thermal: 1. Aging properties
2. Heat transferability
3. Temperature stability
4. Conductivity
5. Expansion and contraction

Paper 59-1293, recommended by the AIEE Electrical Insulation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE National Conference on the Application of Electrical Insulation, Washington, D. C., December 8–10, 1959. Manuscript submitted August 10, 1959; made available for printing September 29, 1959.

M. L. MANNING is with South Dakota State College of Agriculture and Mechanic Arts, Brookings, S. Dak.

Chemical: 1. Resistance to contaminants and corrosive atmospheres
2. Resistance to gases, oils, moisture, and solvents

Electrical: 1. Electric strength
2. Voltage endurance
3. Dielectric loss
4. Dielectric constant
5. Surface resistance
6. Arc resistance
7. Corona resistance
8. Radiation resistance
9. Power factor

Classifying Insulating Materials

What steps are involved in classifying insulating materials or systems by tests?

1. A thermal test procedure may be proposed by an individual or a committee.
2. Temperature class limits are set by tests on materials or systems.
3. Limiting test values are selected for each temperature.
4. A committee may accept a proposed procedure, organize a test program, and publish results.
5. A test procedure may be published as a standard.

Objectives

Following are the objectives of functional testing:

1. To offer suggestions for designing test samples or models.
2. To determine heat-cycling limits, environmental conditions, voltage or end-point tests for developing test procedures.
3. To determine life expectancy of insulation or of insulation systems (life versus temperature relations).
4. To determine the mechanical, thermal, chemical, and electrical properties outlined previously.
5. To determine the effects of high temperature under different environments on the insulation or the system.

What Is the AIEE Doing About the Problem?

Insulating Materials

The AIEE Standards Co-ordinating Committee No. *4* has prepared Test Procedure No. *1D*[2] in which principles are established for the development of test procedures for the thermal evaluation of materials. A test procedure is prepared for each important kind of insulation material such as wire enamel,[3] rigid insulating materials, sheet insulation, and other components.

Materials are assigned to a temperature class to facilitate comparison. It must be remembered that life expectancy under the test conditions chosen may not have uniform relation to the material in actual service. The insulation system in which the material is to be used may have widely different temperature limits.

Insulation Systems

AIEE Committee No. *4* has published a "Guide for Preparing Test Procedures" which provides classification of insulation systems for electric equipment on a temperature basis by test, rather than by chemical composition of the component materials of the system.[4]

Statistical Analysis of Test Data

AIEE No. *1* states that accelerated life tests are recommended to determine the probable life expectancy of insulating materials and of complete insulation systems under different conditions of service.

After the life data from tests are obtained, the problem is to evaluate such data so that the life expectancy of insulation can be estimated. "A Guide for the Statistical Analysis of Test Data" is now available.[5]

Test Procedures for Electric Equipment

For motors, generators, and transformers, several test procedures are available.[6–8] These procedures serve the purpose of accelerating insulation degradation at various temperatures.

Effect of AIEE No. 1 Revisions on Insulating Standards[9–11]

Insulation System Tests Using Models

1. To begin the testing process, simulate the actual insulation system and, if practical, use actual equipment.
2. Provision is made for a composite picture by procedures for short as well as long-time voltage-endurance tests.
3. Thermal aging properties are better determined by a combination of stresses on the complete insulation system at room and at elevated temperatures.
4. Processing procedures are a duplicate of those on equipment and can be reduced to practice.
5. Mechanical properties, such as bond strength, shear strength, compressive strength, and creep properties are obtainable at operating temperatures.
6. Progress is made by steps so that correlation of test results with those found on basic materials is possible.
7. Test procedures recognize degrading effect of associated materials on the system and consideration is given to the decomposition products.
8. Effects of temperature are understood more clearly and lead to the design of equipment for higher temperatures in order to reduce space and weight.
9. Life tests can be accelerated at high temperatures and at high mechanical stresses; high voltage can be used to determine creepage strength; and the effects of corona can be studied.
10. Correlation with machine standards is possible.

Insulating Materials

1. It is impossible to design test samples to simulate actual usage conditions.
2. Insulating materials are usually designed without known end-point use.
3. It is impossible to create electrical, thermal, and mechanical stresses found in equipment.
4. Materials must be evaluated by "screen-testing" methods.
5. Correlation of test results with those found on insulation systems must be made.
6. Tests may predict temperature limits for materials to determine temperature classes.
7. Co-operative work with the American Society of Testing Materials is possible to establish test standards.
8. Development of test procedures must recognize: (*a*). preliminary plans made by experts in materials; and (*b*). the establishment of tests such that they are reproducible and that a reasonable correlation between test life and service life is possible.

How Are Costs of Apparatus Affected?

The AIEE guides, in their philosophy, offer one of the best quality control devices given to a user of electric equipment. They demand that both the manufacturer of insulating materials and of electric machinery must use high-quality materials and should display evidence of functional testing of the complete insulation system. Manufacturers of higher temperature materials will be benefited in the long run. Temporarily, for lower temperature applications, the demand may now be greater for organic insulation materials. As industry progresses and as pressure is generated for space and weight reduction and the minimizing of fire hazards becomes more pronounced, the high-temperature-withstanding materials will be in greater demand.

It seems logical that a purchaser of equipment should take these factors into consideration. Companies who take active part in AIEE committee activities by conducting quite expensive laboratory investigations and tests should be recognized and some method for prorating these costs should be devised. Logically, it would seem that these extra considerations should be factored additionally in arriving at the cost of a product.

Possibilities for Better Insulating Materials and Systems

Without doubt, the complexities of the many forms of insulation and corresponding usage in systems can be sorted out and verified by the new concept of functional testing.[12–23] Research and development demonstrate that chosen temperature limits have many, many facets, such as:

1. Effects of long exposure to high temperature. Do the materials change with respect to mechanical and electrical properties? Do the materials soften, lose weight, or become brittle?

2. The magnitude and time duration of loading imposed on the insulation system.

3. The effect on the physical support of insulating materials at high temperatures. The bonding resins may become brittle, yet the insulation system may continue to function if not disturbed. Forces of thermal expansion and contraction may restrict temperature limitations depending upon the size of electric equipment.

4. Life of insulation is dependent on environment, such as moisture, dirt, chemicals, or solvents, released from the interior of an insulation system. Various industrial atmospheres may have a predominant influence on ventilated apparatus compared with sealed systems which exclude oxidation or contamination.

5. The rate of physical deterioration increases rapidly as temperature increases. The modern concept of determining insulation life at elevated temperature is based upon the idea that the logarithm of insulation life is a function of the reciprocal of the absolute temperature. At three or more temperatures the logarithm of the hours of life found by thermal evaluation tests are plotted against the reciprocal of the absolute temperatures. Usually a straight line results. The life at other temperatures can be estimated. Individual time-temperature life curves for different materials or insulation systems can be determined by thermal evaluation tests.[24]

   Basically, the idea that electrical insulation deterioration is treated as a chemical rate phenomenon stems from the Arrhenius chemical reaction rate equation.[24]

6. Ambient temperature affects the temperature attained by equipment in operation.

7. Insulation life depends on the care and maintenance of equipment on which it is used. Mechanical shocks, such as movement of equipment to different locations, short circuits, and overvoltage, are factors to consider.

In general, a method is needed to grind out, like a mill, functional merit ratings of insulation systems. All of the factors considered may be likened to seven prongs impinging on insulation simultaneously.

A tremendous amount of work lies before the industry. The job cannot be done overnight. Years of demanding co-operative effort between users and manufacturers are required to inaugurate AIEE test procedures, to realize that ratings of machines must be on a temperature basis according to the insulation system within them, and to establish temperature ratings under normal conditions with accelerated test conditions. Excessive time is required at normal temperature conditions to establish life relationships. Accelerated tests may be used to expedite better answers than those now available.

Users of electric equipment can be of great assistance by becoming members of various AIEE Committees and taking active part in establishing test procedures, and by keeping accurate records of performance of equipment subject to overloads or to abnormal environmental conditions.

A 3-dimensional relationship of time (duration of load), magnitude of load, and life of insulation system for apparatus is the answer desired. Such a relationship, resulting in a 3-dimensional graph in terms of per-cent load, will sort out answers to amortization of life of equipment when applications demand 2 hours, 3 years, 6 years, 10 years, or 30 years of life.

Co-operative papers written by electric power representatives and manufacturers are now appearing in publications.[25–27] By actual load charts, by record of environmental conditions, by a careful check of mortality rates on equipment, and by co-ordinated effort, the aims expressed in this paper can be realized.

In this day of space, rockets, guided missiles, and satellites, the "triple alliance" effort of physicists, engineers, and chemists in the field of electrical insulation, will develop new insulation and systems far better than those now known. The past three decades of progress in electrical insulation are quite notable[28] but there is no room for complacency. Unanswered questions concerning insulation and systems, proposed 8 years ago at the National Conference on Electrical Insulation, remain with us.

1. What magnitude of test voltages should be used for end-point tests? What about corona damage at higher voltages?

2. What about the detection of corona in the volume as well as over the surface of an insulation system?

3. What about chemical changes which take place, thereby giving off by-products which affect rate of reaction on other materials in the system?

4. What electrical and mechanical performance is required for a given application?

5. What time versus load duty cycle is expected? Are sufficient data available?

6. What life expectancy and reliability can be realized?

Discussion

H. P. Bruncke (Northern States Power Company, Minneapolis, Minn.): Dean Manning has compiled in his relatively short thought-provoking paper, a world of information concerning tests of electric apparatus. As he has pointed out, apparatus life is dependent not upon the life of the separate materials in the apparatus but upon the life of the insulation system used for this apparatus. The organization of the paper gives much food for thought on the many aspects of the insulation system. As we all know and have experienced, tests in the factory or the laboratory can never duplicate the actual field service conditions. There is always some factor which has been either overlooked or which was not apparent in the design of the tests for the apparatus.

In the past there has been the tendency for manufacturers of insulation systems to depend too much upon tests of the individual materials suppliers. Now the AIEE has amplified AIEE No. *1* to take into consideration the system rather than the individual materials going into the system. Simulated or accelerated tests on materials can never take into consideration the operating conditions of the insulating system.

Both time and ambient temperatures have a very real effect upon the life of insulation. In all testing conditions, emphasis has been placed upon temperature; generally, the higher temperatures. The assumption has been, of course, that high temperatures reduce the life of insulating materials. There is a feeling among the users of electric equipment that not only high temperatures but also low temperatures are very real factors to include in any standard analysis. As an example, we had several cases of trouble with a compound-filled 15-kv class potential transformer. These transformers failed after a period of very cold weather. The failures seemed to be limited to our section of the country. An analysis indicated that during the very cold weather, because of the small heat loss, the compound cracked setting up a corona condition which developed as the ambient temperature increased. In some cases the instrument transformers failed with explosive force. This example is cited to indicate that not only tests for life regarding temperature should be included, but also tests under operating conditions should be included. The AIEE's No. *1* also includes weather conditions in the United States giving maximums, minimums, and averages which give the laboratory much information for operating conditions.

Dean Manning has recommended that the users of electric equipment assist this testing procedure by becoming members of the various AIEE committees and by furnishing records showing normal and abnormal operating conditions. This paragraph of Dean Manning's paper brought to my mind remarks made by the chairman of the AIEE Transformer Committee about a year ago in which he lamented the fact that there were too few members on his Committee from the utilities or the industrial group; that is, the users. Nearly all of the committee members represented the manufacturers. The manufacturers need the information of the user in order to correlate test data.

Dean Manning has offered a challenge to a number of unanswered questions for insulation and insulation systems. He has enumerated those which were proposed at the National Conference on Electrical Insulation which apparently have been left unanswered. One question which the utility users are very much interested in is the detection of corona in insulating materials as well as over the surface of an insulation system. There has been more and more evidence in the analyses of failures that corona is a very real problem. Our usual test methods in the field are not sensitive enough for detection at the start of a corona condition. Apparently the only symptoms of corona problems in insulation are radio, television, or carrier-current interference. When this occurs, then there are methods for isolating the defective piece of equipment. There is a need to detect this corona condition prior to this time.

Dean Manning is to be congratulated on his paper and for the excellent arrangement which brings to our minds the various problems which are factors in the production of satisfactory electric apparatus.

P. L. Alger (Schenectady, N. Y.): I agree thoroughly with the statements made in this paper. Evidently the whole industry will have to go on working in the evaluation field for years to come, and it is a real problem how to select and guide the tasks that each group should perform.

It seems to me that a chief factor in future evaluation work will be to study and control the effects of corona. For, in order to use the new and more expensive insulating materials to advantage it is essential that they be made thinner. This increases the dielectric stress and, therefore, the risk of corona damage. Finding materials that will not be damaged by corona, such as silicone rubber, is one way of progress. Another way is to find means to prevent the occurrence of corona by shielding or environmental control. In either case, methods are needed for quickly evaluating corona effects.

In my opinion, an important step in this direction was recorded in the paper by Rhudy and Mazanek, in which they showed that the use of high frequency, 3,000 cycles, for example, gave results fully comparable to 60-cycle tests on corona damage to organic insulated armature coils, in a small fraction of the time. I regret, therefore, that the author did not mention this article in his extensive bibliography.

P. H. Ware and **D. W. Kitchin**[*] (Simplex Wire & Cable Company, Cambridge, Mass.): Mr. Manning has made a very thorough study of the philosophy underlying the use of testing as an aid to and a verification of engineering design. As he points out, there is a trend away from testing of insulating material per se, and toward the testing of insulating systems.

While we appreciate the fact that insulation when incorporated into systems does not always behave in the same way as the insulation when tested in a form convenient for quick evaluation, we feel that there may be appreciable loss in departing from long-established laboratory practice. The insulation manufacturer, as opposed to the equipment manufacturer, will be severely handicapped if he is to rely on system testing alone. Much of the repetitive testing must be done even to find the materials which show promise. If Thomas Edison had not used methods of quick evaluation for materials, much of his work would have been greatly delayed.

In general, testing of insulation systems in the form of models is more expensive and takes longer to perform. The necessary screening must be done as quickly as possible to find the materials worth putting into model form. The need for sufficient lead time between design and production often precludes a long-drawn-out program of simulated service tests.

One point of which we were reminded by the paper is that accelerated tests do not always produce results which bear a true relationship to service operation. For example, if acceleration is accomplished by using higher than normal voltages, life may be shortened by the effects of corona which does not exist at operating voltage.

Similarly, acceleration using increased temperature may cause a change in state which then will invalidate the entire test.

Basically, we believe that a balanced mixture of the two philosophies is required. To determine the suitability of fundamental properties, screening tests can be devised so that each necessary property of a wide range of materials may be evaluated. Then, once the obviously unfit materials have been weeded out, a carefully designed experiment considering all variables may be performed. In this latter test, the simulation of the actual system can be considered, and the model system may be made as nearly like the equipment it represents as is economically desirable.

In fact, Mr. Manning points out in his discussion of organizational procedure followed by reliable companies that just this balance of material tests and system tests takes place. The paper brings out many facets of the insulation testing problem.

M. L. Manning: The author appreciates the comments of the discussers.

Mr. Bruncke pointed out that time and ambient temperatures have a real effect upon the life of insulation. He illustrates the fact that low ambient temperature is a factor to be considered in compound-filled potential transformers. This amplifies the idea that more users of electric equipment should be members of various AIEE Committees dealing with electrical insulation. The importance of corona detection, as explained by Mr. Bruncke, is interesting.

Mr. Alger brings out an important consideration in the study and control of the effects of corona. Thinner materials, to reduce space factors, will be used in the future. This results in higher electric stresses and resultant corona. Means must be found to prevent corona formation and to find methods to detect it.

Mr. Ware and Mr. Kitchin explain that insulation systems should not be overemphasized in importance, compared with insulation materials alone. This is true, but screen tests on materials should be made first, in line with AIEE procedures. Uniform standard tests should be considered, not a battery of tests made at the whims of a manufacturer. The purpose of the AIEE program is to establish a balance between insulation materials per se and insulation systems in which they are used. As the years go by, it is hoped this philosophy gains much more momentum. As the two discussers point out, reliable companies are in accord with the organizational procedure described in the paper.

It is hoped the aims of this paper will be carried out to much greater extent in the decade before us. Co-operation among all concerned is highly important.
